Not unfrequently these, as well as other varieties of monomania, are associated with hallucinations of the senses; the persons affected hear voices threatening them with their approaching doom; or they see objects of terror, visions of departed friends, or of demons; or they taste poison in their food, or smell the sulphureous vapours of the bottomless pit, of which they believe they are already the hopeless inmates.

Monomania of unseen agency.

4. Allied to these forms of partial insanity are those cases which has been described as *monomania of unseen agency.* Founded, perhaps, upon some morbid sensations caused by flatulence or neuralgia, the unhappy victims of the disease believe that they are the sport of some mesmeric or electrical operations; that gases are injected into their system; that they are subjected to some strange influence during sleep; that persons at a distance control and act upon them, and even strike them; or that some person is actually in the inside of their body, and sways their feelings and actions according to his own will.

Monomania of pride, vanity, &c.

5. Very different, indeed, in their external manifestations and general deportment are the cases of monomania in which the sentiments of self-esteem, pride, veneration, and love of approbation, are morbidly exalted. The delusions under which such monomaniacs may labour are as varied and as numerous as the objects which stimulate to ambition. One may imagine himself endowed with exalted genius,—he is a poet, or philosopher; another, a distinguished musician or vocalist, although able to produce only the most dissonant sounds from his favourite instrument, or to scream in wretched discord with it; another believes he is a royal or divine personage, or a prophet, or endowed with supernatural powers, able to cure diseases, to regulate the fate of empires, or to command the sun; another believes that he has discovered some infallible cure for all human miseries, that he is about to convert all mankind and make them supremely happy; another, that he can direct the elements and give rain, sunshine, or storm; another is possessed of enormous wealth, and has paid off the national debt, and is about to build palaces and endow numerous institutions for the public good. There is, however, in such persons no loss of the idea of personal identity; they are still John Smith, or James Johnston, or Thomas Brown; and they are capable of acting with the utmost want of consistency of character,—performing the most menial acts, or working industriously at some trade or domestic duty.

In some cases a morbid vanity amounts to folly or madness without delusion; and indeed any of the sentiments, passions, or desires may be exalted into morbid action without delusion. In such cases the conduct of the individual may expose him to ridicule or pity, and he may be looked upon as a harmless, half-witted creature; but he may buffet his way through life, supported by his own self-importance, and escape the restraints which society imposes upon the morbid exercise of passions or propensities when they interfere with the comfort, happiness, or safety of others.

Klepto-mania.

In other cases the overt acts of the individual may endanger his own personal safety, may lead to the profuse and foolish expenditure of his means, or may exceed the limits which society deems tolerable; and he then becomes the object of treatment or surveillance, or even of confinement. To a morbid and ridiculous vanity such persons very often unite other depraved and morbid propensities. Of these, the most frequent, perhaps, is the practice of lying, and the art of deceit. A propensity to steal and hoard every article that can be surreptitiously appropriated is not an uncommon symptom in cases of this kind of moral perversion. This propensity to steal sometimes exists as a distinct form of monomania, without any other very obvious departure from sanity in the general state of the mind or conduct. It has been called *kleptomania.* The propensity has sometimes been exhibited by persons in the better ranks of life, who had no motive to steal, but could not resist the incontrollable impulse to purloin on all occasions. It is generally, however, one of the symptoms only of other forms of insanity, and of none more frequently than of those cases of moral perversion just described.

Pyro-mania.

The propensity to tear and destroy, which is so constant in mania, sometimes also, in a minor degree, accompanies partial insanity; in other cases the propensity to set fire to things, described as a special variety of monomania, under the name of *pyromania,* is a characteristic feature, and in some instances, it is said, is the sole morbid impulse.

Of all the symptoms of insanity, those referrible to altered affections, perverted desires, and morbid propensities, are the most constant; and delusions ought rather to be regarded, like hallucinations of the senses, as the accidental concomitants than as the essential features of insanity. In a large proportion of the cases of partial insanity in particular, the grand and distinguishing feature of the disease is, that the *conduct* of the individual is irrational or insane,—different from what it used to be, or from that of other people; or that his tastes, affections, habits, and propensities are *changed,* and no longer regulated, as they were wont to be or as others regulate them, by a due regard to personal welfare and the settled opinions of society. He does things which very often his own reason and conscience revolt at,—things which he deplores and cannot help doing.

Such moral perversion is not unfrequently met with in young persons, and is sometimes associated with some natural peculiarities of character, such as inability to acquire certain elements of education, disregard to personal cleanliness, or the pride, natural to all children, of being well dressed. At an earlier or later period of youth, sometimes about the age of puberty, this moral perversion is developed. The person becomes irrascible, passionate, vindictive, and dangerous; often violent without provocation; sometimes destructive of clothing or furniture; sometimes mischievous and cruel; at other times disposed to wander from home, without object or plan.

Satyriasis and nymphomania.

In persons who have passed the age of puberty this disease sometimes affects the sexual desires or propensities, and is indicated by gross obscenity of language, by licentious and lascivious looks, and acts of the most disgusting kind. This disease, if not a symptom only of other forms of insanity, is called *satyriasis* in the male, and *nymphomania* in the female. It is sometimes a symptom of some serious organic disease of the brain.

In other cases, and these not a few, in this country, the incontrollable impulses of the patient lead him into habits of inordinate drinking; and persons exhibiting those constitutional peculiarities described, not unfrequently display great violence when under the influence of intoxicating liquors—becoming furious and dangerous.

In many of the cases of the kind of moral insanity which are referred to, the principal, and, indeed, in some the sole feature, is an incontrollable craving for stimulants, and the indulgence in them to an extent ruinous to health, and happiness, and every hope in life. It is difficult to distinguish this disease from mere drunkenness; but it is unquestionable that there is a diseased condition of the nervous system, whether constitutional or the result of habit, or partly both, in which the individual drinks without any self-control, in which he cannot control himself, and is therefore a proper object for control, protection, and treatment on the part of others.

Oinomania.

This disease has been termed *dipsomania* by some authorities, by others *oinomania*. Both names are inexact: it being neither a thirst, as the first implies, nor a thirst for wine exclusively, as the second signifies, but a craving for any kind of narcotic stimulants. It is more proper to regard it as one of the varieties of moral insanity, of which this craving for stimulants and insatiable use of them is one of the principal symptoms. It is perhaps in few instances the only symptom. The disease is generally hereditary, and it will be found that the father, mother, or some other near progenitor, has suffered from it. It is very generally associated with a total disregard to truth. Such persons, particularly females, are singularly mendacious. They will resort to every possible device to procure stimulants, to excuse their conduct, to deceive their friends; they generally utterly deny their habits, and display a fertility and ingenuity in deceiving themselves and others which is truly remarkable. This disregard of truth is very often associated also with a great deal of self-esteem and inordinate vanity. Such persons do not drink from the pleasures which the social board affords, but, on the contrary, in company will often preserve a certain amount of decorum. Neither do they drink for the pleasure which the wine gives them, for in the absence of their favourite beverage they will have recourse to any substitute. They labour under an incontrollable craving, and drink because they cannot help it. No considerations of self-respect, no regard to domestic ties, to religion, to the certainty of ruin, shame, or even death, can prevent the individual drinking until he can drink no longer. He sees his impending ruin; deplores his fatal impulse, his inability to control his desires; and will assert with tears, that if hell were yawning on one side of him and a bottle of brandy standing at the other, he could not resist the impulse to drink, although the next moment he were to be precipitated into the gulf beside him. Such persons are now generally regarded as no longer responsible agents,—as insane,—and requiring, therefore, to be constrained and protected against themselves. Our asylums contain many such cases, although some degree of uncertainty prevails regarding the length of time they may be subjected to control; and the want of some legal enactments regarding them is much felt and complained of.

This disease sometimes assumes an *acute* form; and originating in some accidental cause, a constitutional change, or debilitating attack of disease, affects a person of temperate habits and predisposition; and in such cases is, with proper care, generally recovered from. Sometimes it assumes a *periodical* form; and persons have been known, distinguished as merchants or men of professional or literary reputation, who have been subject for many years to periodical attacks of insane drinking. But the most hopeless form is when the disease is *chronic*,—when it has been slowly engrafted upon a constitution hereditarily predisposed to it by systematic indulgence in intemperate habits. Several of our most attractive authors, men of singular and varied genius, have gradually sunk under this disease. One of the most noted of recent illustrations of this state is perhaps afforded by Edgar Poe, the American poet, whose whole life evinced that he laboured under moral insanity. Poor Charles Lamb, who played cribbage to amuse his demented father, and periodically conveyed his weeping sister to an asylum, was, by his own confession, for many years of his life, while he was writing to an admiring circle of readers, but a melancholy wreck, passing one-half of his time in the most wretched distress, and the other half in miserable imbecility.

Monomania of suspicion.

One of the most constant and salient features of insanity is the *suspicion* which forms a prominent symptom in a vast number of cases of all kinds. It is common both to mania and monomania. Even when the mind is carried away by a torrent of emotion or passion this is observed very generally as a marked trait among other symptoms. The patient watches every movement of his friends or medical attendant; suspects they are plotting against him; that he is supposed to be mad, and that some one is about to carry him off to an asylum; or suspects his food is drugged or poisoned. Not unfrequently one of the first indications of insanity is the idea entertained by the patient that every one he meets is looking specially at him; that the clergyman preached at him; that there is some plot of which he is the object. What is thus common to most varieties of insanity comes to be the principal feature in many cases of monomania: some suspicion regarding some person or subject occupies the mind and fills it with apprehension, while the faculties remain comparatively sound in reference to other subjects. Such cases have been designated *monomania of suspicion*.

This variety of monomania is not unfrequently associated with feelings of enmity and a desire of revenge against the perpetrator of the fancied injuries under which the patient suffers. In some cases the vindictive feeling is overpowering, and leads the patient to some dreadful deed of vengeance. These are the cases of insanity which are most dangerous to society. It was by such a monomaniac that the Hon. Spencer Perceval was shot in the lobby of the House; and from such another Mr Drummond met a similar fate, by being mistaken for Sir Robert Peel. (See the works of Georget, Esquirol, Marc; Prichard *On Insanity*; Simpson *On Homicidal Insanity*, &c., &c.)

Homicidal mania.

The propensity to kill, although generally stimulated into exercise by the belief in some imaginary wrongs, is sometimes an abstract impulse without motive,—a morbid craving for blood,—an irresistible impulse to destroy. This constitutes another variety of *moral insanity*, and one which has been generally repudiated in our courts of law as a defence for homicidal acts. That this *homicidal mania* is a real disease, in which the patient is carried away by the incontrollable impulse of a morbid propensity, is established by a large array of cases. The most noted illustrations of this morbid state are those horrible tragedies so frequently recorded in the newspapers of a father or mother deliberately destroying their own offspring. Very often this homicidal impulse is accompanied by a strong effort to restrain it, or to save the victim of it by some timely warning. Such persons have begged to be restrained, to prevent them committing murder; or have called out to their friends to save themselves by flight, before they expended their last effort at self-control.

Monomania of superstition.

Religious madness, as it was called, at one time occupied a large space in works on insanity. It may with greater propriety be called *monomania of superstition*. The subjects of it are generally profoundly ignorant of true religion. They are inspired by fanatical excitement or superstitious fears. One regards himself as a divine personage,—as the Saviour again incarnate,—and is prepared to be immolated for the sins of the world. Another is inspired with the prophetic spirit, and denounces curses upon all around as the worst of sinners. Another is the woman described in the Revelations, who is to give birth to a man-child. Or, again, we find others possessed with demons,—Satan himself,—accursed of God and man: the *demonomania* of former ages.

Demonomania.

Such are the most frequent forms of partial insanity, arranged conventionally, and perhaps accurately enough for practical purposes. But there are innumerable cases which it is impossible to reduce to any classification, where the patient is insane in reference to one particular fact, and not in a faculty or train of thinking. Of such cases are those where persons have imagined themselves cocks, grains of wheat, pumps, pairs of shoes, a half-crown, made of glass or of gold; where men have believed themselves pregnant, and women have believed themselves men; and innumerable other fancies, which might be mentioned were it not that they are as numerous and varied as the fancies which the human imagination can conceive.

III.—DEMENTIA

Dementia.

Consists in impairment or obliteration of the mental faculties,—in a diminished activity of the mental operation, either general or partial. In mania and monomania there is an excessive activity of some feelings, or emotions, or faculties,—a disturbance of the equilibrium of the mind: in dementia there is a mental asthenia, an impaired action, a moral atrophy. This impaired activity may vary from the smallest appreciable weakness to the total loss of all indications of thought, consciousness, or volition,—to complete fatuity.

Dementia is most frequently the sequel of other diseases. It is the most frequent termination of mania or monomania when not recovered from, or may follow apoplexy or repeated attacks of epilepsy; although it is not unfrequently the original and sole form of an attack of mental derangement.

In demented persons external objects are generally viewed with little or no interest, and they appear to be imperfectly appreciated. Hence, perhaps, the impaired power of reasoning, or comparing, or perceiving the relations of things; hence, too, probably the loss of memory, which is a principal feature of dementia. The objects or events around being observed with little or no attention, make no impression on the mind, and are immediately forgotten. Such persons often retain a lively recollection of the events of their childhood, and of everything connected with their history up to the period of their insanity, and yet are totally forgetful of all recent events; so much so, as very often not to remember that they have seen their husband, wife, or children, although visited by them only a few moments before.

In most cases of dementia, along with this impaired memory there is a marked incoherence. The ideas appear to pass through the mind as in dreams or in reverie, without any effort to direct them in a particular channel, without any apparent connection or sequence, such as takes place in the active operations of a healthy mind. Very often such persons repeat words or sentences without attaching any meaning to them; they talk as if they were thinking aloud, or rather as if they were not thinking at all, but merely repeating by rote a series of old forms of speech, or words associated together by their sound rather than their sense.

The activity of the emotions and passions is altogether destroyed, except when, as occasionally happens, a brief paroxysm of excitement lightens up the drear monotony of their stupor. In general they have no desires, no aversions, no hatreds, no affections; they are docile and passive; they have no will of their own; they spontaneously determine no act; they passively obey the will of others; receive the visits of their friends without pleasure, and part from them without regret; they are insensible to all the griefs and pleasures which affect others; at times they laugh at some passing thought, and at others cry, as children laugh or cry in their sleep according as their dreams are pleasant or painful.

Their movements are peculiar: some will walk up and down incessantly; others will dance for hours together, performing some monotonous movement continually repeated. Others, again, will sit for days, weeks, months, or even years, in the same corner, crouched up in the same attitude. Some will repeat incessantly the same words or the same phrase night and day; others will preserve a uniform and unbroken silence. Some clothe themselves in a ridiculous way, and, if permitted, will adorn their persons with a variety of absurd ornaments.

The face is generally pale; the eyes watery; the looks wandering, or fixed on vacancy; the countenance destitute of expression; the body lean and emaciated, or at other times loaded with fat.

The functions of organic life are performed with regularity; the sleep is commonly profound, and the appetite voracious.

Dementia is a rare disease in young persons, unless when complicated with epilepsy, and is most frequently either the termination of other forms of insanity or the accompaniment of advancing age. The varieties may be conveniently referred to different stages or degrees; and in the table of classification we have given the four degrees distinguished by Dr Prichard; namely, 1. That of forgetfulness, or loss of memory; 2. That of incoherence, or loss of the power of reasoning; 3. Incomprehension; and 4. Inappetence, or total fatuity.

Dementia is less curable than most of the varieties of insanity already described. Occurring in young persons, arising from removable causes of a debilitating kind, and occasionally when the result of mania, it may be removed by proper treatment; but a majority of the cases of this kind of mental derangement are very hopeless.

The duration and termination of uncured cases of dementia are very variable. When it is connected with serious diseases of the brain or of other organs, such as the lungs, it may terminate fatally within a short period, but if not so complicated, the patients may prolong their existence to nearly the average term of human life.

General paralysis.

General Paralysis of the Insane.—The insane are more liable than others probably to paralytic attacks; but the disease called *general paralysis* is one of a special character, and may be viewed either as a variety of insanity complicated with a peculiar affection of the motor powers, or as this affection of the motor powers complicated with insanity. The disease was first described by Esquirol and other French *alienistes*, but is now generally known, at least in all large asylums, in this country.

The characters of the mental disease which accompanies this affection are generally so peculiar and distinctive as to have acquired for it the name of *Mania paralytica*. The individual imagines that he is possessed of great wealth, and he is full of projects involving the expenditure of enormous sums of money; he believes that he is possessed also of titles and dignities of the most exalted kind; and, in short, all his delusions are of the most extravagant character (*delire ambitieux*). Conjoined with this there is generally a remarkably facile disposition, so that the patient is easily coaxed and managed. The mental disease is not always of this description; occasionally, but rarely, it presents the features of melancholia or monomania, and generally after a few months, when the violence of the first attack has subsided, it passes into dementia, which gradually increases and deepens until the fatal termination.

The peculiar general paralysis sometimes precedes the development of mental changes, but more frequently coincides with them, or is gradually developed after a maniacal attack. The first symptom is commonly a difficulty in articulating distinctly when speaking. The speech is "thick" or mumbling, like that of a person intoxicated. Next, although sometimes first, the powers of locomotion become impaired, and the person walks unsteadily, balancing himself with difficulty, like a drunk man. This loss of power, or rather of *control* over the muscular movements, gradually and slowly increases until the patient is unable to walk without assistance, cannot speak at all, and can scarcely swallow even liquids.

Patients labouring under this disease are generally subject to attacks of stupor or insensibility, with convulsions somewhat resembling epilepsy. Such attacks in some are frequent and severe, and in others are seldom or very slight.

The disease is regarded as incurable, and death generally takes place within one or two years. The fatal termination sometimes occurs during one of those epileptiform attacks to which the patients are subject; more frequently it is due to the development of other diseases, such as consumption or diarrhœa, or to the gradual exhaustion which accompanies the progress of the affection, accelerated not unfrequently by the formation of bed sores.

Epilepsy.

EPILEPSY WITH INSANITY.—Epilepsy, or the falling sickness, has been known from the earliest ages, and from the terrible character of the symptoms, it was ascribed by the ancients to demoniacal possession or to the anger of the gods. When it attacks young persons and continues to affect them, it appears to arrest the development of the brain, and to produce a permanent imbecility. Persons of maturer years who are subject to frequent epileptic fits have a tendency gradually to become affected by some variety of insanity. Sometimes it assumes the form of mania, maniacal attacks supervening upon the occurrence of the epileptic fits. These maniacal attacks are of short duration, generally passing off in a day or two, but are very frequently characterized by extreme violence. Indeed, maniacal epileptics are the most dangerous of all insane persons; their fury is blind and impulsive, and no control or fear daunts them.

Epileptics are also subject to various forms of monomania, and not unfrequently suffer from hallucinations of the senses.

The most frequent effect, however, of continued epilepsy is the gradual impairment of the memory, of the sensibility, and intelligence, until the subjects of it fall into a complete state of dementia.

The tendency to dementia appears to bear a direct relation to the frequency and persistence of the epileptic fits.

Epilepsy with insanity is generally regarded as incurable, and the principal object in the treatment of the patients is to guard them against the dangers incident to the fits;—to prevent them falling upon sharp corners, or into the fire; or dying of suffocation by turning over on their face upon the pillow during a fit; and to secure them and others from injury during the delirium or violence of the accompanying mental derangement. In the intervals between their paroxysms many of them are active and industrious, and make themselves useful and agreeable; and it seems well ascertained, that by judicious management, good diet, suitable occupation, and freedom from all causes of excitement or irritation, the frequency and violence of their attacks may be very much diminished.

Pathology.

The morbid appearances found in the bodies of those who have died insane are not such as to afford a satisfactory explanation of the symptoms of the disease. Changes indicative of a slow inflammatory action in the membranes of the brain are more or less frequent. Effusion of fluid beneath the membranes and into the ventricles or cavities of the brain is also a very frequent occurrence. These appearances are, however, very varied in their frequency and extent, and are sometimes found in the brains of persons who have not been insane. It is therefore inferred that they are the accidental concomitants of other morbid changes not yet recognised. Our ignorance of the minute anatomy of the healthy structure of the brain, and of those changes in its condition which accompany the exercise of its functions, make it probable that we are yet unable to appreciate by our means of observation those morbid changes which are the cause of mental disease. Some authorities have contended that insanity is a disease of the blood, and that the absence of pathological appearances in the brain, and the analogy between insanity and the effects of alcohol and other poisons which act upon the brain through the blood, afford strong presumptive evidence in support of this hypothesis. Others, again, have maintained that in those cases where no morbid changes have been found in the brain, the mental disease has been symptomatic of some other bodily affection, such as disease of the liver, bowels, or uterus. Lastly, in general paralysis of the insane the morbid changes generally found are more constant, such as thickening and opacity of the membranes of the brain, and effusion of serous fluid; and along with these, softening of the gray matter of the brain, and enlargement of the nucleated cells which enter into its composition. In not a few instances the white matter of the brain is increased in firmness and density. The large quantity of serous fluid found in the cavity of the cranium in many cases must be accompanied by a corresponding diminution of the size of the brain; and it appears also to be determined that the brain undergoes an increase in weight and in its specific gravity during the progress of the disease.

Causes.
1. Predisposing.
Hereditary predisposition.

The predisposition to insanity, it is well known, is engendered by marriages between blood relations. The children of cousins-german are, according to common observation, frequently of imbecile mind, idiots, or predisposed to insanity; and when intermarriages are confined within a limited channel during successive generations, they lead to the production of a greatly deteriorated, scrofulous, imbecile, and insane family.

Besides marriages between blood relations, there are other causes affecting the parents which appear to have an influence in engendering a predisposition to insanity in the offspring. Of this kind are strong mental emotions, hysteria, insanity, over-exertion of the mental faculties, and bad health on the part of the mother, and, perhaps, more frequently than any other cause, excess in the use of wine or other stimulants. Guislain states that he has known a whole generation of lunatics born of a mother who was habitually intoxicated for a series of years, although neither she, her husband, nor any of their families, were predisposed to insanity. He has also known epileptic children born of drunken parents, neither of whom were epileptic or predisposed to disease of the brain.

It is believed that the children of parents advanced in life are more liable to insanity than others; and that any causes which may produce nervous debility on the part of one or both parents tends to produce imbecility or a predisposition to insanity in the offspring.

It may be observed that among the children of parents predisposed to insanity there are remarkable peculiarities; one perhaps is an idiot or imbecile, another is a great libertine or drunkard; one may be distinguished by genius of a particular sort, while another is extremely reserved and secluded in his habits; one is a poet, and another a religious enthusiast; in fine, there are peculiarites and eccentricities which distinguish one or more members of the family in which hereditary predisposition to insanity exists.

The hereditary predisposition is frequently developed at a particular age in successive members of the same family, and father and son, or mother and daughter, will become insane at the same period of life.

The predisposition also is generally to the same form of insanity in successive generations,—father, son, and grandson become maniacal or epileptic,—mother and daughter have puerperal mania,—a parent and a whole family of brothers and sisters die of delirium tremens; and of all facts of this kind, nothing is more remarkable or more constant (according to M. Falret) than the constancy with which the suicidal impulse is transmitted from parent to child. A grandfather, a father, and son, have been known to destroy themselves at the same ages and in the same manner.

In consequence of the dislike which exists among most families to admit that there is any insanity or scrofula in their blood, it is extremely difficult to arrive at correct conclusions as to the frequency of hereditary predisposition to this disease in those affected by it; and accordingly we find the hereditary tendency variously estimated by different writers: by Parchappe, *e.g.*, it is estimated at 15, by Guislain at 25, by Webster at 33, by Thurnam at 34, by Esquirol at 45, by Jessen at 65, and by Holst at 69 per cent.

Lastly, M. Baillarger and Dr Browne deduce from their observations that the predisposition is more frequently transmitted through the maternal than through the paternal side of the family.

Age.

The predisposition to insanity appears to increase gradually with advancing age, being in infancy and childhood very small, and in extreme old age, if we include *senile dementia*, very great. From an extended series of statistical records, it appears that insanity is most frequent between the ages of thirty and forty. Next in frequency is the decennial period between twenty and thirty; and then comes the period between forty and fifty. These results do not, of course, give the number of insane of each age relative to the entire number of the population alive at that age, but only the absolute numbers affected at each decennial period. Making allowance for the successively decreasing number of persons alive at each successive period of life, it may be stated that, with the exception of the first period named, insanity, including dementia and fatuity, becomes more and more frequent with advancing age.

Sex.

Neither sex appears, on an extended view, to be more predisposed to insanity than the other. In some countries and in some districts the frequency of insanity in one sex is much greater than in the other; thus, in France the proportion of insane females to insane males is as 14 to 11, and in Paris as 3 to 2; on the other hand, in Great Britain and Ireland, and in Norway and America, the relation is reversed, the insane males being in the former as 13 to 12, in Norway as 6 to 5, and, taking the states of New York and Connecticut alone, as 2 to 1. These remarkable differences probably depend upon accidental circumstances, such as the greater frequency and poignancy of the *exciting* causes affecting the opposite sexes in these countries, than upon any greater predisposition to the disease in one sex as compared with another; for in collating the available statistics of all civilized countries, Esquirol arrived at the conclusion that the insane males were to the insane females in the ratio of thirty-seven to thirty-eight,—a very inconsiderable difference taking into account the difference in the actual numbers of each sex in the population.

Temperament.

The influence of *temperament* appears rather to determine the form of insanity than to predispose to the disease in one temperament more than another. Persons of a melancholic temperament are more predisposed to melancholia than to other forms of insanity; the lymphatic temperament predisposes to dementia; and the sanguine temperament to acute mania, with great violence and excitement where the temperament is specially pronounced.

Previous attacks.

No cause predisposes more certainly to insanity than previous attacks of the disease, however occasioned. Exposure to the same influences which developed it before will almost certainly lead to its recurrence. The frequency of relapses, as shown by the statistics of asylums, is very great.

Education.

Defective education, over-stimulation of the intellect at an early age, the early indulgence in strong passions and sensual propensities, the neglect of the cultivation of the will, of habits of self-control and self-denial, particularly in mental constitutions naturally ill-balanced, conduce in the greatest degree to the development of a predisposition to mental disease.

2. Exciting causes.

The exciting causes may be either moral or physical,—the former being those which affect the mind directly; the latter such as affect the body first, and through it the mind. It is believed that the moral causes are more frequent and efficient in the production of insanity than the physical. Of this it is believed the greater frequency of mental diseases among highly civilized communities than among barbarous or semi-barbarous nations, affords a strong proof. In uncivilized countries the habits are uniform,—there is the same invariable routine in the domestic history, in the manners, customs, and social institutions. In highly civilized states, on the other hand, where every department of life is full of competition, strife, and activity, the anxieties of living are innumerable; and there is a constant change of customs, of the position in life of individuals,—some rise to fortune, while others suddenly sink to ruin. The political and religious controversies which agitate the community; the arduous pursuits upon which numbers enter, stimulated by avarice or ambition; the race after fame; the jealousies and rivalries of parties; the intrigues of private life; domestic griefs and anxieties, caused by jealousy, misfortunes, and poverty;—are a few of the causes which may serve to account for the extreme prevalence of insanity in the European and North American states. In the tents of the Arabs, the huts of the Indians, and among the savages of Africa and the islands of the Pacific, insanity is said to be unknown. In Nubia and Abyssinia travellers failed to trace it. The insane in the asylums of Cairo and Constantinople are an insignificant portion of the population. In China we are assured it is very rare. The following table, constructed from various sources, shows its frequency in some of the more highly civilized states compared to the population:—

	1 in each
In Italy	4879
... Rhenish Provinces	1000
... France	1000
... Westphalia	846
... Belgium	816
... United States	721
... England	578
... Denmark	549
... Scotland	370
... Norway	329
... Iceland	311

It is difficult to account for the great frequency of insanity in the countries last mentioned, unless it be due to the scanty nature of the population, their miserable means of subsistence, and the greater frequency of intermarriages.

Moral causes.

Pinel estimates the frequency of moral causes, compared with physical, in the production of insanity, as 464 to 219.

The most frequent of all the moral causes are domestic griefs, anxieties, and reverses in fortune. Next in frequency are violent emotions and passions, disappointments in love, grief for the loss of relatives, and wounded ambition or pride.

It is inferred from statistical tables, that married persons are less liable to insanity than unmarried.

Religion was at one time supposed to be a frequent cause; and it might be inferred that a subject calculated to inspire, on the one hand, vivid emotions of happiness, or gloomy forebodings, terror, and despair on the other, would be likely to exercise an important influence on persons predisposed to mental disease, when their minds were absorbed with such feelings. Nevertheless, as a cause it is by no means frequent. Many of the cases ascribed to it are due rather to ignorance and superstition; while most of the cases of religious despondency are due to other causes very often affecting the bodily health.

Physical causes.

By far the most common in this country of the causes of a physical kind is intemperance. Next in frequency is general derangement of the health, particularly of such a kind as exercises a debilitating effect on the body and nervous system. The critical period in females, parturition, and uterine irregularities; blows on the head and diseases of the brain, epilepsy and advanced age, fever, intestinal worms, the suppression of an accustomed discharge or eruption, the metastasis of rheumatism or gout, and various vicious indulgences, are, nearly in the order enumerated, among the most frequent of the other physical causes to which insanity has been ascribed.

Treatment.

The medical treatment of the insane has undergone a great revolution during the present century. At one time large and repeated bleeding was much lauded in the treatment of mania. It is now almost entirely abandoned, and regarded as dangerous to life, or tending at best to convert the case into one of dementia. The general use of blisters and issues, of purgatives and emetics, and of specifics, once in high favour, has now also given place to the use of milder remedies and more rational principles of treatment. It would be out of place to enter into details in this article as to matters purely medical; but it may be stated in general terms that the warm bath, and especially prolonged warm baths with cold applied to the head, have been found of great advantage in allaying the excitement of mania; that the judicious use of opium in certain cases, for procuring sleep, has also been esteemed as a valuable remedy; and that the restoration of the general health by the use of appropriate means, and the removal of local diseases, when they exist, by treating them on the general principles of medical science, constitute nearly all the canons of medical treatment now recognised in regard to mental diseases. It is not now imagined that any particular medicine exerts a specific effect in the cure of insanity; and beyond the judicious and skilful treatment of the patient with a view to the cure of local bodily disease, and the restoration of the whole system to the standard of robust health, the great and important part of the management of the insane consists in what has been called the moral treatment.

Moral treatment.

The great principle upon which the moral treatment of mental diseases is founded is the distraction of the mind from morbid trains of thought or feeling, and its occupation in new and healthy channels. In carrying out this principle, the first and most important object is to remove the patient from the scene of his first attack, and from the presence of his friends. The objects which surround him suggest and preserve in activity the subjects of his excitement or delusion; the presence of friends exerts the same deleterious influence, and as they are commonly with the insane the special objects of dislike and suspicion, their presence irritates and aggravates the disease; while they commonly add to the injury they are thus unconsciously inflicting, the evil of deepening and strengthening all the morbid fancies of the sufferer by vain efforts to reason him into a belief of their absurdity. "Dr Willis," says Esquirol, "who acquired so great a celebrity by having assisted towards the happy termination of the first attack of madness experienced by George III., unfurnished the king's apartments, dismissed his courtiers and domestics, and had him attended by strange servants."

The complete manner in which this change of scene and associations is effected by removal to an asylum, is one of the principal causes which renders early removal to such an establishment an efficient curative agent.

The patient requires to be surrounded by experienced attendants, allowed the greatest liberty, and treated with the utmost amount of kindness compatible with his own safety. All restraint should be avoided; the free use of his limbs, and abundant exercise in the open air, tend to carry off the superfluous energy and excitement of his malady.

A variety of means may be had recourse to, suited to the peculiarities of each case, for carrying out the first principle of treatment,—the healthy occupation of the mind. Of these, useful and rational occupation, particularly in the open air, holds the first rank. Walking, gardening, open-air games, travelling, angling, and other such like amusements, according to the rank, or taste, or disposition of the patient, are next to be preferred. In many cases music exercises a soothing and salutary influence. In others, drawing, and in-door games of all kinds, combined and varied with reading, sewing, knitting, embroidery, and other occupations suited to the peculiarities of the individual. In a large proportion of cases the regulated observance of religious exercises, and attendance upon divine service, contributes to the healthy moral influence of other agents. In fine, everything which can employ and interest a healthy mind, and which is apart in its character or by association from the morbid thoughts of the patient, ought to be brought into exercise for his recovery. These various agents, however, must be judiciously adapted to each case, and must be systematized and directed with prudence and skill, and a constant attention to the great object of establishing a healthy current of thought and feeling through the channel of regulated habits, occupation, and amusement.

These appliances for the treatment of mental diseases are best carried out in a well-managed asylum, where every thing is organized with a view to their development, and directed and superintended by a skilful and experienced physician. The treatment of the insane in private dwellings, even where the most lavish expenditure of money can be commanded, cannot in general secure the same advantages. The patients are exposed to the unkindness or neglect of mercenary and eye-serving attendants, who soon weary of duties which are both trying and onerous if not under the constant supervision of a controlling and directing power.

The arrangements and management of some of our best regulated asylums give at one view the best idea of the proper treatment of the various forms of insanity. These institutions, compared with those of former years, stand out in bold relief as monuments of the progress of the age; and to those whose ideas of insanity are associated with ferocity, danger, and all that is loathsome, they must appear to be among the wonders of modern times; so much has been effected in them by well-directed discipline and enlightened philanthropy in ameliorating the condition of the insane.

Such a house subserves a variety of ends: it is a place for the isolation and safety of the dangerous; it is a retreat and home for the hopeless and incurable; it is a great hygienic hospital for the restoration of the insane to physical and mental health; a house for moral and physical education; it is also a school for elementary, artistic, scientific, literary, and religious education; and an industrial establishment where the busy crafts of artizans and gardeners, and all the homely occupations which can employ the hands and heads of men and women, are called into systematic and daily activity.

The best institutions of this kind are erected on carefully selected sites commanding a wide prospect of cheerful and varied scenery. They are placed in sheltered positions, with a southern aspect, and are inclosed within an ample space of garden and farm. The beneficial influence of cheerful and picturesque scenery upon the minds of the insane is unquestionable; and the occupations afforded by a farm, by flower-gardens, pleasure-grounds, and conservatories, are of the very highest curative effect.

The buildings are constructed with taste and with a strict attention to the means of ventilation and comfort. Everything is avoided which can give the idea of a prison or of confinement; while the arrangements are such, at the same time, as to afford security to the inmates. The galleries are cheerful, spacious, and well lighted; and all the rooms and airing-grounds command an agreeable prospect. Workshops are provided for the industrious, and in these the carpenters, tailors, shoemakers, and other tradesmen, pursue with happiness their several occupations. The females are encouraged in habits of industry, and sew, knit, and embroider in their workrooms, or assist in the culinary department or the more laborious duties of the washing-house and laundry. The rooms and workshops are neatly furnished, and the walls are hung with drawings or paintings. Flowers and singing birds everywhere cheer the eye and the ear. Books, and periodicals, and newspapers, are liberally supplied, and perused with avidity. Each day is commenced with careful ablutions, followed by morning prayers. To a comfortable breakfast succeed the various occupations of the day, when each one follows out the occupation prescribed for him, assisted and encouraged by the kind acts of his attendant, and stimulated to exertion by some trifling reward. Dinner is served with all the comfort and regularity of a private meal; and work is again resumed. At an early hour tea is followed by amusement of some kind; in the summer time by cricket, bowls, quoits, or some other open-air game; in the long evenings by a reading party, a lecture, a concert, or dance, some dramatic representation, or some in-door games suited to the taste and capacity of those engaged. Some are encouraged to prosecute a systematic course of reading or the study of some science, while others are induced to undertake some literary labours. All are as far as possible made to feel themselves happy and contented in the prosecution of some purpose, which carries their mind away from the subject of their disease, and which is adapted to their capacities, their natural tastes, or the peculiar phase of their malady.

This institution is, or should be, regulated and directed, throughout all the details of its management and daily routine, by a physician of the highest natural and professional ability. The qualifications for such an office are indeed of the rarest kind; but they are at the same time indispensable. He must unite the natural endowments of benevolence and firmness. He must be good and humane, and at the same time just and inflexible; courageous and calm, tempering firmness with serenity, and kindness with decision and impartiality. He must be possessed of a sound practical knowledge of human nature in all its phases, and that innate power or tact which enables one to govern others with ease, to acquire their confidence and esteem, and at the same time to command their ready obedience and respect. He must be acquainted with the usages of society among all ranks and among all the varieties of human character. He must be versed in polite literature, and must have a taste for the lighter accomplishments of civilized society, so as to be able to direct and give an impulse to the amenities of asylum life. He must have a general knowledge of business, of house architecture and engineering, of farming and gardening, botany and natural history, and of the various trades and manufactures, so as to qualify him for the superintendence of a large institution where operations in all these departments require to be directed and encouraged. Combined with these general qualifications, he must be skilled in his own profession in all its departments, so as to give the advantage of enlightened professional skill to the medical treatment of his patients.

Under the advantages of such an institution as we have described, and under the care of a physician with such qualifications as those enumerated, it cannot be doubted that an asylum affords the best prospect of recovery in curable insanity, and the best means of affording happiness and prolonged life in the incurable forms of this malady. That many of the best asylums of this and other countries possess all these means and appliances, and are conducted with consummate skill and benevolence, is not now a matter of doubt, but one of grateful reflection to every philanthropic mind.

Increase of insanity.

It is a question of great interest, but of no little difficulty, at the present moment, to determine whether insanity is on the increase in this and other civilized states. The statistics of insanity, the gradual increase in the number of public and private asylums, and the rapidity with which they are filled as soon as erected, all seem to indicate a great increase in the numbers affected with mental disease. On the other hand, it is certain that statistical inquiries have in successive periods been conducted with much greater minuteness; that cases are now sent to asylums which formerly were allowed to go at large or were treated at home; that as the advantages of early seclusion in an asylum are becoming more widely known, and the prejudices against those institutions are dying out, friends more readily resort to them for the care or cure of their relatives, even under the slighter forms of insanity; and lastly, the legal enactments for the provision of pauper lunatics have gradually become more stringent, and few cases of idiocy, or epilepsy, or monomania, are now permitted to wander at large. These causes have given an apparent increase to the number of those returned as insane; and it is impossible at present to determine whether there is actually any absolute increase in the ratio of the insane to the sane portion of the population.

Laws regarding insane.

In England and Ireland no one can be sent to an asylum without an order from a relative, and the certificates of two medical men who have separately examined, the patient, and who are required to state the grounds upon which they formed their opinion in their certificate. In the case of paupers the order of a justice of the peace is required. In Scotland the sheriff of the county grants a warrant for the removal of a patient to an asylum upon an application or petition from a relative or guardian, accompanied by the certificate of one or two medical men. If these rules are not attended to, the person sending and the person receiving a patient into an asylum are liable in heavy penalties.

The restriction of one's liberty by his being placed in an asylum is a means of cure or safety, and does not in itself deprive the individual of his legal rights. He can only be deprived of these by a regular form of inquiry, whereby he is declared insane by a commission, or by the verdict of a jury.

The existence of insanity does not in itself disqualify for legal acts, or exonerate from responsibility for acts of violence or murder. Wills have been held to be good although executed by persons who were confessedly insane; but it was considered that their insanity, or the delusions under which they laboured, were not of such a kind as to interfere with their judgment in the disposition of their affairs. In the same manner persons have been held responsible for criminal acts about whose insanity there was no doubt, but it was deemed not to be of such a nature as to prevent them knowing right from wrong in the act which they committed. These subjects involve intricate and difficult medico-legal questions, and can only be briefly indicated here.

IV.—IDIOCY,

Idiocy.

Or Idiotism, is a natural or congenital weakness of the mental powers, and varies in degree from slight impairment or imbecility, by gradual and insensible shades, down to absolute idiocy, or total absence of intelligence.

Idiocy depends upon some congenital disease of the brain, or the want of the due development of that organ

In the former case the head is often large and misshapen, and in the latter it is generally small, and also irregular in shape. The form of the head; the low, retreating, and contracted forehead; the flattening of the occipital region and the expression of the thick-lipped face; the figure, which is generally small and deformed;—are all familiar, and are strongly indicative of the mental condition.

Idiocy exists to a very great extent in certain districts where goitre or bronchocele (an enlargement of a structure in the neck) is found to prevail. These districts are mostly the valleys at the foot of lofty mountains, where the air is stagnant and humid. This disease is called *cretinism.* It prevails to an enormous extent in some portions of Switzerland, Sardinia, and Austria. In the Canton du Valais 1 in every 25 inhabitants is a cretin, in the Canton de Vaud 1 in every 27, and in the Canton d'Uri 1 in every 83; in Judenburg in Austria there is 1 to every 53 of the population, and in Bruck 1 in every 74. In Upper Austria, along the banks of the Danube, whole families consist of cretins; and in some villages of from 4000 to 5000 inhabitants not one was found capable of bearing arms. In many other mountainous districts in Europe and other parts of the globe this endemic disease is found to exist.

The subjects of this affection exhibit idiocy in its most absolute and loathsome form. They are diminutive creatures with large bellies and misshapen limbs, heads of unusual form or size, blear and sunken eyes, flat noses, and large lips, the tongue protruding, the mouth open, and the saliva running from it. The skin is loose and yellow. The poor victims of this disease can neither see, hear, nor speak; they can scarcely creep from place to place, and are lost to all sense or intelligence beyond the bare instincts of animal life. This description refers to the worst class of cases. Many of them display a certain degree of intelligence; but although treated with extreme kindness, they are obstinate, mutinous, and incapable of gratitude. They seldom live beyond thirty years of age.

The causes of this disease have been sought for in the water which is drunk by the inhabitants of the affected districts, in the confined and humid atmosphere which they breathe, and in their filthy and crowded houses, their intermarriages, and their intemperate and lazy habits.

By Dr Guggenbühl and some other authorities this condition is considered to result from a disease analogous to rickets, and affecting also the cerebro-spinal system, and that by appropriate treatment adopted at an early age it may be cured. His treatment, combined with a gymnastic and educational training, has been successfully pursued for some years in his establishment at Interlachen.

We have already briefly alluded to the various institutions in this and other countries which have been recently organized for the care and improvement of idiots. It remains yet to be seen how far the mental faculties and moral emotions of this class of unfortunates can be developed and elevated by proper training and treatment; but the success which has already attended the philanthropic labours of those who have entered upon this path of benevolence is of the most gratifying and encouraging description.

The following is a condensed bibliography of the more important works on insanity, idiocy, and asylums:—

Celsus, lib. iii., c. 18; Aretæus, *Cur. Chron.*, lib. i., c. 5; Paulus Æginetus, lib. iii., c. 14.; T. Bright, *A Treatise of Melancholie*, 1586; A. Laurentius, *Discours des Mal. Melancholiques*, 1597; Burton, *The Anatomy of Melancholy*, 1624; Harvey, *Morbus Anglicus*, &c., 1666; Battie, *Treatise on Madness*, 1757; Monro, *Remarks on Madness*, 1757; Lony, *De Melancholia*, 1765; Perfect, *Methods of Cure in Insanity*, 1778; Andry, *Recherches sur la Melancholie*, 1786; Arnold, *On Insanity*, 1782; Crichton, *Inquiry into the Nature and Origin of Mental Derangement*, 1798; Haslam, *On Insanity*, 1798; Haslam, *On Madness*, 1809; Haslam, *Illustrations of Madness*, 1810; Haslam, *Considerations on the Moral Management of Insane Persons*, 1817; Pinel, *Traité sur l'Aliénation Mentale*, 1801; Translation of do. by D. Davis, 1806; Hoffbauer, *Untersuchungen über die Krankheiten der Seele*, &c., 1803; Cox, *Practical Observations on Insanity*, 1804; Esquirol, *Des Passions considéreés comme Causes, &c., de l'Aliénation Mentale*, 1805; Crowther, *Practical Remarks on Insanity*, 1807; Chiaruggi, *Della Pazzia in Genere ed in Especie*, 1808; Hallaran's *Inquiry*, &c., 1810; Tuke, *Description of the Retreat, near York*, 1813; Hill, *On the Prevention and Cure of Insanity*, 1814; Fodere, *Du Délire*, 1814; Heinroth, *Storungen des Seelenbebens*, 1818; Spurzheim, *Observations on Insanity*, 1818; Georget, *De la Folie*, 1820; Barrow's *Inquiry*, 1820; Barrow, *Commentaries on Insanity*, 1828; Falret, *De l'Hypochondrie*, &c., 1822; Prichard, *On Nervous Diseases*, 1822; Prichard, *On Insanity*, 1835; Willis, *On Mental Derangement*, 1823; Bayle, *Traité des Maladies du Cerveau*, 1826; Calmeil, *De la Paralysie chez les Aliénes*, 1826; Guislain, *Traité sur l'Alien. Mentale*, 1826; Guislain, *Traité sur les Phrenopathies*, 1835; Do., 1852; Charlesworth, *On the Treatment of the Insane*, 1828; Halliday, *General View, &c., of Lunatics and Asylums*, 1828; Freidreich, *Path. and Therap. der Phsychischen Krankheiten*, 1830; Conolly, *Indications of Insanity*, 1830; Conolly, *Construction and Government of Asylums*, 1847; Conolly, *Treatment of Insanity*, 1856; Combe, *On Mental Derangement*, 1831; Seymour, *On the Medical Treatment of Insanity*, 1832; Uwins, *Treatise on Disorders of the Brain*, &c., 1833; Schlegel, *Das Heimweh und der Selbstmord*, 1835; Browne, *Asylums as they were, are, and ought to be*, 1837; Esquirol, *Des Maladies Mentales*, 1838; Ellis, *On the Nature, &c., of Insanity*, 1838; Mayo, *Elements of the Pathology of the Human Mind*, 1838; Hill, *Total Abolition of Restraint*, &c., 1839; Millingen, *Aphorisms on the Treatment of the Insane*, &c., 1840; Winslow, *The Anatomy of Suicide*, 1840; Leuret, *Traitement Moral de la Folie*, 1840; Voisin, *De l'Idiotée chez les Enfans*, 1843; Twining, *Account of Cretinism*, &c., 1843; Pinel, *Traité de Pathologie Cérébrale*, 1844; Wigan, *Duality of the Mind*, 1844; Thurnam, *Statistics of Insanity*, 1845; Turck, *De la Nature et du Trait. de la Folie*, 1845; Moreau, *Du Hachisch et de l'Aliénation Mentale*, 1845; Boismont, *Du Délire Aigu*, 1845; Boismont, *De l'Emploi des Bains Prolongés*, 1848; Boismont, *Des Hallucinations*, 1852; Boismont, *Du Suicide*, 1856; Sequin, *Traitement Moral, &c., des Idiots*, 1846; Rodrigues, *De la Paralysie Générale*, 1847; Morison, *Lectures on Insanity*, 1848; Coldstream, *The Abendberg*, 1848; H. Monro, *On Insanity*, 1851; Williams, *On Insanity*, 1852; Morel, *Traité des Maladies Mentales*, 1852; Holland, *Chapters on Mental Physiology*, 1852; Cumming, *Notes on Asylums in Germany*, 1852; Parchappe, *Construction des Asiles d'Aliénes*, 1852; J. Falret, *Recherches sur la Folie Paralytique*, 1853; J. Falret, *Leçons Cliniques de Medicine Mentale*, 1854; Wharton, *On Mental Unsoundness*, 1855; Blackie, *On Cretinism*, 1855; *Report on Insanity and Idiocy in Massachusetts*, 1855; Noble, *Psychological Medicine*, 1856; Ideler, *Lehrbuch der Gerichtlichen Psychologie*, 1857; Bertrand, *Traité du Suicide* 1857; Morel, *Traité des Dégénérescenses*, 1857.

MENTSCHIKOFF, or Menzikoff, Alexander, an eminent Russian general and statesman, was the son of a peasant, and was born near Moscow in 1674. While plying his trade as a pastry-cook's boy in the streets of the capital, he attracted the notice of Lefort, the favourite of Peter the Great. Having become the servant of that nobleman, he showed so much talent that his master raised him from the office of a menial, and instructed him in the affairs of war and government. On the death of Lefort in 1699 Mentschikoff succeeded to his place in the favour of the czar. Nor was he an unworthy successor. He distinguished himself at the siege of Schlüsselburg in 1702; and in 1704, so notable had been his services that he was appointed governor of Ingria, and was honoured with the rank of a prince and with the title of major-general. In the war against Charles XII. of Sweden Mentschikoff bore an important part. In 1706 he routed the Swedes in a pitched battle; in 1709 he led on the left wing at Pultowa, and in the flight that followed that decisive victory he compelled Lewenhaupt, the Swedish general, to capitulate. Hitherto his style of living had been simple and unostentatious. But no sooner had Peter the Great in 1711 set out on his expedition against the Turks, and left him in charge of the government at St Petersburg, than he erected a palace, increased the number of his servants, and began to give the most sumptuous banquets. At the same time, his riches swelled to such a suspicious extent, that on the czar's return he would have been punished for embezzlement of the public money had not his former distinguished services palliated the offence. Restored to favour, Mentschikoff was appointed commander of the army in the Ukraine in 1719, and ambassador to Poland in 1722. About this time he was anxiously looking for the death of the czar, and was employing all his penetration to discover the likely successor to the crown. On attaining the object of his scrutiny he timed his conduct so ably, that on the death of Peter in 1725 he was raised to the summit of power under Catherine I. Two years afterwards that princess died, charging her heir, Peter II., to espouse the daughter of Mentschikoff. But the eagerness of the ambitious father to bring about the espousals disgusted the young prince; the suggestions of the Dolgoroukis, the royal favourites, intensified that disgust; and in a few days Mentschikoff was sentenced to be banished to one of his own estates. Obeying the sentence with a defiant haughtiness, he left the city sitting in his handsome chariot, wearing all his badges, and attended by troops of servants. Before he had proceeded far, however, he was overtaken by the emissaries of the czar, stripped of all his pomp and magnificence, clothed in the garb of a peasant, and conducted in a covered waggon, along with his family, into Siberia. His wife had died by the way; his eldest daughter fell a prey to the small-pox soon afterwards; but Mentschikoff himself, while shivering in a rude hut, and digging an inhospitable soil for bread, maintained his spirit unbroken. He began to seek the consolations of religion, and died of apoplexy on the 2d November 1729 while engaged in erecting a wooden chapel. He was the first count and the first prince created by a Russian sovereign, and was the founder of a family which cannot boast of any very distinguished name till we come to his grandson, the present Prince Mentschikoff, the celebrated general who defended Sebastopol.

MENTZ. See Mayence.

MENZELEH. See Egypt.

MEPPEL, a town of Holland, province of Drenthe, on the Reest, near its confluence with the Echtinger and Havelter, 26 miles S.W. of Assen and 6 from the Zuider Zee. The town has two churches, a synagogue, schools, &c.; and establishments for the manufacture of linen and cotton stuffs, canvas, leather, hats, and tobacco; besides breweries, boat-building yards, bleachworks, &c. Pop. 6070.

MEQUINEZ, a town of Morocco, province of Fez, in a fertile valley, 70 miles E. of Sallee and 34 W. S. W. of Fez. The houses, which are generally only one storey high, are neat and well built; but the streets are unpaved. The town is surrounded by a wall 6 feet high, which serves as a defence against the attacks of the Berbers. The principal building is the palace erected by Sultan Muley Ismael, who made Mequinez one of the capitals of his dominions; and it is still occasionally the residence of the sultan. The palace is extensive, but low, and contains fine gardens and marble-paved court-yards. It is built of marble, and adorned with fountains of the same material; while the walls are inlaid with red and blue tiles. The manufacture of leather is carried on in the town; and in the vicinity there are large plantations of olives. Pop. about 70,000.

MERCARA, a town and fortress in the south of India, is situated within the British district of Coorg, of which it is the capital. It was built by Hyder Ally in the year 1773, after he had conquered the country. Upon the conclusion of peace with Tippoo Sultan in 1792 it was given up to the rajah of Coorg; but upon the contumacious conduct of this prince in 1834, it was occupied by a British force under Colonel Lindsay, and the rajah being soon after deposed, the present British establishments were formed. It is 72 miles E. from Seringapatam. Long. 75. 48. E., Lat. 12. 24. N.

MERCATOR, Gerard (the Latin name generally given to Gerhard Kauffmann), one of the most celebrated geographers of his time, was born at Rupelmonde in Flanders on the 5th of March 1512. After completing his elementary studies at Bois-le-Duc, he went through a course of philosophy at the university of Louvain, where he took his degree. Having applied himself with extraordinary ardour to the study of geography and mathematics, he soon received the patronage of the Emperor Charles V., and in 1599 was nominated cosmographer to the Duc de Juliers at Doesburg, where he died in 1594, at the advanced age of eighty-three years. He is principally known from having given his name to the projection generally employed in nautical maps, in which the meridians and parallels are represented by straight lines which mutually intersect at right angles. Besides executing tables of chronology and geography, he published many valuable maps, engraved and coloured by his own hand.

His works are,—*Chronologia a Mundi exordio ad ann.* 1568, Köln., fol., 1569; *Tabulæ Geographicæ ad mentem Ptolemæi restitutæ*, fol., 1578; *Globi Terrestris Sculptura*, 1541; *Globi Cœlestis Sculptura*, 1551; Atlases, 1595, 1628, 1633. He also published two theological works,—*Harmonia Evangelistarum*, 1592; and *De Creatione ac Fabrica Mundi;* the latter forming a dissertation prefixed to his Atlas of 1595, and which was condemned by the church for setting forth certain heterodox views respecting the doctrine of original sin.

Mercator, *Nicolas* (the Latin name of Nicolas Kauffmann), an eminent mathematician, was born at Holstein in Denmark in 1640. He visited England in 1660, when he was chosen a member of the Royal Society, and returned to Paris previous to his death in 1687. He was the first to detect the defect of Gerhard Mercator's projections, afterwards rectified by Edward Wright. Of all his works on cosmography and mathematics, by far the most original and valuable is his *Logarithmotechnia, sive Methodus Construendi Logarithmos Nova; cui accedit Vera Quadratura Hyperbolæ, et Inventio Summæ Logarithmorum*, London, 1668–1674, 4to.

MERCIA, one of the ancient kingdoms of the Saxon heptarchy in England, bounded on the N. by Northumbria,

E. by East Anglia and Essex, S. by Wessex, and W. by Wales; and including the modern counties of Chester, Derby, Nottingham, Lincoln, Salop, Stafford, Leicester, Rutland, Northampton, Huntingdon, Hereford, Worcester, Warwick, Gloucester, Oxford, and Buckingham, along with parts of Hertford and Bedford. It is believed to have been founded by a body of Angles under Crida in 585 A.D. It was conquered by the Northumbrians in the seventh century, but soon after regained its independence, subdued the kingdoms of East Anglia and Kent, and was finally incorporated in his dominions by Egbert, King of Wessex, in the year 825.

MERCIER, Louis Sebastien, an eccentric French writer, was born in Paris in June 1740. After publishing several heroic epistles, and holding for some time the professorship of rhetoric at Bordeaux, he first displayed his satirical power in *L'An* 2440; *Rêve, s'il en fut jamais*, Amsterdam, 1771. In his *Essai sur l'Art Dramatique* he struck at the fame of Corneille, Racine, and Voltaire, and proposed, with grave self-conceit, to replace their dramas by his own productions. The comedians, however, rejected this proposal, and brought down upon themselves the satirical lash of Mercier. A more legitimate subject of satire was the corrupt social system of the French capital. Accordingly, in 1781 Mercier began to attack it in the first two volumes of his famous *Tableau de Paris*. While this work was exciting a great ferment in the nation, the vanity of the author would not suffer him to remain anonymous and to see it attributed to others. He therefore discovered himself to the inquisitor Lenoir, but thought it advisable at the same time to betake himself immediately to Neuchatel, and to publish the remaining ten volumes there. After visiting Germany, Mercier returned to France on the eve of that revolution which he vauntingly attributed to his *Tableau*. He assisted Carra for some time in editing *Les Annales Patriotiques* and *Chronique du Mois*. As a member of the Convention for the department of Seine-et-Oise, he voted for the perpetual detention of the king. Having been admitted in 1795 into the Council of the Five Hundred, he opposed the motion that Descartes should receive the honours of the Pantheon. He also signalized himself by his vehement invectives against education, which he styled "the pest of the human race." On his retirement from this council he was appointed professor of history in the central school, and a member of the newly-formed institute. Mercier died at Paris in April 1814. Among his numerous works are,—*Mon Bonnet du Nuit*, in 4 vols. 8vo, Neuchatel, 1783; *Histoire de France depuis Clovis jusqu'au Règne de Louis XVI.*, in 6 vols. 8vo, 1802; and *Neologie*, in 2 vols. 8vo, Paris, 1801.

MERCURIUS, a Roman divinity. The connection of his name with *merx*, goods, and *mercari*, to traffic, indicates that the first idea of his character was that of the patron of merchandise. As the Latin writers, however, became intimate with the literature of Greece, they identified his life and functions with those of the Greek god Hermes. Mercury, therefore, was said to be the son of Jupiter and Maia, and to have been born in a cave of the Arcadian mountain Cyllene. Scarcely had he seen the light when he seized upon a tortoise, and out of its shell framed the first lyre. He then proceeded to Pieiria, and drove off part of the flock of Apollo to a cave in Pylos. The owner detecting the theft, pursued, and recovered his property; but was so charmed with the music of the newly-invented lyre, that he returned the oxen, and presented to the young god a golden staff called *caduceus*. At the same time Jupiter installed him in the office of herald and messenger of the gods. In this capacity Mercury tied Ixion on the wheel, chained Prometheus to Mount Caucasus, assisted Perseus to kill Medusa, conducted Juno, Minerva, and Venus to Paris, and slew Argos the hundred-eyed. He was also employed to lead the ghosts of the dead to the other world, to infuse dreams into the brain, and to cause or dispel slumber by the passes of his magic wand. From his character as a herald, Mercury came to be considered an adept in eloquence, and therefore the patron of orators, poets, and other men of genius. Since his office also led him to be the promoter of intercourse and agreement between parties at a distance from each other, he was regarded as the god of commerce and of all the other means that produce peace and unity among nations. Yet as he was sometimes sent on hostile missions, and was not scrupulous on these occasions about the devices he employed, he was supposed to listen to the prayers of thieves and robbers. His patronage was likewise extended to shepherds, musicians, travellers, and athletes. He is said to have invented letters, arithmetic, astronomy, music, and the syrinx. The two most celebrated temples of Mercury were situated, the one upon Mount Cyllene in Arcadia, and the other near the Circus Maximus in Rome. His festivals were called *hermæa*. His images, styled *hermæ*, were set up at cross roads and in the porches of temples and mansions. Mercury is generally represented as a naked youth, displaying in his limbs the beauty of the boy mingled with the full vigour of manhood, holding a purse in his right hand and his winged *caduceus* in his left, wearing one pair of wings on his sandals and another on his hat, and bending forward on tiptoe, as if speeding over sea and land on some important errand.

MERGUI, a town of Hindustan, and the capital of the British district of the same name, in the Tenasserim provinces, is situated on the principal mouth of the Tenasserim River. It is about three miles in circuit: the streets are wide; and the houses, which are built chiefly of wood, are raised on piles from the ground. The harbour is spacious, secure, and easy of access for ships of any size. Pop. about 12,000. The place was taken by the British during the first war with the Burmese, and confirmed to the conquerors, with other territory, by the treaty of Yarid-Abhoo concluded in February 1826. Lat. 12. 27., Long. 98. 42. Opposite to the coast is a cluster of islands denominated the Mergui Archipelago, the principal of which are,—the Great and Little Canister, King's Island, Cabossa, Bentinck, Domel, Kisseraing, Sullivan's, and St Matthew's.

MERIAN, Jean Bernard, an eminent philosopher, was born at Leichstall, in the canton of Bâle, in 1723. His father, who was a highly respected pastor in his native town, removed to Bâle, and was placed in 1738 at the head of the Protestant churches of the canton. The objects of study which attracted him most were poetry and philosophy; for he possessed in an almost equal degree a taste for philology and philosophy, for metaphysics and the fine arts. Having received his doctor's degree at the age of seventeen, he soon after entered the church, and distinguished himself as a preacher. After a short residence at Lausanne, which enabled him to perfect himself in the French language, Merian accepted the place of preceptor to the sons of a gentleman in Amsterdam, where he spent four years. In 1748 he received from Maupertuis, president of the Academy of Berlin, an invitation to attach himself to that learned body, with the offer of a pension from Frederick II. Merian did not hesitate to respond to this flattering proposal, but came immediately to Berlin, where, during more than half a century, he exerted a most salutary influence not only over the Academy of Sciences, but over public instruction in general in Prussia. He enriched the philosophical literature of the academy by a series of memoirs on some of the most important problems in morals and metaphysics, and which are generally regarded as masterpieces of clearness and impartiality. On the death of Formey, whose *éloge* he pronounced in 1797, Merian was appointed perpetual secretary to the academy. He died on the 12th of February 1807, lamented by many of the greatest names in Europe, with whom he had been long associated, such as Euler, Lagrange, Sulzer, Lambert, Ancillon, &c.

At the request of Frederick II. Merian translated Claudian's *Enlèvement de Proserpine;* and afterwards published the *Essais Philosophiques* of David Hume, and the *Lettres Cosmologiques* of Lambert. In his philosophical memoirs his main object is to combat the philosophy of Leibnitz. These will be found in the Memoirs of the Academy of Berlin, extending over a period of upwards of forty years, from 1749 to 1804. (For farther information respecting Merian, see the *Eloge Historique* of Fr. Ancillon, published in the Memoirs of the Berlin Academy for 1810; also *Cours d'Histoire de la Philosophie Modern* of Victor Cousin, vol. i., first series; and the *Dictionnaire des Sciences Philosophiques*, Paris, 1849.)

Merian, *Matthew*, an eminent painter, was the son of a distinguished engraver of the same name, and was born at Bâle in 1621. After studying under his father and Sandrart, he travelled to complete his education in his art, and became intimate with Vandyck and Rubens in England, with Vouet and Lesueur in France, with Sacchi and Maratti in Italy, and with Jordaens in the Netherlands. He settled first at Nuremberg, and afterwards at Frankfort-on-the-Main. In the latter city he painted, after the style of his master Vandyck, the portraits of the Emperor Leopold I. and several other German princes. These works were rewarded with both money and honours. Yet at the same time Merian conducted the trade in books and prints which his father had left him. He died at Frankfort in 1687.

Merian, *Maria Sibylla*, a skilful drawer of insects and other subjects of natural history, was the sister of the preceding, and was born at Frankfort-on-the-Main in 1647. She was instructed in drawing by Morell, her step-father, and Abraham Mignon, and soon displayed a notable taste and truthfulness in her sketches of flowers, butterflies, and caterpillars. In 1665 she was married to John Andrier Graff, a painter of Nuremberg, but was still known by her maiden name. Her studies and her scientific excursions were not interrupted, and the first result of her labours was published in 1679–83, under the title of *The Origin of Caterpillars, their Nourishment and Changes,* in 2 vols. 4to, Nuremberg. A Latin translation of this work appeared in Amsterdam in 1717. In 1684 she and her husband were induced by offers of patronage to settle in Holland. Maria Sibylla's enthusiasm for her art increased with her years. In 1699 she crossed the Atlantic with no attendant but her daughter, and spent two years at Surinam in sketching the insects, shells, and plants of the new world. A part of these sketches was published in her *Dissertatio de Generatione et Metamorphosibus Insectorum Surinamensium,* Amsterdam, 1705. Maria Sybilla Merian died in 1717. A new edition of her last work was published soon after her death, with twelve plates by her two daughters. Her former work, enlarged by herself and her daughters, was published in French by John Marret, under the title of *Histoire Générale des Insectes de l'Europe*, folio, Amsterdam, 1730. These two corrected works were published together under the common title of *Histoire des Insectes de l'Europe et de l'Amerique*, folio, Paris, 1768–71.

MERIDA (*Augusta Emerita*), a town of Spain, in the province of Estremadura, and about 35 miles from the city of Badajoz, is situated on a small eminence on the right of the Guadiana. It is tolerably well built; contains two parish churches, two hospitals, four schools of primary instruction, three ex-convents, and two nunneries. Of the two churches, that of Sta. Maria is a clumsy quasi-Gothic edifice, partly built of the innumerable Roman remains; that of Sta. Olalla (*Eulalia*) is said to date from the fourth century, and is dedicated to one of the earliest martyrs of Spain. Her name is also borne by a convent on the Madrid road, and by a statue and chapel in the space called Campo de San Juan; the latter, called El Hornito (*Oven*) de Sta. Olalla, now in ruins. Merida is remarkable for its Roman remains, in the number and magnitude of which it may be almost said to vie with Rome itself. The Guadiana is crossed by a bridge 2575 feet long, and consisting of 81 arches wholly of granite, erected by Trajan. Some of the arches were destroyed in 1812 to impede the advance of Marmont upon Badajoz. Of the colossal wall that formerly surrounded the town, there only remains the part defending the Roman castle called El Conventual. In the town are still some relics of the temples of Mars, Diana, Fortune, and others, and of a triumphal arch (*De Santiago*) 44 feet high, built by Trajan, and now stripped of its marble casing. Of an ancient aqueduct from Lake Albuera thirty-seven enormous pillars are still standing, and ten arches, in three tiers, built of brick and granite. To the east, and crossing the Madrid road, are three pillars of another aqueduct, the materials of which were employed in the construction of that which at present supplies the town with water. Farther east is the circus, 1356 feet by 335, well preserved, and capable of containing on its eighteen tiers of seats the whole present population of Estremadura. East of the circus is the amphitheatre, called the Siete Sillas, from its seven rows of seats, still almost entire, as are the vomitories. Before the French invasion it was used as a Plaza de Toros. Near it is the Naumachia, vulgarly called the Roman Baths, of which the oval form, 400 feet in length, is barely traceable. Augusta Emerita was built in 25 B.C. by the emeriti of the fifth and tenth legions, who had served in the Cantabrian war under Augustus. It rose to great splendour and importance as the capital of the province of Lusitania, was taken by Musa in 715, and reconquered by Alonzo in 1228.

The population is mostly agricultural; the surrounding country producing wheat, oats, legumes, oil, and wine. Large herds of swine are reared, with sheep, goats, and horses. There are manufactures of white soap in the town. Pop. 3780.

Merida, a town of Venezuela, capital of a province of the same name, is situated on a plain 5518 feet above the level of the sea. The town is well and regularly built, with straight streets crossing each other at right angles, and having a clear stream of running water in the centre of each. It was formerly one of the largest towns of Venezuela, but having repeatedly suffered from earthquakes, especially in 1812, it has greatly declined. The town has a cathedral, nunnery, a college, several schools, and an hospital. Woollen and cotton stuffs are manufactured; and the surrounding country produces coffee of great excellence. The province occupies an area of 10,793 square miles. Pop. of the province (1854), 23,967; of the town, 6800.

Merida, a town of Mexico, capital of the state of Yucatan, is situated in a dry plain, 25 miles from the sea, and 90 N.E. of Campeachy. Lat. 20. 50. N., Long. 89. 40. W. The town, which was founded by the Spaniards in 1542 on the site of an earlier native city, is built in the Moorish style. There are eight principal streets, wide and sloping towards the centre; and these are laid out with great regularity, meeting in a large square in the centre of the town, in which stand the cathedral, the bishop's palace, and the government house. The cathedral is ancient, and has a fine appearance, being adorned with domes and pinnacles. The town has also fourteen churches, and the ruins of an old Franciscan convent, which are curious and interesting. The climate is dry and not liable to sudden changes, but it is not very healthy. Merida has a considerable trade. Its port is Sizal, which is but an exposed roadstead with a fort and a sandbank 12 miles in length. Pop. (1851) 40,000.

MERIONETHSHIRE, the most southern county of North Wales, is situated at the middle of the Welsh coast, and is of a triangular form, the apex terminating between Corwen and Llangollen; the base being formed by Cardigan Bay, with a portion of Carnarvonshire; the perpendicular by Carnarvonshire and Denbighshire; and the hypothenuse by Denbighshire, Montgomeryshire, and Cardiganshire. The length from north to south is 56 miles, and its greatest breadth 32 miles. Its area is estimated at 602 square miles, or 385,291 statute acres.

The coast is iron-bound and dangerous, from shoals and banks, as Sarn-Badrig, Sarn-y-Bwch, Dutchman's Bank, &c. At Aberdovwy, however, there is a safe harbour, which might be rendered more so by a little enterprise. Abermaw is another safe creek, though not so safe as Aberdovwy. In fine weather large boats can land in Aberdiswnwy, Moehras, and Traethbach.

This county, in its physical aspect, is one of the most interesting in the principality; and while inferior to some others in stupendous boldness, it equals any in calm sublimity, and is superior to all in richness, variety, and beauty. Its mountains, though not very lofty, greatly excel in colouring and outline; whilst the greater prevalence of trees, blending harmoniously with fantastic crags, dark deep dells, frowning mountains, smiling vales, a sea-board deeply indented with lake-like estuaries, completes such a scene as can never fail to entrance an eye in sympathy with nature.

The Merionethshire mountains may be ranged in five groups, named after the principal eminence in each:—1st. Moelwyn group (2566 feet), being a spur of Snowdon. 2d. Arenig group (2809 feet), extending from Festiniog to Bala. 3d. Rhiniog Vawr range (2863 feet), sometimes called Harlech group. 4th. Aran Mawddwy range (2955 feet), extending from Aberdovwy to Corwen. 5th. Cader-Idris group (2914 feet), being a spur of the Aran Mawddwy range, having Craig-yr-Aderyn (*i.e.*, Bird's Rock), one of the most remarkable rocks in the kingdom, appended thereto.

The Dofwy, the Diswnwy, the Talyllyn, the Mawddach, Festiniog, and the Madawc vales are the most remarkable, and add exceedingly to the exquisite effectiveness of the scenery, permitting a fuller view of the mountains from base to summit than is usually the case in other counties.

The chief rivers are the Dwfrdwy (Dee), which, emerging from Bala Lake, enters Denbighshire near Corwen, then passing through a slip of Cheshire and Flintshire, expands into a vast estuary of the Irish Sea, separating the two counties. The Dofwy, originating in a small lake under Aran Mawddwy, expands into an estuary of Cardigan Bay at Aberdovwy, and is navigable for 8 miles. The Diswnwy, emerging from Llynmwyngil, expands into a small shallow estuary, which contracts into a narrow, tortuous channel as it enters the sea near Sarn-y-Bwch. It is only navigable for boats for 3 or 4 miles.

The Mawddach, issuing from the skirts of Aran Mawddwy, and forming a junction with Llynau-duon and the Wnion, expands into a considerable estuary of Cardigan Bay at Abermaw, and is navigable for 8 miles. The Cynval and others, uniting their streams, form a considerable estuary, called Traethbach, at the bottom of the vale of Festiniog, and is navigable for boats only, being fordable at low water. Glaslyn and Dwyryd (or the Eryri) uniting, enter the bay at Porthmadawc, where the estuary has been embanked, and a vast district recovered, through the enterprise of the late Mr Madox.

The lakes are small, but numerous, amounting to sixty-four or more. The largest are Llyn Tegid (*i.e.*, Fairy Lake), sometimes called Pimble-mere, near Bala, being 4 miles long and 1 broad, its banks being most picturesque; and Llynmwyngil (*i.e.*, the Lake in a Sweet Nook), in the well-known vale of Talyllyn, which, though only a mile long, is perhaps more interesting still, and well deserves its Cambrian name. It is much frequented by anglers, who find ample sport, though the trout is not over delicate. The other lakelets are generally very interesting, both in regard to scenic effect and sport. One of them, Llynewmbychan, has a snow-white deposit of kaolin or porcelain clay.

A good many fine waterfalls exist, which add greatly to the romantic beauty of the prospect. The most considerable are Rhaiadr-y-Glyn, near Corwen, and Rhaiadr Mawddach and Pistill Caen, near Dolgelley; the latter being 150 feet high.

The prevailing geological formations are felspathic trap, porphyry, and other unstratified rocks; whilst the secondary hills are composed of different kinds of schist, interspersed with unstratified elvan. Along the Dee a bluish-gray limestone is found, and white limestone at Corwen. This formation is surrounded by primitive argillaceous slate.

Gold, silver, copper, and lead mines abound, but as yet they have not proved profitable speculations. The extravagant royalty which is demanded by proprietors is a serious bar to mining adventure here. Llyn-y-Pair mine, near Aberdovwy, is now very promising, and the mining interest consequently beginning to look upon the county with greater favour. There are extensive deposits of iron, manganese, and other minerals, but royalty and transit expense render their working unprofitable.

The slate quarries of Festiniog and Corris are extensive and most remunerative speculations. In the former at least 3000 persons find constant employment; Mrs Oakley, Lord Palmerston, and Messrs Greaves and Holland being the principal proprietors. The most extensive quarry at Corris is that of Aberllefeni, the property of R. D. Jones, Esq. This slate is of a deep blue, of considerable tenacity and hardness, but yet easily worked. It is preferred for roofing important buildings and the manufacture of articles enamelled by Magnus's beautiful process.

The variety of altitude and aspect incident to a mountainous yet maritime country results in producing a variety in the climate; Aberdovwy, for instance, being proverbially mild, the myrtle standing the winter as well as any common shrub; whilst neighbouring places differently situated are bleak and cold.

More than half the county is uninclosed, and much even of that is unproductive. Considerable portions of marsh land have been reclaimed in the estuaries, and much more requires only capital and enterprise in order to bring it to as fertile a condition as any in the county. The proportion of arable land being small, it is consequently high-rented. The best is found about Towyn and Dyffryn-Ardwydwy.

The farming is generally of an inferior kind, and the farm buildings and cottages worse still; whilst rents, wages, and taxes are high. Being essentially a pastoral county, extensive herds of sheep are kept, which are small in size, but their flesh is delicate, and their wool of very fine quality. Large droves of black cattle of a very superior kind are also bred and annually sold in England, where good feeding converts them into the most tender of beef.

Manufactures are few, except that of flannel, which is produced in large quantities and of very fine quality. The women in some localities are still noted for knitting stockings, gloves, and Welsh wigs, which are exported, but to a much more limited extent than formerly, when it amounted to some L.25,000 per annum. That of slates should be included amongst manufactures, as distinct from quarrying, and this would increase the importance of the manufacturing interest of Merionethshire considerably. Brush-handles, clogs, gloves, and leather for the same, are also manufactured to a limited extent.

The chief commercial outlets are Aberdovwy and Abermaw. The trade of the former place is extensive and increasing. The exportation consists mostly of slates, poles, bark, and ores The importations are,—shop goods, corn, limestone, culm, coal, timber, &c. The trade of Barmouth has rather declined of late years. There is a harbour trust there who have managed to squander much money to very little purpose in attempting to build a lighthouse.

Aberdovwy, Towyn, and Abermaw or Barmouth are much frequented in the bathing season. Towyn frequently has its population trebled in a week by the influx of the industrial classes on their annual pilgrimage to the sea-coast; a privilege for which express stipulations are made in hiring engagements in Montgomeryshire, from whence most of them come.

There are two royal ferries; and their management does not reflect much credit upon the Board of Works, by whom they are leased to parties who do not appear to be particularly studious of the convenience and interest of the public. The want of railroads is much felt by strangers; but it is hoped that the proposed new railroad to Machynlleth will soon go far to remedy this serious hinderance to the material progress of the county. Dolgelley and Bala, where the assizes are alternately held, are two interesting little county towns of a purely Welsh character. The former has been lately lighted with gas; but both are very defective in sanitary arrangements. Corwen is a delightful and progressive place, from its proximity to a railway; Aberdovwy is also an improving locality, and must become a most important seaport, from its fine harbour, when the Machynlleth Railway is finished. Abermaw is a romantic watering-place much frequented. Of Harlech and Dinas-Mawddwy very little remains, save a fine old castle in the one, and a sinecure corporation in the other. Festiniog is a populous slate-manufacturing town surrounded with beautiful scenery. The following is the population of the principal towns:—

Names of Towns.	1841.	1851.	Males.
Aberdovwy and Towyn	2907	2769	1322
Dolgellau	3695	3479	1578
Bala and Llanycil	2461	2431	1198
Festiniog	3138	3460	1878
Abermaw and Llanaber	1709	1672	725
Corwen	2129	2069	1029

The Anglican Episcopal community is the church established by law, but it has few adherents and little influence among the people. The county is ecclesiastically divided between Bangor and St Asaph. The deaneries of Ardwydwy, Estimaner, and Talybont, are in the former; and Mawddwy, Penllyn, and Edeyrnion, in the latter. The number of parishes is about thirty-four, and, for a poor country, they are well endowed.

The dominant non-established church is Presbyterian, in the form called Welsh Calvinistic Methodism. The Wesleyans, Congregationalists, and Baptists have also numerous congregations.

Education is carried on by means of some hundreds of Sunday schools, and sixty day schools. There are two colleges at Bala for the education of Methodist and Congregational ministers: the former is being endowed as a fitting monument to the great and good Thomas Charles, who was to Welsh Methodism what Wesley was to Wesleyanism, and who lived and laboured in this town for many years.

In the earliest historical period Merionethshire was included in the territory of the Ordovices, a tribe so called through a Roman corruption of their Celtic designation, *Ardovwysiaid*, or "dwellers upon the placid stream." During the Roman occupation it was included in the province of *Britannia Secunda*, being (some say) called *Mervinia*; if so, it would seem to indicate an earlier origin for the word Merioneth (or Merion's Land) than the fifth century, when the Cantrev, or district situated between the Dofwy and the Mawddach, was bestowed upon Meirion-ab-Tybiawn-ab-Cynedda for his services in expelling the Gwyddelians (Irish) from Gwynedd. Perhaps *he* may have taken his name from the district allotted to him, as it is still as often called Meirion as Merionydd. The *Via Occidentalis* passed the whole length of the county, being joined at *Heriri Mons* (the Mountain of Eryri, now Tomen-y-Mur, near Trawsfynydd) by a branch of the Southern Watling Street. During the Saxon and early Norman period we have not much interesting information respecting it, as it seems to have been to the Kymro a safe and mysterious refuge, into which the Saxon had a wholesome hesitation in following. But in proportion as the Anglo-Norman power became consolidated these impregnable fastnesses became the scene of strife. Here Owen Gwynedd defeated Henry II., and brave Glyndwr rose in arms at the call of friendship and patriotism to resist the usurper of the throne of gentle Henry, and the enslaver of his loved Wales. Tradition and records tell of bloody deeds done here in those and later days by freebooters daring and cruel; the Gwylliaid-cochion, the Gwylliaid-duon, and Ievan ap Robin Herwr, the sea-rover of Aberdovwy, and his *trefrydd* or "bloody home," &c. The whole county is rich in Celtic, Roman, and mediæval remains. The castles of Harlech and Bere, the Cadvan, Porus, and Calexus (a Manx king probably) inscribed stones, the Llanegryn rood screen (restored by W. W. E. Wynne, Esq., M.P.), cromlechau, circles, mounds, cairns, camps, &c., invite the notice of the antiquary.

Only one county and no borough member is returned. Real property was returned in 1815 as L.111,436; in 1850 as L.168,236; showing an increase of L.56,800. We extract the following table of the population from the census of Great Britain in 1851:—

1801	29,506
1811	30,854
1821	34,382
1831	35,315
1841	39,332
1851	38,843

In 1851 there were in the county 8159 houses inhabited, 372 uninhabited, and 31 in process of erection.

MERLIN, or MERDHIN, the name of two ancient British wizards:—

Ambrose Merlin was the reputed son of a demon and of the daughter of a British prince, Demetius, and flourished about the end of the fifth century. He was brought up at a city called Caer-Merlin (the City of Merlin), and supposed to be the present Caermarthen. When a mere boy he recommended himself by his supernatural powers to the notice of King Vortigern. He was afterwards the inseparable counsellor of that monarch, and of his immediate successors Ambrosius, Uterpendragon, and Arthur. His alleged miraculous insight is supposed by Leland to have been merely a knowledge of mathematics far transcending the comprehension of his contemporaries. Allusion is made to Merlin in the *Faëry Queen* and in other old poems. A book of Prophecies attributed to him was printed in French in 1498, in English in 1529, and in Latin in 1554. *The Life of Merlin Ambrosius, his Prophecies and Predictions Interpreted, and their Truth made good by our English Annals*, by T. Heywood, was published in 1641, and reprinted in 1813.

Merlin the Wild, *Merlinus Caledonius*, or *Merlinus Sylvestris*, was a native of Caledonia, and lived in the sixth century. From the *Scotichronicon* of Fordun we learn, that in penance for the death of his nephew, he fled into the woods of Tweeddale, and there lived like a squalid savage for the rest of his days. The same authority also states, that being pursued into his fastnesses by a band of rustics, he sprang from a rock into the Tweed, was impaled on a stake fixed in the bed of the river, and thus, in accordance with his own prediction, died by means of earth, wood, and water. But Geoffrey of Monmouth, in his metrical history of Merlin, ascribes this fate to a page whose death Merlin had prophesied in the terms mentioned above. The grave of Merlin is still shown beneath an aged thorn at Drummelzier, a village on the Tweed. The book of prophecies which has been generally ascribed to Ambrose Merlin is sometimes attributed to Merlin the Caledonian, and was published at Edinburgh in 1615 under the name of the latter. (See part ii. of "Thomas the Rhymer" in Sir W. Scott's *Minstrelsy of the Scottish Border.*)

MEROË, an island, or rather peninsula, of Nubia, formed by the Nile and its tributaries the Atbara and Bahr-el-Azrek, and having the mountains of Abyssinia on the E. and the desert of Bahiouda on the W. It is about 400 miles in length from N.W. to S.E. by 200 in breadth, and consists of extensive plains. In ancient times Meroë was very productive and well cultivated; and although the soil is still good, the country is now for the most part covered with trees and herbage, or barren and desert, while very little cultivation is carried on. The ancient inhabitants of this district had attained to so great a degree of civilization and commercial prosperity that it has been by some supposed that the arts of cultivated life were transmitted from this country to Egypt. This, however, is not very likely, and the most probable conjecture that can be formed seems to be, that in the seventh century B.C. the military caste of Egypt, having left their country on account of some injustice received from the king, settled in Meroë, reduced to subjection the natives of that region, and established there a system of government somewhat similar to that of Egypt, but differing from it in the restraints put upon the power of the kings, and the greater influence of the priestly caste. The ruins of Meroë, the capital, are situated on the right bank of the Nile, 26 miles N.E. of Shendy, and they consist of pyramids and temples for the most part in a state of great dilapidation. The pyramids are in number about 80; and they vary in size from 12 to 60 feet square at the base. The largest is about 160 feet high. They are not of great antiquity, and bear traces of a declining period of art, compared with that of the Egyptian monuments. At various other places in the island of Meroë similar remains and brick mounds have been discovered, from which it would appear that in ancient times this district had been thickly studded with towns and villages.

MERRICK, JAMES, a learned divine and poet, the son of a doctor of medicine, was born in 1720, and attended the school at Reading. Enrolled in 1736 as a student of Trinity College, Oxford, he became tutor to Francis North, afterwards the celebrated First Lord of the Treasury. Merrick's classical scholarship was shown by his edition of the Greek text of Tryphiodorus in 1741, and led to his election as probationer fellow in 1744. He entered into orders, but was prevented by his delicate health from undertaking the duties of a pastorate. After a life spent in congenial study he died in 1769. Merrick was characterized by Bishop Louth as "one of the best of men, and most eminent of scholars." His most important works are,—*Prayers for a Time of Earthquakes and Floods*, London, 1756; *A Dissertation on Proverbs, Chapter* ix., 4to, Oxford, 1744; *The Psalms Translated or Paraphrased in English Verse*, second edition, 12mo, Reading, 1766; and *Annotations on the Psalms*, 4to, Reading, 1768. Of his small poems inserted in Dodsley's collection, the fable of "The Chameleon" is the best known.

MERRY, ROBERT, an English dramatic writer, was the son of a merchant, and was born in London in 1755. After receiving his education at Harrow and at Christ's College, Cambridge, he entered Lincoln's Inn, but was never called to the bar. After his father's death he purchased a commission in the Horse Guards, where he held the post for some years of lieutenant to the first troop under Lord Lothian. Anxious for a change, and desirous of seeing the world, he quitted the service, and visited France, Switzerland, Italy, Germany, and Holland. He spent a considerable time in Florence; and during his residence there had the honour of being made a member of the celebrated Della Cruscan Academy. He became a chief contributor to the *Florence Miscellany*, a periodical produced by the joint efforts of a few English residents. In return for the honours done him by the Della Cruscans, Merry attached the name of the academy afterwards as a signature to many of his poetical effusions which appeared in the journals and newspapers of this country; and so great was the success of the English Della Cruscan that in a short time Merry found a race of enthusiastic imitators, who flourished luxuriantly till Gifford, with the caustic satire of his *Baviad* and *Mæviad*, so ruthlessly blasted their growth. Merry went to America in 1796, and died at Baltimore two years afterwards. His dramatic pieces are,—*Lorenzo; The Magician no Conjuror; Fenelon;* and *Ambitious Vengeance.*

MERSEBURG, a town of Prussia, capital of a government of the same name, in the province of Saxony, is situated on the left bank of the Saale, 15 miles W. of Leipsic, and 56 S.S.E. of Magdeburg. The town is old and irregularly built; it is walled, and has four gates; and there are two suburbs, one of which stands on the other side of the river, and is approached by a stone bridge. Merseburg possesses a fine cathedral, built partly in the twelfth and partly in the fifteenth century, and containing many ancient monuments and one of the largest organs in Germany. The monument of Rudolph of Swabia in this cathedral, consisting of his figure in relief on a bronze plate, is believed to be one of the oldest specimens of mediæval art. The choir contains several paintings by Cranach. The castle of Merseburg, once the residence of the Dukes of Saxe-Merseburg, is a building of the fifteenth century, and is now occupied by the government offices. The town also possesses a monastery, situated in one of the suburbs, several Protestant churches, schools, a military hospital, and other establishments. The inhabitants are employed in the manufacture of linen and woollen fabrics, leather, paper, tobacco, vinegar, and beer; for which last Merseburg is famous. The trade of the town is considerable. The government of Merseburg has an area of 3994 square miles, and is in general low and undulating, with no eminences rising above the height of 1800 feet. The nature of the soil is various, but for the most part it is of considerable fertility; and the country is watered by the Elbe and its tributaries the Schwarze Elster from the E., and the Saale and Mulde from the W. Pop. of government (1855), 781,947; of the town, 11,264.

MERSENNE, MARIN, an eminent philosopher and mathematician, of the religious order of the Minimes, was born at Oysé in France in 1588, and studied at the college of La Flèche, where he made the friendship of Descartes, then a student at the same institution,—an intimacy which was kept up during their lives. He afterwards studied at the university of Paris and at the Sorbonne; and in 1613 he became a priest of the order of the Minimes. In his new sphere he commenced the study of the Hebrew language, and very soon mastered it. He held the philosophical chair of Nevers during the three years preceding 1619, when he became superior of the convent of his order in the neighbourhood of Paris. He afterwards travelled in Germany and Italy, and became acquainted during his visit to the latter country with the recent discoveries of Torricelli respecting a vacuum. Mersenne ultimately settled at Paris, where he died in 1648, lamented by a large circle of distinguished friends, who admired alike the gentle engaging manners of the man and the profound sagacity of the philosopher.

Some have ascribed to Mersenne the first discovery of the *cycloid;* an honour, however, to which he does no seem to be entitled. Some of the wits of his time affected to hold him in low esteem, and he was even charged with plagiarism by the Abbé Le Vayer, who calls him "*Le bon Larron;*" but it is a sufficient vindication of the Father's talents and character that the celebrated Descartes not only clung fast to him as a friend, but, as his correspondence amply testifies, consulted him on the most important points of his speculations. Mersenne's most famous work is the *Harmonie Universelle, contenant la Theorie et la Pratique de la Musique*, 2 vols., Paris, 1636-7. This work he afterwards translated into Latin, with important alterations and additions, rendering it almost an entirely new treatise, and entitled *Harmonicorum libri xii., de Sonorum Natura, Causis et Effectibus*, Paris, 1648, fol.

MERSEY, a river of England, is formed by the union of several small streams which take their rise in the hills near the borders of Yorkshire, Cheshire, and Derbyshire, where these three counties meet in a single point. The principal of these streams are the Tame and the Goyt; and from Stockport, where these two unite, the river thus formed takes the name of the Mersey, flows to the W., forming all along its course the boundary between Cheshire and Lancashire, and after a course from Stockport of 55 miles in length, falls into the Irish Sea below Liverpool. The principal tributaries of the Mersey are,—the Irwell, which flows past Manchester, and falls into the Mersey from the N., below the junction of which the river becomes navigable; and the Weaver, which joins it from the S. just before it expands into a large estuary. This estuary, which is 17 miles in length and 3 miles across at the broadest part, contracts at its mouth to a breadth of little more than three-quarters of a mile, so as to have the appearance, from several points of view, of a large inland lake. The country through which the Mersey flows is level; but in some parts the scenery is very picturesque. The principal towns and villages on its banks are,—Stretford, Warrington, Hale, Garston, and Liverpool, on the right bank; and Stockport, Runcorn, Ince, and Birkenhead, on the left.

MERTHYR TYDVIL or Tydfil, a parliamentary borough and market-town of South Wales, Glamorganshire, situated on the Taff, 22 miles N. by W. of Cardiff, and 171 W. by N. of London. The town, although it is said to be named after an ancient British martyr of the name of Tydvil, is entirely of modern origin, and consists chiefly of the cottages of workmen, meanly and irregularly built. Of late, however, the town has been much improved, and it now contains some regular and well-built streets, a court-house, a market-house, several elegant private residences, and a large number of excellent shops. The town contained in 1851 no fewer than 84 places of worship belonging to the following denominations:—Independents, 20; Baptists, 19; Church of England, 10; Wesleyan Methodists, 10; Welsh Calvinist Methodists, 10; Unitarians, 2; Primitive Methodists, 2; Wesleyan Reformers, 2; isolated congregation, 1; Roman Catholics, 1; Latter-day Saints, 6; Jews, 1. There were also at that time 68 Sunday schools, 16 public and 43 private day schools. The town has a library and reading-room, as well as several book-clubs;—all which facts afford evidence of the progress which the inhabitants are making in education and intelligence. Merthyr Tydvil, situated in a bleak and barren country, was at an early period known as a place for the smelting of iron ore, but it was never carried on to any great extent till Mr Anthony Bacon in 1755 obtained a lease of a district of land, 8 miles in length by 5 in breadth; and from that time may be dated the rise of the prosperity and importance of the town. Having erected extensive ironworks, and made a contract with the government for supplying the arsenals with cannons, he acquired an immense fortune, and finally disposed of the land in smaller portions to other individuals. From that time the works have gone on increasing in extent and in prosperity; and it is not difficult to account for the rapid rise of a large town in the vicinity, seeing that from 4000 to 5000 hands are employed in one establishment alone, and that upwards of L.1,000,000 is paid annually as wages in the four large ironworks in the district. There are now nearly fifty blast-furnaces in the vicinity of the town, producing annually from 150,000 to 200,000 tons of iron; which are for the most part conveyed by railway or canal to Cardiff, whence they are shipped to their various destinations. In the vicinity of Merthyr Tydvil there are numerous country seats, belonging principally to the wealthy proprietors of the different ironworks. Since the passing of the Reform Bill Merthyr Tydvil has returned one member to the House of Commons. The market-day is Saturday; and there are three annual fairs. Pop. (1851) of the borough, including the town of Dowlais, 63,080.

MERV, or Meru, a town of Turkestan, province of Khiva, situated on the caravan road between Meshed and Bokhara, about 12 miles E. of the Moorghab, and 300 S.E. of Khiva. The town was originally founded by Alexander the Great; but having been destroyed, it was rebuilt by Antiochus I., and received the name of *Antiochia Margiana.* The captive soldiers of Crassus were settled here by Orodes. In after times it was one of the four imperial cities of Khorassan, and many of the Persian monarchs made it their capital; but in 1786 it was taken and sacked by the Usbecks,—a blow from the effects of which it has never recovered. The surrounding country, which bears the name of Maroochak, was formerly celebrated for its fruits; but it is extremely unhealthy. The population is estimated at 3000.

MESHED, or Mushed, a town of Persia, capital of the province of Khorassan, is situated in a broad valley, 455 miles E. by N. of Teheran, and 500 N.E. of Ispahan; Lat. 36. 18. N.; Long. 59. 35. E. The town is surrounded by strong walls; but the houses are in general meanly built of brick, and nearly half of it is in ruins. The principal street, which passes through the town from E. to W., is wide and lined with handsome shops, and has a canal passing through its centre. The chief building is that which incloses the tombs of Imam Reza and of the Caliph Haroun Al-Raschid, on account of which Meshed is accounted a holy city, and visited by crowds of pilgrims. This edifice, which stands in the centre of the town, is a splendid building, with a gilt dome and two gilt minarets; possessing also splendid gateways and silver gates. Close to it stands a mosque, considered one of the finest in Persia, with a lofty blue dome and minarets. Besides this, the town contains a palace, which is an insignificant building hardly deserving the name; a large and well-supplied bazaar; and a caravansary, which is in an unfinished state. Meshed once had 16 medresses or colleges, but only a few of these now remain. The manufactures of the town consist of velvets, silks, jewellery, hardware, sword-blades, &c.; and there is a considerable trade carried on with Bokhara, Candahar, Herat, Yezd, &c. The position of the town on the great roads of Persia, and the numerous caravans continually passing, render Meshed a place of some importance as the emporium of the surrounding country. Pop. believed to be between 40,000 and 50,000.

MESJID, or Musjeed, Ali, a town of Asiatic Turkey, in the pashalic of Baghdad, is situated in a dry plain on the Euphrates, 90 miles S. by W. of Baghdad, and 28 S. of the ruins of Babylon. The town is well built, and surrounded by strong fortifications. The principal building is the mosque of Ali, containing the grave of the caliph of that name, visited by great numbers of pilgrims. Pop. about 6000.

Mesjid, or Musjeed, *Hossein*, a town in the pashalic of Baghdad, is situated about 50 miles S.W. of Baghdad, and 28 N.W. of Babylon. It derives its name from Hossein, the son of Ali, who is buried here in a mosque much venerated and frequented by Persian pilgrims. Pop. about 8000.

MESMER, Friedrich Anton, the author of the doctrine of *Mesmerism*, was born in 1734 at Marsburg in Baden. After attending the schools of Dillingen and Ingoldstadt, he studied medicine at Vienna, and subsequently settled in that city as a physician. It was there in 1766 that he gave the first rude outline of his theory in a treatise entitled *De Planetarum Influxu*. He founded his speculation on the supposition that there is an element of extreme subtlety which pervades the entire universe and permeates every body. He then asserted that this element, like the sea and the atmosphere, was influenced by the heavenly bodies, and that it communicated this influence to the nervous systems of all animals. In this way he accounted for the periodical affections of certain invalids. But this theory, in the form in which it was divulged, could not afford a basis for any art that might minister to the eager cupidity of its author. Mesmer therefore thought of making magnets perform the office of the heavenly bodies, and of using them to cure the diseases of the human frame. No sooner, however, had he begun the healing art than it appeared that a Vienna professor, Father Hell, had already been using magnets for the same purpose. A controversy ensued between the rival leeches touching their respective claims to the discovery. Mesmer was worsted; but effected a safe retreat from the contest by averring that he was not restricted to one instrument, for he could employ animal magnetism with the same effect as he had employed mineral. The efficacy of this new appliance he endeavoured by every means to prove to the public. He solicited the opinions of the Royal Society of London, the Academy of Sciences at Paris, and the Academy of Berlin. None of these bodies, except the last, deigned to give him even an unfavourable reply. As unsuccessful was his alleged cure in 1777 of Mademoiselle Paradis, a popular vocalist, who was suffering from *gutta serena* and convulsive affections in the eyes. The young lady was afterwards discovered to be as blind as ever; and Mesmer was obliged to flee from the punishment of his imposture. After practising his art for a short time in Germany and Switzerland, he repaired to Paris in 1778. At this time the French people, free from all political excitement and from all interest in foreign affairs, were ever on the alert for novelties and wonders. Accordingly, they received with eager curiosity the handsome and imposing foreigner who professed to unveil the secret workings of nature, and to effect a painless cure of all diseases by a simple process resembling the passes of a magician. Within a short time Mesmer had gained a great practice, had converted to his opinions Deslon, one of the faculty, and had published an account of his theory. Of this account many refutations by scientific men appeared. Mesmer condescended on one occasion to reply, and with cool self-complacency described himself as a man of genius and a benefactor of the human race. About the same time he was soliciting from the government a chateau and its lands as a reward for his services, and was threatening to leave France if they should attempt to cheapen the price of his labours. His request was not granted; but a life-rent of 20,000 francs per annum was offered to him. A yearly sum of 10,000 francs was also guaranteed, on the condition that he should permit three persons nominated by the ministry to inspect and report his proceedings. Mesmer was not pleased with the condition, and he put his former threat into execution by rejecting the offers of the French government, and by setting out with some of his patients to Spa. There his enthusiastic admirers, headed by Bergasse, promised to raise a subscription for his behoof if he would agree to reveal the secret of animal magnetism to all the subscribers. Mesmer grasped at the offer; and having returned forthwith to Paris, opened a spacious hall, and attracted all classes around him. In a luxuriously furnished room, pervaded by perfumes and echoing with soft music, he was wont to seat his patients round a species of magnetic battery called a *baquet*. When this co-operation of exciting causes began to produce as its necessary effect a nervous agitation through the entire circle, Mesmer appeared with his magic wand to regulate the action in each separate individual. So many cures were alleged to have been effected by this process, that at length, in 1784, the French government thought it their duty to examine into this apparent mystery. The proceedings of Deslon, the pupil of Mesmer, were accordingly scrutinized by a committee of inquiry consisting of the physicians Majault, Sallin, Darcet, and Guillotin, and the academicians Franklin, Leroi, Bailly, De Bory, and Lavoisier. The report, drawn up by Bailly, thoroughly exposed the falsehood and imposture of the Mesmeric process. About the same time the Royal Society of Medicine published another report equally condemnatory. These two testimonies from the scientific world were printed by the order of the government, and circulated throughout France. The disciples of animal magnetism attempted to check the advance of their enemies by forming themselves into societies. Mesmer, more politic, escaped amid the general confusion, carrying with him a subscription of 340,000 francs, and at the same time the secret for which that sum had been given to him. After living for some time in England under an assumed name, he repaired to Germany, and published in 1799 a new exposition of his doctrine. He died in obscurity in his native city in 1815.

MESOLONGHI, or Missolonghi, a town of Greece, in the government of Ætolia, is situated on the edge of a marshy plain on the N. shore of the Gulf of Patras, 22 miles W. of Lepanto. It is separated from the sea by a lake, 10 miles long and 5 in breadth, from which it probably derives its name, through the Italian *mezzo* and *laguna*. This sheet of water is so shallow, that there are few passages by which any but small boats can approach the town. Mesolonghi has a school, custom-house, and a small harbour. It is chiefly remarkable for the siege it sustained from the Turks in the Greek war. At the outbreak of the Greek revolution the place was indeed fortified, but the defences were in such an inefficient state from neglect, that it was necessary to increase and strengthen them in order to secure the safety of the town. The Greeks accordingly surrounded the city on the land side by a ditch, and a mound of earth and stones; but the approach of the Turks prevented any further improvements being made in the fortifications. In the beginning of 1825, by the arrival of Greeks from other parts of the country, and of volunteers from various nations of Europe, the garrison was raised to the number of 5000, who were commanded by Nothi Bozzaris; and on the 25th April of the same year a Turkish force of 20,000 under Reshid Pasha appeared before Mesolonghi. Nor was the inequality less, in the number and size of their artillery, between the besiegers and the besieged, than in the amount of their forces. On the 11th of May the first bombardment began, and for the space of two months afterwards the town was exposed to numerous bombardments and assaults; but the defenders were not less active in answering the enemy's fire, and making sallies from their defences, by which means they succeeded in repelling their assailants, and inflicting on them considerable loss. During this time they were supplied with ammunition and provisions by the fleet, which was stationed at the entrance of the lake; but on the 10th of July, a superior Turkish fleet, after compelling the ships of the Greeks to retire, succeeded in landing a strong reinforcement to the besiegers. The assaults on the town were then renewed with increased fury, and the cannonade of the Turks carried destruction to its frail ramparts, and death among the ranks of its brave defenders. Yet the garrison, though reduced to the number of 4000, continued to maintain their ground until, in the month of August, the Greek fleet appeared in the offing, and, by defeating the Turkish squadron, relieved Mesolonghi for a time from the blockade. But the sultan was resolved at all hazards to reduce this stronghold of liberty; and in the end of November, the Greek ships were again driven off, and the blockade renewed by the combined Turkish, Egyptian, and Barbary fleet. In the beginning of 1826 the besieging army was reinforced by the arrival of 14,000 troops under Ibrahim Pasha, who superseded Reshid Pasha in the command. On the 25th of January a bombardment was begun, which lasted for three days, and reduced the town to ruins, but could not shake the resolute courage of the Greeks. The repeated assaults of the enemy were still repulsed with great loss. At last, reduced to the utmost extremities by famine, and seeing on all sides nothing but the ships and tents of their enemies, yet never entertaining any thought of surrender, the Greeks determined to force their way through the opposing ranks, and thus convey themselves, with their wives and children, to a place of safety. Although by treachery the enemy was made aware of their design, and thus prepared to meet them, they were not able to prevent nearly 2000 of the besieged from making their way to the mountains. Many prisoners fell into the hands of the Turks, and the remainder, who were unable from their wounds or weariness to accompany their fellows, continued to defend themselves among the ruins until the explosion of a powder magazine, destroying alike friends and foes, put an end to the bloody conflict. Such was the siege of Mesolonghi, which attracted during its continuance the eyes of all Europe, and in which the Greeks showed themselves the worthy sons of the heroes of Marathon and Thermopylæ, and

> "Snatched from the ashes of their sires
> The embers of their former fires."

Near one of the gates of the town a mound of earth has been raised bearing an inscription in honour of those who fell in this famous siege. Lord Byron died at Mesolonghi on the 19th April 1824.

MESOPOTAMIA, an ancient country of Western Asia, was bounded on the N. by Armenia and Mount Masius, on the E. by the Tigris, on the S. by the Median Wall, and on the W. by the Euphrates. Its early name, as we learn from Scripture, was *Aram Naharaim* (Syria of the Two Waters), and was thus derived, like its after-name, Mesopotamia, from its peculiar position. The same cause has evidently induced the modern Arabs to call it *Al-Jezireh* (the Island). In addition to the Tigris and Euphrates, it is watered by the Chaboras (*Khabúr*), the Mygdonius (*Hermas*), and the Belas. Its principal towns were Nisibis (*Nisibin*), Edessa (*Orfa*), Circesium (*Karkesia*), and Carrhæ (*Harran*), the Haran of the Bible. According to Xenophon in his *Anabasis*, this country was a vast plain as level as the sea, diversified with no woods, abounding in sweet-scented wild-flowers, and haunted by wild asses, ostriches, buzzards, antelopes, and other animals; yet later writers represent it as affording rich pasturage for abundant herds, and possessing stately forests, especially on the banks of its two great rivers. Mesopotamia is seldom mentioned in history before the date at which it became a Persian province. Under the Romans it was divided into two parts,—Osrhoëne, on the W. of the River Chaboras, and Mesopotamia on the E. It was very impatient under the yoke of Rome, and continued to waver between revolt and submission until A.D. 363, when it was surrendered by Jovian into the hands of the Persians.

MESSALLA, CORVINUS MARCUS VALERIUS, a Roman general and orator, was born in 59 B.C. After studying at Athens he returned to Rome shortly after the death of Cæsar, and became the attached follower of Cassius. His name was accordingly inserted by the triumvirs in the list of those whom they devoted to death, but was afterwards erased at the petition of his friends. Refusing the proffered friendship of the triumvirate, Messalla followed the fortunes of the republican army, and stood next in command to Brutus and Cassius. On the field of Philippi he turned the flank of Augustus, stormed his camp, and was once on the point of taking him prisoner. The death of the two republican generals left him in charge of the shattered remains of their army. He effected a safe retreat to the island of Thapsos, and there he accepted honourable terms from Antony. Provident and politic, Messalla foresaw the downfall of Antony, and opportunely transferred his allegiance to Augustus. His military talents were successfully exerted in the service of the latter. He routed the Alpine tribe of the Salassians in 34 B.C., commanded the centre of the fleet at Actium in 31 B.C., and reduced the province of Aquitania in 27 B.C. For the last achievement he was honoured with a triumph on his return. Messalla had been appointed consul in 31 B.C., and was now, in 27 B.C., nominated prefect of the city. Shortly afterwards, however, he resigned all his public offices except his augurship. After suffering such a total derangement of his intellect that at times he forgot even his own name, he died about 11 A.D.

Of Messalla's many works—oratorical, historical, grammatical, and poetical—some of the titles alone remain. Yet a vague estimate of his literary merit may be formed from the testimonies of his contemporaries and successors. His works are eulogized by Seneca, Quintilian, and the two Plinies. The author of the dialogue *De Oratoribus*, attributes greater elegance and chasteness to his orations than to those of Cicero. Kind-hearted, and a lover of literature, Messalla employed his opulence and political power in aiding and encouraging literary men. He restored Tibullus to his estate, and loved to gather round his table such men as Horace, Varius, Pollio, and Mæcenas.

MESSANA, or MESSENE (*Messina*), an ancient town of Sicily, was, according to all authorities, of Chalcidic origin. Its first inhabitants were Chalcidians, according to Thucydides and Pausanias, from the colony of Cumæ in Italy, but, according to Strabo from Naxos in Sicily. The original name of the city was *Zancle* or *Dancle*, from the form of the harbour resembling that of a sickle. The date of its foundation is not known with any precision; but it was probably in the latter part of the eight century B.C.; and within the first 100 years of its existence, it had attained to such a degree of prosperity as to be able to send off two colonies on the N. coast of Sicily, Mylæ, and Himera, the latter of which rose afterwards to considerable importance. When the Ionians in Asia Minor were subdued by the Persians, and were compelled either to live in slavery or to leave their country, they were invited by the Messanians to settle on the coast of Sicily. This invitation was taken advantage of by the Samians, along with some other Greeks from Asia; but they having landed in Italy, were persuaded by Anaxilas, the tyrant of Rhegium, to make an attack on Messana during the absence of Scythes, the king of that city. This they accordingly did, and were successful; but although Scythes was unable to regain his dominion, the Samians were equally powerless to retain it; and were soon after deprived of their sovereignty by Anaxilas, who introduced into the city a large body of settlers from his own city, and changed the name of their new abode from Zancle to *Messana*, in memory of his mother-country in Greece. These events must have occurred between 493 and 476 B.C. After continuing for some time under the power of the Kings of Rhegium, the Messanians succeeded in 461 in throwing off the yoke of these monarchs, and establishing a republican form of government, under which they continued for some time to enjoy freedom and prosperity. In 396 B.C. a large Carthaginian army under Himilco landed in Sicily, and advanced along the northern coast to Messana, which they took and levelled to the ground. But in the next year the Carthaginians were defeated and expelled by Dionysius of Syracuse, who then proceeded to rebuild Messana, and to repeople it with the old inhabitants and with colonists from Italy and Messœnia. Soon after 289 B.C. Messana was seized by the Mamertini, or worshippers of Mamers, a band of mercenaries who had been brought from Italy by Agathocles, King of Syracuse, and had been discharged at the death of that monarch. They endeavoured, without success, to change the name of the city to *Mamertina*. The Mamertines were afterwards attacked by Hieron of Syracuse, and being unable themselves to hold out against his power, were only saved from destruction by the arrival of a Carthaginian force under Hannibal, the son of Gisco. But an alliance with Carthage was distasteful to a party among the Mamertines; who gaining the predominance in the state, applied for aid to the Romans against the Carthaginians. This request was readily acceded to, and thence arose the first Punic war, during the course of which Messana was taken by the Romans, and thus became the earliest dependency of that people out of Italy. The city was first an ally of Rome, and afterwards a municipium; but its subsequent history in ancient times is not remarkable for any great events.

MESSENE, the capital of Messenia in Greece, was founded by Epaminondas in 369 B.C. In the building of this city, which was situated at the foot of Mount Ithome, the Thebans, along with the Messenians and their other allies, took part, and the buildings and fortifications were finished after eighty-five days. As Messene was erected in order to enable the Messenians to regain their independence and form a check to the power of Sparta, which then threatened the liberties of Greece, the place was made one of great strength, being inferior in that respect to few Greek cities. The citadel of Messene, which is inclosed within the city walls, stands on Mount Ithome, an elevation 2631 feet in height, which was celebrated in the first and third Messenian wars for its defence against the Spartans. The town of Messene was situated in a hollow to the S.W. of the citadel, and having Mount Eva on the S.E., between which and Ithome the walls were carried along a narrow ridge. The whole circuit of the walls is about 6 English miles; and the town was probably made of such an extent in order to accommodate the inhabitants of the neighbouring country, who might take refuge here in time of war, as a great part of the inclosed area must have been quite unfit for building. A description of the town and its principal edifices is given by Pausanias; and Strabo mentions the resemblance between the rock of Ithome and that of the citadel of Corinth. The town continued to exist until towards the end of the Roman Empire; but after that time it fell into decay, and the site is now partly occupied by the modern village of Mauromati, near which many remains are yet to be seen of the ancient buildings and walls.

MESSENIA, one of the ancient divisions of the Peloponnesus in Greece, was bounded on the N. by Elis and Arcadia, on the E. by Laconia, on the S. by the Messenian Gulf, and W. by the Ionian Sea. The area of the country is estimated by Clinton at 1162 square miles. The principal mountains in Messenia are those in the N., near the sources of the Neda and Pamisus, from which one ridge extends to the W. along the Neda, turns to the S., and terminates at the promontory of Acritas; and another chain of mountains stretches E., and joins the ridge of Taygetus. Its chief rivers are the Pamisus (*Pirnazza* and the Neda (*Buzi*). The cities worthy of notice were —Messene, Stenyclarus, Ithome, and Ira, all inland; Corone (*Petalidi*), on the Messenian Gulf; and Methone (*Modon*), Pylos, and Aulon, all on the Ionian Sea. Messenia is described by ancient writers as having a rich and fertile soil, and a mild and temperate climate; and modern travellers confirm the remark of Pausanias, who calls Messenia the richest country in the Peleponnese. This country is said to have been first inhabited by the Leleges under Polycaon, the son of Lelex, who called it *Messenia*, after his wife Messene. After more than a century the country came into the possession of Æolians under Perieres, son of Æolus, and the western part was occupied by Neleus, an Æolian from Thessaly. When the Dorians conquered the Peloponnese, Messenia fell to the lot of Creophontes, who established his capital at Stenyclarus, and divided his kingdom into five parts. Soon afterwards, however, the richness and fertility of Messenia excited the cupidity of the Spartans, and after numerous disputes and incursions on both sides an open war at length broke out, which is known in Greek history as the first Messenian war. This war lasted for twenty years (743–723 B.C.), and during its continuance the Messenians under Aristodemus defended themselves against the Spartans in the fortress of Ithome; but this was finally taken by the Spartans, and the Messenians became helots or slaves of the conquerors. After remaining for some time in this condition, they made an effort to regain their independence in 685 B.C.; and thus began the second Messenian war, which lasted till 668 B.C. The leader of the Messenians on this occasion was Aristomenes; and it was in this war that the Spartans received the assistance of Tyrtæus from Athens, to animate by his warlike songs the courage of their soldiers. When their country was a second time subdued by the capture of Ira, a large body of Messenians fled from their country, and settled, partly at Rhegium in Italy, and partly in various parts of Greece. Others remained at home, and became helots. Another attempt was made by them to regain their freedom in 464 B.C., when Sparta was destroyed by an earthquake. In this third war the fortress of Ithome was again occupied by the Messenians; but after a contest of ten years was surrendered to the Spartans. In 455 B.C. the Messenians were allowed by the Spartans to retire from their fortress, and were settled by the Athenians in Naupactus, a town which the latter had recently obtained from the Locrians. From this place the Messenians were expelled in 404 B.C., at the end of the Peloponnesian war; but they were restored to Messenia by Epaminondas in 389 B.C., where they continued independent until the conquest of Greece by the Romans in 146 B.C..

MESSIAH. See CHRIST, and JESUS.

MESSIER, CHARLES, a skilful astronomer, born at Badonviller in Lorraine, on the 26th of June 1730. He came to Paris at the age of twenty to seek his fortune. Having learned to write a good hand and to draw, Delisle employed him as a copyist in the observatory, and Libour, his secretary, taught him to make use of the common instruments of astronomy, to observe eclipses, and to look out for comets, which was the principal business of his subsequent life, for he was never much of a theoretical or philosophical astronomer. Delisle obtained for him a clerkship in the hydrographical department of the navy, previous to his appointment as astronomer to the admiralty.

After having discovered twelve comets, he obtained a seat in the academy in 1770. He had afterwards the honour of being made an academician of Berlin; and through Laharpe's interest he obtained the same distinction from St Petersburg. He was also made a fellow of the Royal Society of London in 1764. The highest compliment that he ever received was paid him, perhaps without sufficient reason, by Lalande, who inserted in his celestial globe of 1775 a constellation with the name of *Messier*, or *Messium custos*, in the neighbourhood of Cepheus. When Herschel had discovered the Georgian planet, Messier was very diligently engaged in observing its motions; but his studies were unfortunately interrupted by an accident, from the effects of which he was long of recovering. He received a pension on this occasion from the royal bounty, of which, however, he was soon after deprived by the Revolution. Messier was in some measure compensated for his pecuniary losses by being made a member of the Institute, of the Bureau des Longitudes, and of the Legion of Honour. He died on the 11th of April 1817.

A variety of his observations, especially of Comets, are published in the *Mémoires des Savans étrangers*, v. vi., and in the Memoirs of the Academy from 1771 to 1790. There is also a *Catalogue of Nebulæ* in 1771; *An Account of Points of Light seen on Saturn's Ring* in 1774; and of *An Apparent Fall of Globules over the Sun's Disc*, 1777. He also contributed some articles to the *Connaisance des Temps* and to the *Astronomical Ephemerides*.

MESSINA, a town and seaport of Sicily, capital of a province of the same name, is situated at the N.E. corner of the island, on the Straits of Faro or Messina, here about 4 miles in breadth, 8 miles N.W. of Reggio, and 120 E. by N. of Palermo; Lat. (of lighthouse) 36. 18. N., Long. 59. 35. E. The appearance of Messina from the sea is very grand and beautiful. The town is built on the slope of a hill in the form of an amphitheatre, behind which rise mountains covered with dark forests, which heighten by contrast the beauty of the white buildings in the town. The greatest part of the town is built on the W. side of the harbour; the streets are broad and well paved with lava, and the houses are handsome, and in general two storeys high. The town is defended by walls and bastions, as well as by a citadel and numerous forts; so that Messina is reckoned a first-rate fortress. Among the principal buildings in Messina there are about 50 churches, the most remarkable of which is the cathedral, in the Gothic style, built shortly after the Norman conquest of Sicily. The nave of this edifice is supported by ancient granite pillars, which were formerly a part of a temple of Neptune. The altar and the roof of the choir are of mosaic work, and the pulpit is adorned with very beautiful carved work by Gaggini, the Sicilian sculptor; but the general appearance of the building is heavy and tasteless. There are numerous convents and nunneries in the town. The palace of the viceroy is a very fine building, and has a large open space laid out in gardens and walks. Besides these, there are an archbishop's palace, senate-house, college, public library, hospital, lazaretto, two theatres, &c. The harbour of Messina, which is the best in Sicily, is formed by a narrow strip of land in the form of a sickle, which incloses it on all sides but the N., where there is an entrance about 700 yards in breadth. It is thus somewhat difficult of access, but when once entered, it is large and deep. Men-of-war can anchor in the harbour; while merchant vessels come alongside of the quay. The position of the town and the excellence of the harbour give Messina great importance in a commercial point of view. The exports of the place consist principally of oranges, lemons, currants, raisins, wine, brandy, oil, liquorice, sheep and goat skins; and the chief imports are cotton and woollen stuffs, sugar, coffee, hides, and hardware. The inhabitants are also employed to a large extent in the tunny, coral, and other fisheries. The principal manufacture is that of silk stuffs, especially damasks and satins. Messina was almost entirely destroyed by an earthquake in 1693; and in 1743 was visited by the plague, supposed to have been conveyed thither by a vessel from the Levant. Afterwards, in 1780 and 1783, the town was again exposed to the calamities of earthquakes, and on the last occasion was more than half destroyed; since which time it has been built in a much superior style. In 1848 Messina, along with the other large towns of Sicily, went with the popular party, and was bombarded by the Neapolitan fleet. After a bombardment of four days, in which a large part of the city was laid in ruins, it was compelled to surrender.

The province of Messina is bounded on the N. by the Mediterranean, E. by the Straits of Messina, S. by the province of Catania, and W. by that of Palermo; and is 60 miles in length by 30 in breadth. It is occupied in the interior by the mountain range which traverses the N. of Sicily; and though destitute of large plains, it has many valleys, some of which are very rich and fertile in wine, oil, and fruits of various sorts. Pop. of the town (1850), 97,074; of the province (1854), 380,279.

MESTRINO, Nicolo, a famous violinist and excellent composer, was born at Milan in 1748, as is proved by his letter, dated at Brussels 18th August 1786, and addressed to the then governors of the Netherlands, to whom he applied for the vacant post of their master of music. They bestowed the place upon Witzthumb, a native of Baden, who had been long employed as a musician at the court of Brussels. At that time Mestrino had been in the service of Prince Esterhazy, and next of Count Ladislas Erdoedy, as first violin; and had travelled in Italy, Germany, and other countries, with a high musical reputation. Disappointed in his views at Brussels, he proceeded to Paris, where he played one of his concertos at the Concert Spirituel on the 17th December 1786. His extraordinary skill attracted immediate attention, and he was appointed leader of the orchestra of the chief theatre; and, in 1789, director of the excellent orchestra that had been formed by Viotti for the Italian Opera at Paris. He died in September 1790. The late celebrated contrabassist Domenico Dragonetti assured the writer of this article that Mestrino was the best violinist he had ever heard. One of Mestrino's effects in playing was the *slide* performed with the same finger on the same string in passing from one sound to another, a 3d, 4th, or 5th, &c., higher or lower. An example of this is given at page 43 of the second edition of Woldemar's *Grande Méthode pour le Violon*. Mestrino trained several good pupils, and among these, Mademoiselle de la Jonchère, afterwards known as Madame Ladurner. When he arrived in Paris and attracted public attention, the circumstances of his previous artistic life were not known; and thence arose false and absurd stories, invented against him by persons who were jealous of his superiority. It was said that he had long been a street-fiddler, that he had been imprisoned, and had practised the violin incessantly during his confinement: stories utterly destitute of foundation. The late celebrated violinist Paganini was assailed by similar stories, and even by atrocious imputations of murder: all mere fabrications of jealousy. The genuine works of Mestrino, which were published at Paris, consist of twelve Concertos for a principal violin and orchestra; four sets of Duets for two violins; Studies and Caprices for a violin alone; Sonatas for a violin and bass. (G. F. G.)

METAPHOR, a species of rhetorical trope founded on the resemblance which one object bears to another. It is in reality only comparison or simile expressed in an abridged form. For example, the sentence,—"These men are lambs in the family, but lions in the field," is an example of metaphor; but to say, "These men are *like* lambs in the family, &c.," is an instance of simile or comparison. In short, the peculiar distinction between these two figures is, that in simile we say one object is *like* another, while in metaphor we drop the word expressing the similitude, and say one object *is* another. And hence the peculiar boldness which characterizes metaphor, and which is not to be found in the same degree in any of the figures of rhetoric. Those ordinary metaphors which long use has sanctioned have a tendency, in all languages, to sink to the level of common terms.

METAPHYSICS.

Introduction.

Among the various changes which the language of philosophy has undergone in the gradual progress of human knowledge, there is none more remarkable than the different significations which, in ancient and modern times, have been assigned to the term Metaphysics—a term at first sight almost equally indefinite in its etymological signification and in its actual use. As regards the origin of the name, the most recent discussions appear on the whole to confirm the commonly received opinion, according to which, the term *Metaphysics*, though originally employed to designate a treatise of Aristotle, was probably unknown to that philosopher himself. It is true that the oldest and best of the extant commentators on Aristotle refers the inscription of the treatise to the Stagirite;[1] but in the extant writings of Aristotle himself, though the work and its subject are frequently referred to under the titles of the *First Philosophy*, or *Theology*, or *Wisdom*,[2] no authority is found for the latter and more popular appellation. On the whole, the weight of evidence appears to be in favour of the supposition which attributes the inscription τὰ μετὰ τὰ φυσικά to Andronicus Rhodius, the first editor of Aristotle's collected works. The title, as given to the writings on the first philosophy, probably indicates only their place in the collection, as coming *after the physical treatises* of the author.[3] In this respect, the term *Metaphysics* has been aptly compared to that of *Postils;* both names signifying nothing more than the fact of something else having preceded.[4]

The title, thus indefinite in its etymological signification, does not at first sight appear to admit of more precision with reference to its actual application. Mr Stewart, towards the end of his dissertation on the progress of metaphysical and ethical philosophy,[5] notices "the extraordinary change which has gradually and insensibly taken place, since the publication of Locke's Essay, in the meaning of the word *Metaphysics;* a word formerly appropriated to the ontology and pneumatology of the schools, but now understood as equally applicable to all those inquiries which have for their object to trace the various branches of human knowledge to their first principles in the constitution of our nature." "This change," he continues, "can be accounted for only by a change in the philosophical pursuits of Locke's successors; a change from the idle abstractions and subtleties of the dark ages, to studies subservient to the culture of the understanding; to the successful exercise of its faculties and powers; and to a knowledge of the great ends and purposes of our being. It may be regarded, therefore, as a palpable and incontrovertible proof of a corresponding progress of reason in this part of the world."

This change in the pursuits, and consequently in the language, of philosophy had been noticed shortly before by a philosopher of another country in a very different spirit. Hegel, in 1816, introduced his lectures on the history of philosophy in the following words:—"In the other countries of Europe, in which the sciences and the cultivation of the understanding have been prosecuted with zeal and credit, every remembrance and trace of philosophy, the name only excepted, has perished and disappeared. Among the Germans alone, it has maintained itself as a national possession. We have received from nature the higher mission to be the preservers of this sacred fire, as the Eumolpidæ of Athens were intrusted with the preservation of the Eleusinian mysteries."[6] Between these opposite conceptions of metaphysics or philosophy (for in the language of Hegel, the two terms may be regarded as synonymous), it is not easy for an expositor to select his point of view. A definition of metaphysics which would include both, would be defective philosophically from its vagueness: one which would exclude either, would be defective historically from its incompleteness. To omit the view indicated by Hegel would be to neglect the whole of the ancient and a great part of the modern history of the science. To omit the view indicated by Stewart would be to overlook almost entirely the important share which the writers of our own country have contributed towards the solution of the great problem of philosophy. Yet the reader who has perused a few pages of Aristotle's *Metaphysics* or the later works of a cognate character, on the one hand, and of Locke's *Essay* or Stewart's *Elements*, on the other, will probably be at a loss to conjecture what possible common notion can be found to unite together works so utterly distinct in their aim and method. A few preliminary observations on this point may, it is hoped, in some degree assist in throwing light on this obscure and almost imperceptible link of connection.

Speculative philosophy is divided by Aristotle into three branches—physics, mathematics, and theology. The first investigates the special attributes of this or that body as such; the second considers the properties of bodily figures abstracted from their material accompaniments; the third contemplates pure existence, apart from the sensible accidents of matter or figure.[7] This division, however, is one which could not have been made until after philosophy had attained to some considerable development. In the earlier stages of its history, philosophy in general would naturally be identified with one or other of the above branches only, according as its first cultivators sought to explain the principles and causes of things by means of this or that fundamental assumption. Hence it is, that while the history of *philosophy* in its widest sense opens with inquiries identical in their aim with those afterwards pursued by the metaphysician, the history of *metaphysics* proper can hardly be said to have commenced until the progress of thought and the failure of previous speculations led men to attempt the solution of the general problem of philosophy in a particular manner.

[5] See *ante*, vol. i., p. 227.

[6] *Hegel's Werke*, vol. xiii., p. 4. English philosophy, name and thing, is especially honoured with the contempt of this critic. "The natural sciences," he says, "are in England denominated Philosophy. An English *Philosophical Journal* treats of chemistry, agriculture, and manure, of housekeeping and professional knowledge, and communicates discoveries in these departments. The English call physical instruments, such as the barometer and thermometer, philosophical instruments. Theories, especially in morals and moral sciences, which are derived from the feelings of the human heart or from experience, are called Philosophy, as well as those which contain principles of political economy. Thus the name at least of Philosophy is honoured in England." *Ibid.*, p. 72. See also vol. vi., p. 13. In the same spirit are dictated his criticisms on Bacon, Locke, and Newton; the latter of whom, he says, has exhibited in his Optics a perfect specimen of the manner in which experiment and reasoning should not be conducted.

[7] *Metaph.* v. 1. See also *De Anima*, i. 1. The distinction may be illustrated by an example. Suppose the object of contemplation to be a wooden square; the physical philosopher considers it *quâ* wooden; the mathematician, *quâ* square; the theologian or metaphysician, *quâ* something which exists.

Philosophy in general may be defined, as nearly as a conception so vague admits of definition, as an inquiry into the principles and causes of things.[1] Metaphysics has been defined by Aristotle (and the definition may be for the present provisionally accepted), as the science which contemplates being as being, and the attributes which belong to it as such.[2] The latter definition, while verbally resembling the former, exhibits, in fact, an important modification of it; for it implies that the progress of philosophy had necessitated the division of things in general into beings, or things as they are, and phenomena, or things as they appear. The material principles assumed by the Ionians and the mathematical relations of the Pythagoreans were theories of the universe, falling under the general conception of philosophy; but the origin of metaphysics must rather be dated from the period when the Eleatics denied the reality of the sensible world, and confined the region of truth to the supersensible unity which can be obtained only by contemplation.[3]

Philosophy becomes synonymous with metaphysics in the view of those philosophers who regard thought alone as the channel by which men can attain to reality and truth—a point of view which predominates in the speculations and language of ancient Greece and of modern Germany. Our own countrymen have for the most part erred in the other extreme, and limited the province of philosophy too exclusively to the investigation of the phenomena of sense. And the result has been that, while in Britain the name of metaphysics has been rescued from contempt only by an abuse of language which identifies it with a branch of inductive science, in Germany it is not unusual to represent the country of Bacon, Newton, and Locke, as one which has produced no philosophy.

The first step towards a definite conception of metaphysics was attained by regarding it as *the science of real existence*. But this conception, like the wider one of philosophy in general, becomes in its subsequent process developed from different and even contradictory points of view, till the resulting systems appear to have nothing in common but the name. The notion of being, as distinguished from phenomenon, corresponds in its original signification with that which the mind conceives as permanent and unchangeable, in opposition to that which is regarded as transitory and fluctuating. Such an object of inquiry may be approached from two opposite sides. It is the real in itself, and it is contemplated by the mind as such. The problem has thus a twofold aspect, as related to the conditions of being and to the conditions of thought; and its solution may be attempted from the one or the other starting point. We may commence with abstract principles of being in general, and endeavour to deduce *à priori* the essential characteristics of existence *per se;* or we may commence with an examination of the actual constitution of the human mind, and endeavour to ascertain empirically how the conception of reality is formed, and what is its consequent value. And either of these methods of inquiry may be so conducted as in the end to lose sight of the original relation which binds them together; and each may thus present an aspect of irreconcilable antagonism, in place of the mutual pursuit of a common object. The *à priori* reasoner may pervert his conception of absolute being into a form which finds no counterpart in the human consciousness, and, confident in the infallibility of his own process, may condemn as worthless the mirror which refuses to reflect back the distorted image. And the investigator of the facts of consciousness, when his imperfect analysis has failed to discover the hidden element of reality, may proclaim reality itself to be a dream and a delusion, and the mind and all that it contains a mere aggregate of phenomena. Deceived by the apparent parallelism of the distant rays, the opposing theorists forget that those rays must converge somewhere in a common centre: they forget that philosophy itself is but the articulate development of consciousness; that from consciousness all inquiries set out, and to consciousness they must all return.

And such, history tells us, has been the actual fate of metaphysics. The clue to its distant mazes, lost almost at the outset of the journey, became more and more irrecoverable as the paths diverged more and more from their common centre; till its latest expositors on both sides were unconscious of its existence. If Aristotle for a moment grasped the important truth, that the laws of things and the laws of thought were alike objects of metaphysical inquiry,[4] the conviction produced hardly any result in the details of his treatment: his psychology allied itself chiefly to physics; his metaphysics, after its introductory chapter, deserted the track of psychology. If Locke laid the foundation of a better method of metaphysical inquiry when he declared, that "before we set ourselves on inquiries of this nature, it was necessary to examine our own abilities, and see what objects our understandings were or were not fitted to deal with,"[4] he prematurely excluded the very question which his method was required to solve, by asserting that we have no ideas of body or spirit as substances, but merely suppose an unknown substratum to our external or internal ideas.[6] The barrier thus interposed between the sister streams of thought was widened as each flowed on: the ontological philosophers of modern Germany gloried in being not merely independent of, but even contradictory to, the testimony of consciousness; while the psychological teachers of France and Britain confined themselves more and more within the charmed circle of phenomena, till D'Alembert declared that the office of metaphysics was to prove that all our ideas come from sensation;[7] and Stewart denounced the inquiries of ontology as "the most idle and absurd speculation that ever employed the human faculties."[8] But the principle on which this conclusion logically rests is, as regards the Scottish philosophy, an excrescence rather than an integral portion of the system. We may refuse to admit the unproved dogma which denies to the human mind any conception of substance, and yet avail ourselves of the psychological researches of Reid and Stewart, as a valuable, if an incomplete contribution to

Introduction.

the philosophy of consciousness, and, through that, to the solution of those fundamental problems of metaphysics to which consciousness gives rise.

As the metaphysical writings of Aristotle and his followers are likely to be but little known to the majority of modern readers, it may be useful to add a brief account of the ancient method of treating the subject, which will serve at the same time to exhibit more clearly the chasm which separates the earlier conception of the science from that of the modern disciple of Locke or Stewart. "There is a certain science," says Aristotle, "which contemplates being in so far as it is being, and the attributes that belong to it essentially as such. This science is not the same with any of those which are called particular sciences; for none of these inquires generally concerning being as being, but each selects some separate portion of being, and contemplates the properties of that alone; as, for example, mathematics. But since we are seeking for the principles and highest causes of things, it is clear that these must have some nature to which they properly belong. We must therefore take as the object of our inquiry the first causes of being as being."[1]

A similar conception of the great problem of philosophy had been previously exhibited by Plato in his sketch of the office of dialectic—a science which, though differing in name and method, is in its purpose and aim identical with the first philosophy or theology of Aristotle. In the sciences of geometry and arithmetic, he tells us, certain principles of numbers and figures are assumed by hypothesis as self-evident, but not investigated by any process of reasoning; and from these assumptions the proposed questions are demonstrated. But in dialectic the same hypotheses are employed, not as first principles, but as stepping-stones to some higher truth and absolutely first principle, which is grasped by the intellect without hypothesis, as that on which all other reasoning ultimately depends.[2]

The problem of metaphysics, as conceived by both these philosophers, may be perhaps more clearly stated in modern language as follows:—"To determine the relation that exists between the subjective necessities of thought and the objective necessities of things." In mathematical demonstration, for example, we start from certain axiomatic principles, of which, as mathematicians, we can give no other account than that they are *self-evident;* that is to say, that we are compelled by the constitution of our minds to admit them. But this opens a further question. What is the relation of self-evidence to reality? Is the necessity, of which I am conscious, of thinking in a certain manner any sure guarantee of a corresponding relation in the objects about which I think? In other words, are the laws of thought also laws of things; or, at least, do they furnish evidence by which the laws of things can be ascertained? Is thought identical with being, so that every mode of the one is at the same time a mode of the other? Is thought an exact copy of being, so that every mode of the one is an adequate representative of some corresponding mode of the other? Or, finally, is thought altogether distinct from being, so that we cannot issue from the circle of our ideas, to seize the realities which those ideas are supposed to represent? Does anything exist beyond the phenomena of our own consciousness? and, if it does exist, what is the path by which it is to be reached?

The ancient and mediæval metaphysicians adopted almost unanimously the *à priori* method of reasoning downwards from the assumption of abstract principles of being,—as the moderns have laid the foundation of the inverse method of reasoning upwards from the phenomena of thought. A short analysis of the principal subjects treated of in the *Metaphysics* of Aristotle will serve to exhibit the details of the former method, as far as our present limits will permit. In the order of the books we shall follow the common arrangement, which, though far from unexceptionable, is perhaps not more liable to objection than others which have been proposed in its place.

The first book comprises a psychological account of the nature of science and its origin in the human mind, followed by a history of the researches of previous philosophers into the principles and causes of things. To this is subjoined a kind of appendix (the book known as *A minor*), containing an argument in favour of the existence of a first principle of things, and consequently of the possibility of attaining to a knowledge of it; with a caution concerning the method to be pursued, and the necessity of accommodating the mode of reasoning to the nature of the object.

The second book commences with a list of questions, which are to be answered in the course of the treatise, and which may be regarded as furnishing a sort of table of contents to the rest of the work.[3] They may be briefly summed up as follows:—1. Do the principles of being and those of demonstration belong to the same or to different sciences, to one science or to many? 2. Are there other substances besides objects of sense; and, if so, of how many kinds? 3. To what science does it belong to take cognisance of identity and difference, similarity and dissimilarity, priority and posteriority, and such like? 4. Are the principles of things to be sought in their genera, or in the material elements of individuals, or does there exist a cause or causes other than matter, and separable from it? 5. Are there the same principles of things perishable and imperishable, and are all principles themselves imperishable? 6. Are being and unity the essence of all things, or must other elements be added? 7. Are the principles of things universal or individual, potential or actual, active or passive? 8. Are numbers, lines, figures, and points substances or not; and, if substances, do they exist separate from the objects of sense? A further development of the difficulties involved in these questions occupies the remainder of this book.

The third book is occupied with the sketch of a science of being as such, which has for its object both the principles of things and the laws of reasoning. In it the philosopher maintains the truth of the logical principles of contradiction and excluded middle against the objections of Heraclitus, Anaxagoras, and others, and establishes the distinction between being and appearance, and consequently between truth and error.

The fourth book is an explanation of the various significations of several philosophical terms. The terms defined are,—principle, cause, element, nature, necessity, unity, being, substance, identity, distinctness and diversity, similarity and dissimilarity, opposition and contrariety, priority and posteriority, power, quantity, quality, relation, perfection, limitation, in respect of and in itself (*καθ' ὃ* and *καθ' αὑτό*), disposition, habit, passion, privation, possession, derivation, part, whole, imperfection, genus, falsehood, accident.

---

[1] *Metaph.* iii. 1. The same view is also exhibited more fully in v. 1, in a passage too long for quotation.

[2] *Republic*, vi., p. 510.

[3] The correspondence, however, is by no means exact. Michelet observes,—"En général, il faut remarquer ici que l'énumération et le développement des problèmes contenus dans ce livre ne répondent pas exactement à leurs solutions donneés dans les autres livres. Car beaucoup de problèmes sont transposés; quelques-uns n'y sont qu'effleurés; plusieurs y sont réunis, à cause de l'affinité qu'il y a entre eux; d'autres enfin sont traités en différents endroits." (*Exam. Critique*, p. 131.) The division of the questions themselves admits of considerable variety. Michelet and Ravaisson enumerate as many as seventeen. Mr Maurice (*Moral and Metaphysical Philosophy*, p. 183) reduces them to six.

The fifth book continues the sketch of a science of being which was commenced in the third. This science (called by Aristotle "Theology," and afterwards known as Metaphysics) is distinguished from physics and mathematics. Being *per se*, the proper object of metaphysics, is distinguished from other senses of the term,—such as accidental existence, which is not an object of science, and truth in judgments, which belongs to thought and not to things.

The sixth book is a continuation of the same subject. Being, in the highest sense of the term, is identified with substance, to the exclusion of the other categories. But substance, again, is used in various senses; sometimes for the essence of a thing, sometimes for its universal attributes, sometimes for the genus, sometimes for the subject of attributes, or the individual. A discussion of these different senses, and of the philosophical theories connected with them, occupies the remainder of the book.

The seventh book continues the discussion of substance. The essence of sensible things may be considered in two points of view,—as regards the *matter* or potential essence, and as regards the *form* or actual essence, corresponding to the genus and difference in a definition. The unity of such objects must be sought for in the principle which unites these two. Intelligible objects, which have no matter, are one by virtue of their form.

In the eighth book the distinction between matter and form, or potential and actual existence, is further discussed. The distinction between the potential and the actual is defended against objections. The actual is prior to the potential in the order of nature and of reason, and, in one sense, in that of time also. It is prior in the order of reason; for power has no meaning but in relation to performance. It is prior, too, in the order of time in the species, though not in the individual; for the powers of any thing are produced by its efficient cause, and the cause, as such, is in action. Hence it follows, that the distinction between the potential and the actual exists only in relation to things perishable; for that which is eternal cannot have become what it is, and therefore can never be potentially that which it is not actually. In other words, there is a cause of change which itself acts unchangeably, and which is prior to all change. The chief good and highest principle is thus ever active, and there is no eternal principle of evil; for actual evil is a corruption posterior to the possibility of evil. The book concludes with a discussion of the nature of truth and falsehood; the latter of which can have no place in relation to first principles, which must either be absolutely known or absolutely unknown.

The ninth book is a digression, treating of the opposition between the one and the many. The various senses of unity enumerated in the fourth book are now reduced to four,—the continuous, the whole, the individual, and the universal. Unity is identified with existence, and declared, in opposition to the Pythagoreans and Platonists, to be not a substance, but an universal notion predicable of every kind of subject in the several categories. The opposition between unity and plurality is shown to be not one of contrariety, but of relation. The book concludes with a further digression on some points connected with the opposition of contraries.

In the tenth book, as well as in the ninth, the connection of the argument is somewhat interrupted. This book, in fact, contains little more than a recapitulation of matters treated of in some of the earlier books. The concluding chapters of this book are an abridgment of a portion of the *Physics* of Aristotle, and appear altogether out of place in their present position.

The eleventh book is the most important of all; and though apparently incomplete in itself and in its connection with its predecessors, may be regarded as containing an outline of Aristotle's views on the profoundest problems of metaphysical philosophy. In this book, after some preliminary remarks on the nature of substance, change, and causation, the philosopher resumes his inquiry into the nature of the first cause—the unchanging principle of all change and motion. Sensible substances, the objects of physical science, are subject to change; and all change implies a progress of the same subject from one of two opposite states to the other; from not being to being, or the reverse. Hence change implies three elements: the form, the privation, and the matter potentially susceptible of both. But change itself must take place in consequence of some cause; we must, therefore, add a fourth principle to the three elements. We are thus led to the notion of a substance which is the efficient cause of change, and this substance must be eternal; for even change and time are conceived as imperishable, and these depend upon a substance. The cause of change must therefore be a being eternally acting, and which, consequently, cannot be conceived as having a power to act prior to the exercise of that power. In other words, the first cause (as was said before in the eighth book) can never be potentially that which it is not actually. The first cause is thus active without being passive; it moves all things without being itself moved. The action of an unmoved cause of motion may be regarded as analogous to that of an object of desire on the appetite, or of an object of contemplation on the intellect; for these excite to action without being themselves acted upon. Thus the principle of change may be conceived both as first cause and as final cause or chief good, which all things desire, and by the desire of which they are moved.[1] This first cause is God, who, as the highest object of intellectual contemplation, must himself be conceived as Intellect, as ever active, as living (for the activity of intellect is life), as immaterial, having neither finite nor infinite extension, and consequently no parts, as impassive and unchangeable. To this sublime theology are appended some curious astronomical speculations, apparently intended to reconcile the unity of the Divine Mover with the seeming variety in the celestial motions. To these speculations, which are chiefly derived from previously existing astronomical theories, the philosopher himself does not appear to attach much importance. Resuming the theological argument, he maintains that the Deity, as an ever active and unchanging Intellect, must have an unchanging object of contemplation, and as there is no other such object, he must contemplate himself. The book concludes with a criticism of previous philosophers, whose opinions, as he considers, are irreconcilable with the existence of one supreme Ruler of the Universe.

The two last books must be considered either as an introduction to the eleventh, which most modern commentators regard as the conclusion of the whole treatise, or as a controversial appendix, intended to fortify the positions which that book had established. The controversy is chiefly directed against the Pythagorean and Platonic philosophies, which sought the eternal principle of the universe, the one in the theory of numbers and geometrical magnitudes, the other in that of ideas. The details of this controversy, part of which is little more than a repetition of the arguments of the first book, are chiefly valuable in a historical point of view, as throwing light on the Pythagorean and Platonic doctrines; but they contribute little to the elucidation of Aristotle's own conception of metaphysics.

The Aristotelian first philosophy, as exhibited in the above sketch, has certainly little enough in common with an inductive science of the human mind; and its speculations will probably appear to a modern reader sufficiently vague and

---

[1] Κινεῖ δε ὥς ἐρώμενον. *Metaph.* xi. 7.

Introduction.

barren. But they have a value, historical and philosophical, far beyond their apparent significance to a superficial inspector. They have a historical value, as representing the course of metaphysical inquiry which was pursued, with scarcely an exception, for nearly twenty centuries, and which even now exercises a legitimate influence over the minds of men hardly less extensive than its former absolute dominion. And they have a philosophical value, of which their historical position is the index. However wide may be the gulf that separates the ancient and modern systems of philosophy, they have this at least in common, that both are the produce of human minds, thinking under the same laws, and impelled to speculation by the same irresistible motive of yearnings unsatisfied, and doubts unsolved. Each seeks to comply with the requirements of the same nature; each sets out from the ground of that common consciousness which, in intellect no less than in affection, makes the whole world kin. "Homo sum; humani nihil a me alienum puto," is a maxim no less applicable to the most abstruse speculations of philosophy than to the affairs of our every-day life. Philosophy, in all its aspects, is a contribution to the history of humanity; an attempt, successful or unsuccessful, to carry out the great end and purpose of man's existence. The study of the master-minds of the human race is almost equally instructive in what they achieved and in what they failed to achieve; and speculations which are far from solving the riddle of existence have their use in teaching us why it is insoluble.

Thus it appears that the term METAPHYSICS has been at different times used in two principal senses: 1. As synonymous with Ontology, to denote that branch of philosophy which investigates the nature and properties of *Being* or *Reality*, as distinguished from *Phenomenon* or *Appearance*. 2. As synonymous with Psychology, to denote that branch of philosophy which investigates the *faculties, operations, and laws of the human mind.* These two sciences may be regarded, as has been already observed, as investigations of the same problem from opposite points of view; but this feature of relation has been practically overlooked by the majority of writers on either side; and the link which is to connect the actual contents of each remains still to be pointed out. One, indeed, but hardly definite enough, has been indicated by Dugald Stewart. "On comparing together," says that distinguished philosopher, "the multifarious studies now classed together under the title of Metaphysics, it will be found difficult to trace any common circumstance but this—that they all require the same sort of mental exertion for their prosecution; the exercise, I mean, of that power (called by Locke *reflection*) by which the mind turns its attention inwards upon its own operations, and the subject of its own consciousness." This passage seems to point out a closer connection between the different sense of the term *Metaphysics* than that which it actually expresses. For it refers us not merely to a common method of inquiry, in the process of *reflection*, but also to a common object, in the *facts of our own consciousness.* But to exhibit this connection clearly, the latter term must be extended to a somewhat wider signification than that sanctioned by Stewart's use of it.

On this term, Sir William Hamilton remarks,—"Aristotle, Descartes, Locke, and philosophers in general, have regarded consciousness, not as a particular faculty, but as the universal condition of intelligence. Reid, on the contrary, following probably Hutcheson, and followed by Stewart, Royer-Collard, and others, has classed consciousness as a co-ordinate faculty with the other intellectual powers, distinguished from them, not as the species from the individual, but as the individual from the individual. And as the particular faculties have each their peculiar object, so the peculiar object of consciousness is *the operations of the other faculties themselves, to the exclusion of the objects* about which those operations are conversant.

"This analysis we regard as false. For it is impossible, in the *first* place, to discriminate consciousness from all the other cognitive faculties, or to discriminate any one of these from consciousness; and, in the *second*, to conceive a faculty cognisant of the various mental operations, without being also cognisant of their several objects.

"*We know;* and *we know that we know:*—these propositions, *logically* distinct, are *really* identical; each implies the other. We *know* (*i.e.*, feel, perceive, imagine, remember, &c.) only as we *know that we thus know;* and we *know that we know*, only as we know in *some particular manner* (*i.e.*, *feel*, *perceive*, &c.). So true is the scholastic brocard:—'*Non sentimus nisi sentiamus nos sentire; non sentimus nos sentire nisi sentiamus.*' The attempt to analyse the cognition *I know*, and the cognition *I know that I know*, into the separate energies of distinct faculties, is therefore vain.

"But the vice of Reid's analysis is further manifested in his arbitrary limitation of the sphere of consciousness; proposing to it the various intellectual operations, but excluding their objects. . . . The assertion that we can be conscious of an act of knowledge, without being conscious of its object, is virtually suicidal. A mental operation is only what it is, by relation to its object; the object at once determining its existence, and specifying the character of its existence. But if a relation cannot be comprehended in one of its terms, so we cannot be conscious of an operation without being conscious of the object to which it exists only as correlative. For example, We are conscious of a perception, says Reid, but are not conscious of its object. Yet how can we be conscious of a *perception*, that is, how can we *know* that a perception exists,—that it is a perception, and not another mental state,—and that it is the perception of a rose, and of nothing but a rose,—unless this *consciousness* involve a knowledge (or consciousness) of the object, which at once determines the existence of the act, specifies its kind, and distinguishes its individuality? Annihilate the object, you annihilate the operation; annihilate the consciousness of the object, you annihilate the consciousness of the operation." [1]

Extending the term *facts of consciousness*, in accordance with the principle of the above criticism, to denote all those phenomena of mind whose existence in a definite form, as operations of a particular kind, and the knowledge of that existence, are identical; we may find in these facts an adequate object for the investigations of *Metaphysics*, in the most general sense of the term; and in this sense, accordingly, we would define the science of which we are treating, as "Metaphysics, or the philosophy of the facts of consciousness, considered subjectively, in relation to the mind knowing, and objectively, in relation to the things known." Metaphysics will thus naturally divide itself into two branches,—PSYCHOLOGY, or the science of the facts of consciousness as such; and ONTOLOGY, or the science of the same facts considered in their relation to realities existing without the mind.

Neither of these two branches of metaphysics, thus treated, can be considered as exhausting the senses in which their respective names have been used. Psychology, both in its earliest and in some of its latest developments, has been treated in connection with physiology, and thus extended to phenomena beyond the range of the facts of consciousness properly so called. Aristotle, the first systematic expositor of the science, enumerates, in conjunction with the threefold division of the facts of consciousness into those of sensation, thought, and volition,[1] a fourth function of nutriment and growth, the existence of which cannot be identified with the consciousness of it. *I perceive*, and *I know that I perceive; I think*, and *I know that I think; I will*, and *I know that I will*:—these propositions are severally equivalent to each other; but not so *I digest*, and *I know that I digest.* Modern writers on psychology have treated it with a similar extension to physiological phenomena. Ontology, in like manner, has, in modern times especially, sought a foundation for its speculations beyond the domain of consciousness, and even contradictory to it; nearly the whole of the systems of German metaphysicians since Kant being a series of attempts, more or less plausible, to account for the origin of the facts of consciousness themselves, by postulating a principle of which we are not and cannot be conscious. Neither of these extensions of the field of inquiry will be adopted in the present article. We shall, indeed, have to borrow largely from physiology in illustration of the bodily conditions on which mental consciousness depends; but the two sciences will be considered as distinct branches of inquiry, though the conclusions of the one may throw some collateral light on the researches of the other.[2] On the other hand, the transcendental method, which seeks to found a philosophy of being in a point above consciousness, will be rejected, from a conviction of its utter inability to furnish any reliable or even intelligible results. All such theories are open to two fundamental objections: they cannot be communicated, and they cannot be verified. They cannot be communicated; for the communication must be made by words, and the meaning of those words must be understood, and the understanding is a form of consciousness and subject to the laws of consciousness. They cannot be verified; for, to verify, we must compare the author's experience with our own; and such comparison is again an act of consciousness, and subject to its laws. This consideration must serve as our apology for the neglect of systems which are indeed entitled by their celebrity to a prominent place in the history of metaphysical philosophy, but which cannot, except upon the ground of their truth, claim admission into a treatise on the science itself.

---

[1] *Discussions*, p. 47.

There is a wide application of the term *consciousness*, in which it is coextensive with the whole cycle of human knowledge; for we can know nothing without being conscious that we know it; and we can investigate no objects but those whose existence, real or apparent, must be made known to us by consciousness. In this sense, what is out of consciousness is out of the field of human knowledge altogether. But this consideration does not affect the definition which assigns the facts of consciousness as the proper object of metaphysical science. For in other sciences those facts are considered, necessarily indeed, but secondarily only, as the means by which the direct objects of such sciences are made known to us. The manner in which consciousness operates as the instrument of the physical sciences is not taken into account by those sciences, nor is the nature and veracity of its testimony called in question. Physical science does not trouble itself with the inquiry, whether the objects which it investigates are real or apparent; qualities of matter or modes of the spectator's own mind; whether they are gained directly or indirectly; by innate or acquired powers; by one faculty of the mind alone or by the union of many. Its researches are not in any way affected by the adoption of this or that theory of consciousness itself; though consciousness is the means by which its objects are conveyed to it. In metaphysical science, on the other hand, consciousness itself is the direct object of our inquiries; and that in two points of view: 1. In its *phenomenal character*, in relation to the conscious subject; in which we consider the several affections of the human mind in which consciousness consists, and the faculties, operations, and laws, upon which those affections depend. 2. In its *real character*, in relation to the objects of which we are conscious; in which we consider the veracity of its testimony in reference to things without the mind, and the indications which it is supposed to furnish of the actual constitution of those things. Of these two inquiries, the first is preliminary and auxiliary to the second; both because it is necessary to know what the facts of consciousness are in themselves, before inquiring into their ulterior relations, and because the light which the former inquiry is calculated to throw on the laws and limits of human thought, will be of importance in determining how far it is possible to obtain a satisfactory answer to the latter. We commence, then, with the first portion of our inquiry.

I.—PSYCHOLOGY, OR THE PHILOSOPHY OF THE PHENOMENA OF CONSCIOUSNESS.

Consciousness, in its relation to the subject or person conscious, is of two kinds; or rather, is composed of two elements—the presentative or intuitive, and the representative or reflective. The phenomena of the former class may be distinguished by the general name of *intuitions;* those of the latter by that of *thoughts.*

Presentative or intuitive consciousness is the consciousness of an *individual object*, be it thing, act, or state of mind, immediately present before me, *here* or *now;* that is to say, with a definite position in space or in time, or in both. Representative or reflective consciousness is the consciousness, *primarily* and *directly*, of a *general notion or concept*, indifferently related to any number of possible individuals; *secondarily* and *indirectly*, of *one or more actual individuals*, conceived as exhibiting at the moment, in an unity of representation, the several attributes which the general notion involves. For example, I see a triangle drawn on paper. I need not know that the figure now lying before me is called a triangle. I may be unable to give any definition of it. It is enough that I see a figure, which I did not construct for myself according to any pre-existing notion, but found there already constructed. This is *presentative consciousness*, or *intuition*. The triangle is before me, as an object seen in itself, not necessarily representative of anything else. But, having seen the triangle, I gather a general notion of its figure, indifferently applicable to it or to any other specimen; and I imagine a particular figure, at another time and in another place, as embodying that notion. This is *representative consciousness*, and in a two-fold manner. First, the general notion is representative of any number of possible triangles, even when none is actually present to the consciousness. Secondly, the same notion is now actually exhibited in an image; which image represents the original figure from which the notion was derived. The same distinction is applicable to mental as well as to bodily phenomena. I feel an emotion of anger; I am conscious of its presence now, as a definite state of mind distinguishable from others. This consciousness is *presentative.* When the angry fit is over, I meditate upon my past state, and recal in imagination the emotion which I have experienced. This consciousness is *representative.* Presentative consciousness contains two constituent elements—the conscious subject, and the object of which that subject is conscious. Representative consciousness contains three elements—the subject, the object (*i.e.*, the image), and the concept or general notion mediating between them. A fourth element is implied as a condition, though not actually present in consciousness, viz., the original intuition from which the notion was derived, and which the object or image represents.

---

[1] I have ventured to use the term *volition*, as nearly equivalent to the *motive principle* of Aristotle; though the connection of the latter with the will is but imperfectly exhibited in his treatise, owing to the want of a strict distinction between the phenomena of human consciousness and those of animal life.

[2] The limits of psychology and physiology are defined in an excellent essay by M. Jouffroy, *Nouveaux Mélanges Philosophiques*, p. 222. The phenomena of consciousness, which are known only as affections of myself, belong to the former science; those of animal life, which can be discerned by observation of foreign bodies, belong to the latter.

The ultimate object of all consciousness is thus an *individual;* for all intuitions are directly cognisant of individuals, and all concepts, to be realized in consciousness, require to be individualized in an image. Without the application of this test, we should not be able to distinguish between the conceivable and the inconceivable; between signs indicative of notions and signs indicative of no notions at all. I may define a *triangle* as a rectilinear figure of *three* sides; and I may also define a *biangle* as a rectilinear figure of *two* sides; and nothing but the attempt to construct the corresponding images can show me that the one term denotes a conceivable object, and that the other is an inconceivable piece of nonsense. The individual is thus the ultimate object of all actual consciousness; in intuition directly, and in thought indirectly. To complete our explanation, we must therefore determine what is meant by an *individual.*

By the term *an individual,* is meant, in psychology, no more than an object occupying a definite position in space or time. It is indifferent, in this point of view, whether the several individuals thus distinguished can or cannot really exist apart from each other; or whether the portion of space or time which each occupies is distinguished from other portions naturally or arbitrarily. The leaf which I see before me is an individual; so is the bough; so is the tree; so is the forest. Each has its own position in space, which nothing else can occupy along with it. A chain of six feet long is an individual; whether it exist separately, or only as part of a longer chain. Every link, and every fragment of a link, of the chain is again an individual, in so far as, with or without physical separation, it may be made a distinct object of sight or thought. What space is to material individuals, time is to individual phenomena of mind. I may feel anger or fear many times in succession; but each has its own peculiar portion of time; and the passion which I felt yesterday, however similar in other respects, is numerically distinct, as an individual state of mind, from that which I felt the day before yesterday, or that which I am feeling at this moment. We need not at present inquire whether each of these distinct individuals has in reality a separate existence apart from our point of view or not. They may be independent units: they may be fractions of larger units: they may be multiples of smaller units: they may be constituent parts of one only real unit, the universe. They may be modes of my own mind, or they may be attributes of something distinct from myself. These questions belong to ontology, not to psychology. It is sufficient for our present purpose to state, that whatever occupies a distinct portion of space, however arbitrarily distinguished, is an individual object of external intuition; and whatever occupies a distinct moment of time, without extension in space, is an individual object of internal intuition.

On the other hand, general notions or concepts, as such, have no definite position in time or space; though, when realized in an individual act of thought, they *must* have a relation to the former, and *may* have to the latter. The definition of a triangle, as a rectilinear figure of three sides, is indifferently applicable to a triangle in England or to one in America; to one drawn on paper or to one engraved on stone; to one conceived yesterday or to-day. But when actually employed in conception, it becomes *my present thought about a triangle;* and this has its definite position in time, and is related to an image conceived as occupying a definite position in space. The verbal description of a particular coin is indifferently representative of all coins struck from the same die; but two shillings of the same coinage, though they may be undistinguishable in other respects, are yet separate individuals, as occupying distinct portions of space. The general notion is thus *potentially* representative of many individuals; that is to say, it may, *in different acts of thought,* be employed in relation to any member of a certain class; but when *actually* so employed, *in any one single act of thought,* it becomes amalgamated with the individual in which its attributes are united, and is only conceived along with the special characteristics of the individual. Thus the notion of a triangle, as such, does not imply that it is equilateral, isosceles, or scalene; but I can never actually conceive a triangle which is none of these, or all of them at once. I must conceive it as some one of them only. But, *in successive acts of thought,* the same general notion may be represented in the imagination, at one time with three equal sides, at another with two, at another with all unequal. The notion is thus not the adequate and actual representative of any single object, but an inadequate and potential representative of many.

We have thus one characteristic of the concept or general representative notion; namely, *that it cannot in itself be depicted to sense or imagination;* though, in every complete act of representation, it forms one element of an image which is so depicted. The mere notion of a triangle, apart from the consideration of the equality or inequality of its sides, is not an object of imagination; nor the notion of an equilateral triangle, without a given length of the sides; nor, again, the notion of an equilateral triangle whose sides are each two feet long, without the additional limitation of its occupying a particular position in space;—under which limitation, it is no longer general, but individual, and can be constructed in the imagination as an object of intuition. A second characteristic of all general notions is, *that they require to be fixed in a representative sign.* The general notion, as such, is not a sensible image, but an intelligible relation; and such a relation, as far as our experience can testify, cannot be apprehended without the aid of *language,* *i.e.*, of some system of signs, verbal or other. The case of the deaf and dumb is no exception to this rule; for *language,* in the above sense, is not synonymous with *articulation.* The mental development of the deaf and dumb is effected by the substitution of a system of signs addressed to the eye or the hand, in the place of one addressed to the ear; and this system performs precisely the same office in relation to them that speech performs in relation to others: it constitutes, in fact, *their language.* Language in this sense appears, as far as experience can inform us, to be necessary, not merely to the communication, but even to the formation of thought. The notion, as such, must be emancipated from all special relation to space or time. The definition of a triangle must not imply where it exists; nor the definition of anger, when it takes place; and this emancipation is never completely effected, except by means of symbols, verbal or other, by which the notion is fixed as a relation in the understanding.[1] We have thus, in the complete exercise of thought, three successive representations. The sign is representative of the notion; the notion is representative of the image; and the image is representative of the object from which the notion was formed.

---

[1] The distinction between intuition and thought thus corresponds to that noted by Leibnitz between *intuitive* and *symbolical* knowledge. See his *Meditationes de Cognitione Veritate et Ideis,* where, however, the distinction is hardly marked with sufficient precision.

Presentative and representative consciousness, thus distinguished, must be considered, in their actual exercise, as indicating a logical rather than a real division; as pointing out the elements of a perfect act of consciousness, which are separable in thought, rather than two distinct acts existing separately in practice. In every complete act of consciousness offered to us for analysis, the presentative and representative elements are combined; and without such a combination, it would appear as if consciousness, properly so called, could have no existence. To have a complete consciousness, for example, of any particular object of sense, say of an oak tree, two conditions are necessary: first, that certain impressions should be made upon the organ of sensation; and, secondly, that these impressions should be discerned as constituting an object; *i.e.*, that they should be separated from all other objects, and considered by themselves as constituting a whole, which can be compared with and distinguished from other wholes. To the mere sight the oak is presented along with the surrounding scenery; but to recognise it as an oak, the trunk must be considered separately from the ground from which it springs, and the branches and the leaves must be discerned as parts of the tree, and separated from the surrounding objects. The reception of the whole scene presented to the eye is an act of mere intuition; but the knowledge of each impression as being what it is, and the combination of a portion of such impressions into a separate whole, is an act of reflection or thought.[1] Neither of these two elements alone can constitute a complete act of consciousness. Let us suppose, for instance, the existence of a being furnished with human organs of sensation, but with no power of remembering or reflecting upon the objects presented to them, and no continuance of any impression beyond the moment of its actual presence. It is probable that, in such a case, though diverse objects might be successively presented to the senses, yet there would be no consciousness of their diversity; for such consciousness requires the juxtaposition of the objects in the mind, and this can only be effected by memory. Animals, trees, and stones, might be successively placed before his eyes. Pleasure and pain and fear and anger might possibly take place within him; but as each departed, he would have no knowledge that it had ever existed, and consequently no power of comparison with anything else. He would thus have no distinct consciousness of each object *as referred to a separate notion:* he could not say, this which I see is a tree or a stone; this which I feel is fear or anger. His consciousness, if consciousness it could be called, would probably be no more than an indefinite sense of uneasiness, a feeling of momentary irritation in the organ affected, but without discerning in what manner it is affected, and without distinguishing the permanent self from its momentary affection.[2] This is the lowest degree of intelligence, the germ of consciousness, but not itself entitled to the name; as being deficient in the essential conditions of limitation and difference, having not realized the distinction between subject and object, or between one object and another.[3] But let us go one step further, and suppose the same being to be capable, not merely of receiving, but of retaining and associating together, various impressions, though still destitute of the power of reflecting upon them. Let us suppose; that is to say, that the impression, once made, may continue for a time in conjunction with others, and spontaneously recur upon certain occasions; though the subject of the impression is unable to set it apart as an object of thought, or to recal it by an effort of his own will. We have now a second stage of intelligence—a partial consciousness, embracing a variety of objects and relations of similarity or dissimilarity between them; we have the recurrence, moreover, of certain feelings upon the repetition of the circumstances under which they were originally excited. In a word, we have *an association of intuitions.* But the conditions of consciousness are not yet complete; for memory, at this stage of its development (the μνήμη of Aristotle), though it implies a repetition of phenomena, does not as yet imply a knowledge that it is a repetition. An animal at this stage of intelligence might, for instance, be beaten for a fault, and the recurrence of the fault might naturally suggest an imagination of the pain; but this imagination need not be consciously regarded as a remembrance of pain felt at a former time. The reproduction would be spontaneous, not voluntary, and probably not accompanied by any conscious reference to past time. Let us now assume another step in the scale of intelligence, and suppose our imaginary being to possess, not merely a power of receiving and retaining impressions, but also of recalling them by a voluntary effort (the ἀνάμνησις of Aristotle). This implies that the leading features of the impression remain fixed in the mind, independently of the presence of the object at a particular place or time. This is the distinctive feature of the concept or general notion, in which, whether by a conscious process or not, the mind abstracts the leading attributes of an object from the condition of limitation in space and time, and is able, under the guidance of those attributes, to recognise the object when presented to it at other times, and, under the same guidance, to reproduce at will the image of the object when absent. Here we have the cooperation of thought proper, as evidenced by a conscious recognition of objects as such, and of their several relations to the one conscious self, whose permanence and personal identity is necessarily discerned in every act of consciousness properly so called, as the continuous subject of successive modifications. This is the only form of intelligence which can properly be expressed by the judgment, *I know*, or *I know that I know;* and at this stage we have reached the point of true consciousness, in which the existence of a phenomenon is identical with the knowledge of its existence, and the mind, in the act of being affected in any manner, is at the same time cognisant of being so affected.

The above stages must not be regarded as corresponding to a chronological development of the actual phenomena of the human mind. Logically, perhaps, the several elements by whose co-operation consciousness is produced, may be thus analysed; but in the actual progress of the mind by education, the several elements are so mingled together, that it is impossible to point out any particular time at which one exists separately from the rest, or to mark the period of each new accession. Classifications, which we are unable to form for ourselves, are, from the earliest dawn of intelligence, given to us, already formed by others. The child, in learning to give names to the objects placed before him, and to repeat those names at each recurrence of the objects, learns, unconsciously to himself, to perform the acts of reminiscence and generalization, along with that of sensation, and advances by imperceptible degrees to a definite consciousness. To point out each successive stage of the process by which sensibility gives birth to intuition, and intuition to thought, is as impossible as to determine the several moments at which the same child receives each successive increase of his stature, or each successive development of his bodily powers. The mind, like the body, acquires its functions by insensible degrees, "unseen, yet crescive in its faculty;" and we find ourselves in the possession and exercise of nature's gifts, without being able to say how we acquired them.

---

[1] Cheselden says of his patient, who had been couched for cataract,—"He knew not the shape of anything, nor any one thing from another, however different in shape or magnitude." The language is ambiguous; it may mean that he was unable at first to separate the different objects in the field of vision from each other, or it may mean only that he could not distinguish them by their right names. Condillac goes beyond the warrant of the original in rendering "Il apercevoit tous les objets pêle-mêle et dans la plus grande confusion." (*Traité des Sensations*, p. iii., ch. 5.) But Cheselden's experiment, besides the want of precision in the report, is not decisive for other reasons: 1. Because a cataract does not produce total blindness; 2. Because the other senses had been educated before the operation was performed.

[2] A state of representation very nearly resembling this is supposed by Leibnitz to exist in his monads. This state he calls perception without apperception or consciousness, and considers it as the characteristic state of existence of simple monads, as distinguished from souls, which are capable of memory and distinct consciousness. (See *Monadologie*, sect. 14, 19.)

[3] If the testimony of psychology is to be trusted, the sublime intellectual condition in which subject and object are identified, a condition longed for by mystics of all ages, and proclaimed as the basis of philosophy by modern German metaphysicians, is a degradation of man to the level, possibly, of a zoophyte. Yet there have not been wanting philosophers to proclaim this lowest possible manifestation of animal existence as the exaltation of man to the level of God—as the state of Deity contemplating itself.

Consciousness proper, as above described, must possess in some degree the attributes of *clearness* and *distinctness*. Using the same term in a wider and less accurate sense, we may distinguish between an *obscure* or an *indistinct*, and a *clear* or a *distinct* consciousness. An act of consciousness, whether presentative or representative, is *clear* when its object as a whole can be distinguished from any other; when this cannot be done, it is *obscure*. An act of consciousness is *distinct* when the several parts constituting its object can be distinguished from each other; when this is not the case, it is *indistinct*.[1] To form a clear or distinct consciousness, an act of reflection must accompany the intuition. An obscure or indistinct consciousness may in some degree be obtained by intuition alone. The latter contains all the materials of the former, though not disposed in the same relations to each other. In an obscure or indistinct intuition, we may be dimly aware of the existence of differences of some kind, but be unable to say what they are. In order to obtain this latter knowledge, the first step must be to separate our confused intuition into distinct portions; and in performing this task, we are, as a matter of fact, invariably assisted by the distinctions of language; that is to say, by a classification already performed by the reflection of others. By learning to recognise under their names the different portions of a confused intuition, we take the first step towards a clear and distinct consciousness of things and thoughts. It is obvious, however, from what has been said before, that the terms *clear* and *distinct* are rather relative than absolute, and that a perfectly obscure consciousness is no consciousness at all in the proper sense of the term.

What has been said concerning the relation of thought to language may perhaps suggest two other questions, which have often been discussed without any satisfactory answer. It may be asked, in the first place, how we are to account for the origin of language itself, and how the distinctions which language now helps us to make could themselves have been made available in the original imposition of names; and, in the second place, it may be asked how the different phenomena of consciousness can be distinguished from each other by the lower animals, who have no nomenclature to assist them. Both these questions admit of many ingenious conjectures, but of no scientific answer. And the reason is obvious; for both relate to states of consciousness which we never have experienced and never can, and which are so utterly unlike our own, that we have no reliable data for examining them. To conceive an inventor of language, we must conceive a man existing in the full maturity of his faculties; those faculties not having been developed by any of the means that are indispensable now, and consequently not having assumed the same form in their development. Such a being is to us as inconceivable as one of a wholly different mental constitution. His thoughts are not our thoughts; his conditions of speech are not ours. Our experience is so unlike what his must have been, that it will but mislead us if we reason from it; and if we conjecture without the aid of experience, we deal in fiction, not in philosophy. Nor is the difficulty lessened if we suppose language to have been of Divine origin; for the real problem is, not to determine how the system of signs came into being, but how man learned to associate it with his own distinctions of thought; or how, independently of it, he came to have such distinctions at all. The origin of language must ever remain a mystery; but it is a mystery which has its parallel in every other phenomenon of the sensible or intelligible world; for of all, while the existence is undeniable, the generation is inconceivable. That a man living in solitude from his earliest infancy, supposing him to be preserved to animal maturity, or any number of such men brought together into a separate society, apart from other men, could never acquire the mental power to invent a language, seems as nearly certain as such a point can be. Beyond this we have no means of speculating on the origin of language at all. Nor are we much better off in relation to the second question, as to the mental condition of the lower animals. To analyse a dog's consciousness, it is necessary that we should have a dog's consciousness ourselves; and besides this, that we should retain a distinct recollection of it after we have acquired a human one. The dog can distinguish his master from a stranger; that is clear. He can be educated by associations of pain or pleasure; that is clear also. But when conscious of his master's presence, does he recognise him as a being distinct from all other objects—as an object that can be observed or contemplated alone? When he is uneasy at losing him, has he a distinct consciousness of what it is that he wants? When he is educated, does he consciously represent to himself the association between tit-bits and sitting upright? And if he does so, does he do it by the aid of any system of representative signs, which, though unintelligible to us, performs an office analogous to that of human language?[2] In a word, does his state of intelligence more nearly resemble the second or the third stage of our supposed development of consciousness? Instinct resembles reason in many of its results; does it therefore resemble it in its manner of obtaining them? We may speak positively on these points with all the hardihood of ignorance; but in doing so, we are speculating on the nature of an intelligence different from our own, and whose conditions cannot even be conjectured, except by the arbitrary assumption of its partial similarity to our own.

---

[1] The difference between *clear* and *obscure, distinct* and *indistinct* or *confused* cognitions, is due to Leibnitz. (See his *Meditationes de Cognitione Veritate et Ideis.*)

[2] Mr Morell states positively the view which we have only ventured to hint interrogatively. "While the brute perceives objects, and acts in reference to them only *instinctively*, either for the satisfaction of its appetites, or for self-preservation; a conscious separation is instantly effected by the *human* faculty between the subject and the object. In this separation lies the first distinctive act of *human intelligence*, an act to which there soon succeeds an apprehension of *qualities* in the external object, totally different from any intelligence that can take place in the case of the lower animals. The animal does not think within itself, I am a dog, or a horse, and that is a hare, or a corn-field; it is simply impelled *by the force of instinct* towards the object, without any apprehension of its own personality, as distinct from the thing presented to it. On the other hand, the child or the savage, without the least culture whatever, *consciously* separates self from the objective world in the very first distinct act of *perception*; and it is exactly here, in this very act, that the *intellectual* quality of perception is first manifested." (*Elements of Psychology*, p. 141.)

Human consciousness, then, in the only form in which it can be examined and described, is a compound of various elements, of whose separate action, if it ever existed, we retain no remembrance, and therefore no power of reproducing in thought. It is impossible to have a distinct conception of an act of pure sensation, *i.e.*, of an affection of the organs of sense only, unaccompanied by reflection upon it; for such an affection, though possibly the earliest step in our mental development, could not at that time be recognised as such, nor leave traces that could be recognised afterwards. Our personal consciousness, like the air we breathe, comes to us as a compound; and we can no more be conscious of the actual presence of its several elements than we can inhale an atmosphere of pure azote. Hence it follows, that in distinguishing and describing the several phenomena of consciousness, we must describe them according to their *predominant characteristics as compounds*, not according to their *separate natures as simples*. The phenomena, for example, of sensation, are so called from their prominent feature; the presence, that is to say, of an object affecting in a certain way the organs of sense; though the consciousness of the manner of that affection in each case, and consequently its existence as a distinct phenomenon, depend likewise upon the co-operation of other faculties, which play a necessary though a subordinate part. The neglect of this consideration constitutes the weak point in Condillac's celebrated hypothesis of the statue becoming conscious. He starts with the assumption that the possession of a single organ of sense is sufficient for the discernment of distinct sensations as such, for remembrance and comparison of various sensations, for the preference of one to another, for voluntary efforts to recal them, and for self-consciousness throughout. Whereas, in truth, though the existence of the sensation in a perfect state is identical with the consciousness of that existence, yet we are by no means warranted in assuming that either can be brought into that state by the operation of an isolated organ of sense. With this preliminary caution as to the relation of the several faculties and acts of consciousness to each other—a caution which must be carefully borne in mind throughout—we shall now proceed to examine and describe the various phenomena of consciousness separately, so far, at least, as separation in this case is possible.

OF PRESENTATIVE OR INTUITIVE CONSCIOUSNESS.

The distinctive feature of presentative consciousness consists in the fact, that it is caused by the actual presence of an individual object, whether thing, act, or state of mind, occupying a definite position in time, or in space, or in both. It is true that this object is not discerned as such, and the consciousness of it, therefore, is not fully realized without the co-operation of the representative faculties; and it is true also that representative consciousness, when complete, is exhibited in an individual unity of representation; but as the presence of the individual object is in the one case the principal, in the other only an accessory feature; and as in the one it may be regarded as the cause, in the other as the effect of the accompanying representation, it furnishes a sufficient principle of distinction between the two. We shall therefore class under the general denomination of *Intuitions*, all those states of consciousness in which the actual presence of an object, within or without the mind, is the primary fact which leads to its recognition as such by the subject; and from these will be distinguished, under the name of *Thoughts*, all those states of consciousness in which the presence of the object is the result of a representative act on the part of the subject. In the former case, the presence of the object is involuntary; in the latter it is voluntary. In both the presentative and representative faculties act in combination, for this is the condition of all complete consciousness; but in the former case the object is *given to*, in the latter it is *given by*, the conscious act. For example, while I am in the company of a friend, I have by sight an intuitive consciousness of his presence. I do not cause his presence by any mental effort of my own: it is *given to* me; and so long as my eye is turned towards him, I cannot help seeing him. But if I am thinking of an absent person, and endeavour to recal to mind his features, I make a voluntary effort, and thereby bring into consciousness a mental image which becomes internally now present; but the presentation is one of my own making, constructed by means of the reflective or representative faculty. In adopting the term *presentation* or *intuition*, to express the consciousness of any individual affection of the mind, a writer may be liable to the charge of innovation, in what was at least in the last generation the established language of English philosophy. But in this case necessity has no law. We need a term which shall indifferently express the presence of an individual sight or sound in the eye or ear, and of an individual emotion or volition in the mind; and if none such exists in current use, there is no resource but to coin one. It may be added, that if such a term had been in use in the days of Locke, his writings need not have been liable to the perpetual misunderstanding which arises from his ambiguous use of the term *reflection*. The same apology must serve for the occasional introduction of other philosophical terms, which, though gradually coming into use, are hardly as yet in general circulation.

Presentative consciousness, thus distinguished, appears, like all consciousness, in the form of a relation between the subject or person conscious, and the object, or that of which he is conscious. These two terms are correlative to each other, and imply each other. The subject is a subject to the object, and the object is an object to the subject.[1] The subject can only be conscious by knowing itself to be affected in a particular manner by an object; the object can only be known as affecting the subject in a particular manner. Thus the two are given in relation as mutually determining and determined by each other. We are affected in various manners by various objects presented to us. But these objects again exist for us as objects, only in so far as they are discerned by our faculties of consciousness. The subject and the object are thus only cognisable as existing in and affected by their mutual relation. We cannot be conscious of a pure *ego*, or subject affected in no particular manner; nor yet of a pure *non ego*, or object out of relation to our own cognitive powers. Hence arises a distinction between *phenomena*, or things in consciousness, and *things in themselves*, or things out of consciousness. We know the object only as it stands in relation to our faculties, and is modified by them. We are not sure that, if our faculties were altered, the same things would appear to us in the same form as they do now: we are not sure that they do appear in the same form to all existing intelligent beings; for we know not how far the faculties of other beings resemble our own. But, on the other hand, we have no right to dogmatize on the negative side, and to assume, with equal absence of ground, that things *are not* in themselves as they appear to us. This question, however, belongs to ontology, and will be examined in its proper place. Psychology is concerned with *the phenomena of consciousness as such.* It has nothing to do with the ulterior realities whose existence and nature consciousness perhaps indicates, but certainly does not ascertain.

---

[1] A word in passing on the often used and often misused terms *subjective* and *objective*. All consciousness has a subject and an object; but sometimes the object determines the character of the subject, and sometimes the subject determines the character of the object. In the former case the product is objective, in the latter it is subjective. Thus, a nervous affection dependent on the constitution of my animated organism is subjective; a quality perceived or conceived as existing in the constitution of the object is objective: a code of morality which allows each man to fix his own standard of right and wrong, is subjective; one which requires the opinions of men to conform to a rule independent of themselves, is objective. This explanation, however, applies only to the modern signification of the terms.

Nevertheless, though consciousness exists, and can be conceived to exist, only in the psychological relation of a subject to an object, it is possible in some degree to distinguish between the elements apparently due to each. Not that these can be directly discerned apart from each other; but that in their combination each exhibits certain features which appear to indicate a subjective or an objective origin. If there are in every act of consciousness certain invariable elements, which no change of consciousness can ever obliterate or alter, which no effort of thought can get rid of or conceive as absent, and without which consciousness itself cannot be imagined as possible,—these may be conjectured to owe their existence to the constitution of the subject, which remains one and unchanged in successive acts; while the changeable features which distinguish one mode of consciousness from another, are probably due to the different constitutions of the several things of which the subject is successively conscious.[1] The former may therefore be distinguished as constituting the *form* or subjective ingredient of consciousness; the latter as constituting the *matter* or objective ingredient.

OF THE FORM OF CONSCIOUSNESS IN GENERAL.

The analogy which gives rise to the terms *form* and *matter*, as used to denote the subjective and objective elements of consciousness, is obvious. In a work of art, the *form* is that which is given *by* the artist; the *matter* is that which is given *to* him. The sculptor, for instance, receives the unshaped block of marble, and imparts to it the form of the statue. The conscious mind, in like manner, receives its materials from without, and imparts to them a form by its own act, according to its own laws. The form of consciousness in general consists in *relation to a subject.* Whatever variety of materials, whether for intuition or thought, may exist within reach of my mind, I can become conscious of them only by recognising them as *mine.* By this the several materials are in each case set apart or united, and known as *an object*, of which *I am conscious;* and without such knowledge no act of consciousness is possible. Relation to the conscious self is thus the permanent and universal feature which every state of consciousness, as such, must exhibit; while in every other respect the several states may differ from each other, being distinguished as sensations, volitions, thoughts, &c.; or more particularly, as states of sight or hearing, as virtuous or vicious acts, as conceptions or judgments; or more minutely still, as the sight of a tree or the hearing of music, as an act of benevolence or ingratitude, as the conception of a triangle or the judgment that the angles of a triangle are equal to two right angles. But in all alike there is a necessary relation to one and the same conscious self; the sight is *my* sight, the act is *my* act, the thought is *my* thought. If we further examine the manner in which this universal relation manifests itself in the particular case of presentative consciousness, we shall find two special forms or conditions common to all possible states of external or internal intuition respectively—namely, SPACE and TIME.

OF THE FORMS OF INTUITIVE CONSCIOUSNESS—SPACE AND TIME.

Space is the form or mental condition of our perception of external objects. The phenomena of the material world may vary in an infinite number of ways; but, under every variety, they retain the condition of existing in space, either as being themselves sensibly extended, or as having a local position in the sensitive organism. Without this condition, their existence at all as phenomena is inconceivable. We may suppose the phenomena changed as we will in other respects, but we cannot suppose them to exist out of space. We may suppose any given phenomenon to be non-existent, but the non-existence of space is beyond our power of supposition. Hence space is necessarily regarded as infinite (though not positively conceived as such), for to suppose it finite is to suppose a point at which it ceases to exist. It has thus the characteristics of universality and necessity which appear to mark it out as an *à priori* law or condition of the conscious mind, not as the adventitious result of any special experience. And this conclusion is confirmed by other considerations. For the consciousness of space, though accompanying the perceptions of various senses, cannot be regarded as properly the object of any one of them. There is a visible extension, or apprehension, of space as occupied by light and colour; there is a tangible extension, or consciousness of certain portions of the organism as occupied by tactual impressions; and there is probably a certain consciousness of locality in the exercise of the other senses. But pure space is not identical with any of these; for the blind man may form as positive a notion of it as the seeing man, and one debarred from the sensation accompanying the act of touch would not thereby lose all consciousness of space; and the same argument applies still more clearly to the other senses. Again, the exercise of the locomotive faculty implies a consciousness of space as containing our own body; but the idea of space cannot be said to be derived from locomotion, since the mere volition to move implies a prior consciousness of this relation. Space is thus not by itself an object of sensible intuition, but forms one element of all such objects, being presented in the form of a relation between parts out of each other, and hence being distinctly conceivable only in conjunction with the things related. Pure space has thus one character in common with concepts or general notions, namely, that it cannot by itself be depicted to sense or imagination; but in all other respects it is essentially different from them. A concept is logically as well as chronologically posterior to the individuals which it represents. It implies a prior perception of them, and it has no objective existence but in them. Space is logically, and in some degree chronologically, prior to the objects of sense. It is the condition of their existence as objects, and is itself necessarily conceived as existing independently of any *given* contents.[1] A concept is indifferently representative of many objects. Space is presented to consciousness as one only (for the division of space is purely arbitrary), and thus is not conceived as comprehending individual objects under it, but as containing them in it. Space is thus an element of the sensitive consciousness, presented in itself, not derived from or representative of anything else; and, though always manifested on the occasion of some special experience, it cannot be regarded as the product of experience, nor its notion be constructed from empirical data. It cannot properly be described as an *innate idea*, for no idea is wholly innate; but it is the innate element of the ideas of sense which experience calls into actual consciousness. To describe experience as the cause of the idea of space, would be as inaccurate as to speak of the soil in which it is planted as the cause of the oak; though the planting is the condition which brings into manifestation the latent powers of the acorn. To maintain that the mind contributes nothing to the formation of consciousness, because experience contributes something, is as unreasonable as to assert that the acorn may indifferently become an oak, or an ash, or an elm, according to the soil in which it is planted. Yet such reasoning has often been used to prove that the mind is but the passive recipient of impressions from without.

---

[1] An apparently opposite use of this criterion is made in some of the current theories of philosophy. Thus, in the distinction, which we shall shortly have to notice, between the primary and secondary qualities of body, those attributes of which the cognition is common to the several senses are usually regarded as existing in the bodies themselves; while those which are peculiar to this or that act of sensation are considered as affections of the sentient subject. But in truth the opposition is rather apparent than real. For the secondary qualities, as they are commonly distinguished, depend for their cognition, not on the constitution of the pure mind or subject proper of consciousness, but on that of the nervous organism as animated; and this latter, though in particular acts of sensation it is regarded as pertaining to the subject, yet, in reference to consciousness in general, and to the personal self properly so called, must be regarded as belonging to the object, and, as such, is present or absent in different acts of consciousness. Indeed, the above distinction between form and matter, though not thoroughly carried out in reference to the sensibility till the time of Kant, had, in relation to thought, been long previously an established canon in logic.

In the actual development of human consciousness, the condition of space accompanies every complete exercise of the bodily senses; for in all there is a local relation to a particular organ; and without this relation no kind of sensation can be fully realized as a mode of consciousness. And this is all that it is necessary to observe, so long as we are describing consciousness as it is, not constructing it as it might be. Whether any single organ of sense—smell, for instance, or hearing, supposing it to exist isolated from the rest—would be competent to furnish the empirical conditions under which the consciousness of space is realized, is a question which can only be approximately and conjecturally answered by a special examination of each sense. But such an examination would throw but little light on human consciousness as it actually exists. Consciousness is the result of a human intellect acting in conjunction with a human organization; and if we withdraw or mutilate either element, we produce, not an actual man, but a hypothetical monster. A being endowed, according to the hypothesis of Condillac, with a sense of smell only, and identifying himself with his successive sensations (it would be more correct to say, having no notion of self at all), would not, properly speaking, be in any sense a *conscious being*. He would be deficient in the essential conditions of consciousness, the distinction of subject from object, and of objects from each other. To be conscious of a particular sensation, we must know it as such; and to know it as such implies a concomitant knowledge of other sensations as different, and thus of the bodily organism as extended, or as *occupying space*.

Much of what has been said of space is applicable to time also. This is the condition, not merely of external perception, but of the entire consciousness, external and internal alike. Consciousness in every form implies a permanent and a variable element—a continuous self subject to successive modifications. It is thus necessarily manifested as a *change*, and that change as taking place in time. Pure time, like pure space, is not in itself an object of consciousness, but an element which, to be realized in consciousness, must be combined with the results of experience. We can form no notion of time *per se* with no events taking place in it. Time is thus manifested in the form of a relation of successive modes of consciousness to the one conscious self. It might be conjectured with some plausibility that a being not subject to any change of consciousness, or, on the other hand, one not cognisant of his personal identity in the midst of change, would have no idea of time. But then such a being would have no consciousness at all, in the proper sense of the term. Time, like space, cannot be annihilated by any act of thought, and cannot be conceived as subject to any limitation, as having either beginning or end, or as absent from any mode of consciousness. Indeed, these conditions mutually imply each other; for to conceive a limit of time would be to conceive a consciousness in which time is present, preceded or followed by another from which time is absent. Time has thus, in common with space, the characteristics of universality and necessity, which appear to indicate a subjective condition or law of consciousness itself. Like space, too, it is manifested in conjunction with and on the occasion of experience, being manifested simultaneously with the empirical element of change, the apprehension of which constitutes the first step of positive consciousness.[2]

We are not at present concerned with the question whether space and time have any real existence apart from that of the mind which gives these forms to the objects of its consciousness. This question belongs to ontology, not to psychology. Space and time are known to us as formal conditions of consciousness; whether they are anything more than such conditions, is a question which at present we have no means of answering. The laws of consciousness must be primarily manifested as binding upon the conscious mind. As such, they necessarily accompany every manifestation of consciousness; and in their utmost objective reality they could do no more. But we do not deny the real existence of space and time, though at the present stage of our inquiry we are not able to affirm it. We shall hereafter have occasion to consider whether this question can be answered at all. It is sufficient for the present to say that it cannot be answered by psychology.

OF THE MATTER OF INTUITIVE CONSCIOUSNESS.

The matter of intuitive consciousness cannot be specified with the same exactness as the form; for while in all cognate acts of consciousness the form is one and the same, and therefore admits of a distinct examination apart from the several modes of consciousness into which it enters, the matter is the variable element by which one act of consciousness differs from another, and which, therefore, can only be fully analysed by a separate examination of each individual case. The various phenomena of the matter of consciousness, however, admit of being classified and partially described under certain general heads; and such a classification has accordingly been attempted in the distinctions, which form the substance of most psychological treatises, between the various states, operations, and faculties of the human mind.

The matter of intuitive consciousness, in its widest sense, denotes all that comes to the mind from without,—all, in short, that is due to this or that special *experience*. Of experience there are two principal sources: 1. *Sensation*, or *external intuition*, by which we become cognisant of the phenomena connected with our material organization; and, 2. *Internal intuition* (called by Locke *reflection*),[3] by which we become cognisant of the several successive states of our own minds. To the former we owe the materials of our knowledge of what takes place without us; from the latter, in like manner, is derived our knowledge of what takes place within us. The subdivisions of these two constitute the several states and operations of the human mind.

---

[1] Space, though not positively conceived as devoid of all contents, is yet necessarily conceived as separable from any given contents, and thus as independent of each in succession.

[2] The apparent paradox, on the one hand, that consciousness must have had a beginning in time, and, on the other, that consciousness is only possible under the form of a change of state, will be further explained in the sequel.

[3] There is an ambiguity in Locke's use of the term *reflection*, which has given rise to considerable misunderstanding. Etymologically, the term should denote a *turning back* of the mind upon an object previously existing, so that the existence of a state of consciousness is

OF SENSATION AND PERCEPTION.

Sensation, in its most general acceptation, is sometimes used to signify the whole of that portion of consciousness which comes to us by means of the bodily organs of sense. *Perception*, too, has been used by various writers in a wider or a narrower sense—sometimes as synonymous with consciousness in general, sometimes as limited to the apprehensions of sense alone.[1] Under the latter limitation it has been found convenient to make a further restriction, and to distinguish between *sensation proper* and *perception proper*.

Sensation proper is the consciousness of certain affections of our body as an animated organism.

Perception proper is the consciousness of the existence of our body as a material organism, and therefore as extended.

The sensitive organism may be considered in two points of view:—1. As belonging to the *ego*, or conscious subject, which, in its actual concrete existence, is susceptible of consciousness only in and by its relation to a bodily organism. 2. As belonging to the *non ego*, or material object of consciousness, from which the mind, as an abstract immaterial being, is logically separable; though, in actual consciousness, the two are always united. The bodily organism is thus the debatable land between self and not-self. In one sense, my eye is a part of my conscious self; for sight is an act of consciousness, and sight cannot exist except by means of the eye. In another sense, my eye is not a part of myself; for a man whose eyes are put out continues to be the same person as before. Hence the organism, as the vehicle of sensation, exhibits in the same act attributes of mind and attributes of body. In the former point of view, the act of sensitive consciousness is regarded as a *sensation*; in the latter, as a *perception*.

Perception is sometimes defined as "the knowledge we obtain, by means of our sensations, of the qualities of matter."[2] This definition may be admitted, if *matter* is understood as comprehending our own bodily organism, as well as the extra-organic objects to which it is related. The former is the only kind of matter that is *immediately* cognisable by the senses. The existence of a material world, distinct from, though related to, our organism, is made known to us, not by the senses themselves, but, as will be noticed hereafter, by the *faculty of locomotion*. Sensation and perception, as above explained, are always correlative to each other; every sensation being accompanied by a consciousness of the extension of the sensitive organism, and this consciousness being a perception. But, though always coexistent, they are not proportionally coexistent. On the contrary, the sensation, when it rises above a certain low degree of intensity, interferes with the perception of its relations, by concentrating the consciousness on its absolute affection alone. Hence Sir William Hamilton, from whom the above remark is taken, has enunciated the important rule, *that, above a certain point, the stronger the sensation, the weaker the perception; and the distincter the perception, the less obtrusive the sensation.* In other words, *though perception proper and sensation proper exist only as they coexist, in the degree or intensity of their existence, they are always found in an inverse ratio to each other.*[3]

OF THE FIVE SENSES.

Sensation and perception, according to the above law, coexist, though in an inverse ratio to each other, in each of the five senses. But in addition to the relation which each bears to the other, when viewed with reference to the same sense, they are also found to be combined in different proportions when one sense is compared with another. In some the sensation so far predominates over the perception, that the sense manifests itself as a source of feeling rather than of knowledge, and has often, though erroneously, been regarded as consisting of the former element only. In others the reverse is the case; the perceptive element, or cognition of an object, predominating over the sensitive element, or consciousness of a personal affection. In this point of view, the senses of smell and taste may be distinguished as especially subjective or sensational; those of hearing and sight as objective or perceptional. Touch, inasmuch as it has no special organ, but is diffused in various degrees over the various parts of the body, will require a separate consideration. In other words, smell and taste are chiefly known as vehicles of the mental emotions of pleasure and pain; hearing and sight, as informing us of the nature of the bodily attributes of sound and colour. Touch may contribute to the one or the other end, according to the part of the body in which it resides, and the manner in which it is brought into exercise.[4]

Of Smell.

In smell, as in the other senses, it is necessary to distinguish between the sensation itself, and its object, which, in ordinary language, are not unfrequently confounded together. Thus we speak of the organ of *smell*, and of the *smell* of a rose, using the same term indifferently to signify the act of inhaling an odour and the odour inhaled. The act of smell, apart from the physiological inquiries connected with it, requires no description, being familiar to every one from his own experience. It will be sufficient for our present purpose to distinguish the sensation from the accompanying perception; and this will be best accomplished by an examination of the object.

The true object of smell is to be found in the odorous particles in contact with the organ. It is incorrect to say that we *smell a rose*, meaning by *a rose* the flower as seen or touched. We smell only the effluvia emanating from the rose and coming in contact with the nervous organism. What these effluvia or odorous emanations are in them-

---

distinct from the reflection on that state. In this sense, a sensation, like any other mode of consciousness, may be an object of reflection; and those philosophers who understood Locke in this sense were only consistent in reducing his two sources of ideas to the single one of sensation alone. But, in the greater part of Locke's essay, reflection is treated of in a different sense, namely, as the immediate consciousness of our internal states of mind—a consciousness identical with the existence of those states, and thus forming an original source of ideas.

[1] Thus Locke enumerates sensation and reflection as the two sources of our ideas, meaning by *sensation* what, in the language of Reid, would be sensation and perception together. In this he is followed by Condillac. The distinction between sensation proper and perception proper originated with Reid; but its most accurate development is due to his editor, Sir William Hamilton. From the notes of the latter, the greater part of the remarks in the text have been taken.

[2] Stewart, *Outlines of Moral Philosophy*, sect. 15.

[3] *Reid's Works*, p. 880. The same rule had been in substance previously given by Kant, *Anthropologie*, sect. 20.

[4] This remark of course applies only to the senses as they exist in the human subject. A similar general rule, indeed, probably holds good with regard to the lower animals; but it is differently manifested in the several senses. Of the senses of taste and smell it has been observed by Sir W. Hamilton, that "precisely as in animals these latter senses gain in their objective character as means of knowledge, do they lose in their subjective character as sources of pleasurable or painful sensations. To a dog, for instance, in whom the sense of smell is so acute, all odours seem in themselves to be indifferent." (*Reid's Works*, p. 863.) Compare Kant, *Anthropologie*, sect. 15, whose distinction slightly varies from that given in the text.

selves, natural philosophy is unable to determine. "Although it may be surmised," says Dr Carpenter, "that they consist of particles of extreme minuteness, dissolved as it were in the air, and although this idea seems to derive confirmation from the fact that most odorous substances are volatile, and *vice versa*, yet the most delicate experiments have failed to discover any diminution in weight, in certain substances (as musk) that have been impregnating with their effluvia a large quantity of air for several years; and there are some volatile fluids, such as water, which are entirely inodorous."[1] But whatever these odorous particles may be, it is important to remember that they, and not the bodies from which they proceed, are the proper objects of smell; and, consequently, that this sensation (and the same may be said of all the others) is in fact a modification of touch. Hence it is incorrect to speak, as Aristotle and many subsequent writers have spoken, of the object of smell as perceived through a medium, such as the atmosphere. The atmosphere is not the medium of communication between the sensitive organ and its object, but only the vehicle by which the object is brought into contact with the organ.

Smell conveys to us no knowledge of the existence of extra-organic matter. The only matter of which we are directly conscious in this, as in other actions of sense, is our own organism as extended; and this consciousness constitutes the *perception* of smell, as the consciousness of the same organism as affected constitutes the *sensation*. In the remarks upon the consciousness of space as the form of all sensitive intuition, enough has been said to explain in what sense the consciousness of locality and extension form part of the energy of smell as it actually exists, and to show that the lowest degree of intelligence that is sufficient for sensation proper is sufficient for perception also. But the object perceived is not a quality of body as such, but only the proper action, or rather passion, of our nervous organism; an action or passion of which the external cause is, so far as perception is concerned, wholly unknown, and which may even be excited in a similar manner by totally different causes. This is not so evident in the case of smell as in some others of the senses; yet it is a known fact in physiology that the sensation of smell may be produced in the olfactory nerve by electrical action without the presence of any odorous body. This fact is sufficient to show that the operation of a sense by itself does not afford any legitimate grounds for determining the qualities, or even the existence, of an extra-organic world. On this subject we shall have more to say when we come to treat of the distinction between the primary and secondary qualities of body.

Of Taste.

The principal characteristics of the sense of smell are common to that of taste also. The two senses resemble each other in being both powerful as instruments of feeling, and proportionally weak as sources of information. Tastes, like smells, admit of hardly any classification, except in respect of their relation to the sensitive organism as pleasant or painful. Like smell, too, the sensation appears to be produced by means of sapid particles emitted from the body, and brought into contact with the nerves; and these particles, which constitute the object of the sense of taste, are in their own nature as little known as those of smell, and can as little be regarded as bearing any resemblance to the sensations which they excite. Taste, like smell, is thus a modification of touch; the object in contact with the organ being the sapid particles, and not, as might at first be supposed, the body from which those particles proceed. The body is in contact, not with the nerves, but only with their exterior covering; and in order to produce the distinctive sensation of taste, it appears to be necessary that the sapid particles should be dissolved in the saliva, and thus penetrate through the investments of the papillæ into their substance.[2] But, not to enter here on questions more properly belonging to physiology, it will be sufficient for our present purpose to observe, that taste, like smell, conveys no knowledge of the existence of extra-organic matter, and that the sensation, properly so called, consists in the consciousness of the organism as affected in a particular manner, agreeable or disagreeable; while the perception is to be found in the corresponding consciousness of the locality of the affection in the organism as extended. Though these two are always to a certain extent co-existent, yet the former predominates so far over the latter as to form the principal characteristics of this class of sensations. For this reason, the organs of taste and smell are distinguished as being pre-eminently the sources of *sensation* in the strict sense of the term.[3]

Of Hearing.

In hearing, the functions of sensation and perception are perhaps more nearly balanced than in any other of the senses. The subjective character of various sounds, as sources of pleasure or pain to the hearer, may be contrasted with their objective character, as resembling or differing from each other; and as in the latter relation this sense affords more accurate distinctions than those of taste and smell, so in the former the sensation is less capable of being carried to an extreme degree of pleasure or pain.[4] Hearing, therefore, though contributing in different degrees both to enjoyment and to information, may be characterized as a source of the latter rather than of the former; and if, according to the rule already mentioned, the sensation and the perception are in an inverse ratio to each other, it will follow, that in proportion as our attention is more directed to the discrimination of various sounds from each other, we are less immediately conscious of the pleasure or pain which they are capable of communicating. In hearing, as in the senses previously described, we are directly cognisant, not of the sonorous body, but of the change in the condition of the auditory nerve produced by contact with a medium by which the vibrations are transmitted (the fluid inclosed in the labyrinth of the ear), and hence hearing, like the other senses, is a modification of touch, and does not directly inform us of the existence of any other material object than our own nervous organism. Hence it follows, that neither the *distance* nor the *direction* from which a sound proceeds is immediately perceived by the ear; and this conclusion is confirmed by the facts connected with the exercise of this sense in its uneducated condition, as by children, and occasionally also by adults. The child does not appear to be conscious at first of the direction or distance of voices that attract his attention; and a remarkable instance of the same kind in a grown person is mentioned by Dr Reid. "I remember," he says, "that once lying a-bed, and having been put into a fright, I heard my own heart beat; but I took it to be one knocking at the door, and arose and opened the door more than once, before I discovered that the sound was in my own breast." . . . . "It is probable," he continues, "that, previous to all experience, we should as little know whether a sound came from the right or left, from above or below, from a great or a small distance, as we should know whether it was the sound of a drum, or a bell, or a cart?"[1] In this respect, the sense of hearing presents a remarkable analogy to that of sight; and this property of both will be considered when we come to treat of acquired perceptions.

---

[2] Carpenter's *Principles of Human Physiology*, p. 900.

[3] Kant, *Anthropologie*, sect. 15; Tissot, *Anthropologie*, vol. i., p. 37.

[4] A lover of music might perhaps demur to the conclusion that the pleasures of hearing are less intense than those of taste or smell. In explanation, it should be remembered that we are speaking only of the pleasure conveyed by the sensation itself. The pleasure derived from music is mainly intellectual, and is chiefly derived, not from the sound heard in any one sensation, but from the cognition of its relation to others, which are not heard but remembered; or from associations which may be suggested by, but are not actually contained in, the sound as heard. In short, the natural sensation, which is common to all mankind, must be distinguished from the acquired sensation which is in a great degree the result of education.

Of Sight.

Sight is of all the senses the most communicative as a vehicle of information, and consequently the one in which there is the least immediate consciousness of pleasure or pain in the exercise. Most of the knowledge, however, which this sense, in its matured state, conveys to us, belongs to its acquired, not to its original power, and is the result, not of a direct perception, but of an inference from a perception. In sight, as in the other senses, the direct perception is produced by contact; and the proper object of this sense is not the distant body from which the rays of light are emitted or reflected, but the affection of the organ of sight (the retina and the nervous system connected with it) produced by the rays impinging upon it. The essential characteristics of this affection are *brightness* and *colour*, which, however, are necessarily accompanied by a consciousness of *extension;* for a luminous point, however small, must itself occupy some portion of space, and can be perceived only as in contrast to a surrounding expanse of obscure or differently coloured surface.[2] The immediate object of sight being in contact with the extremities of the optic nerve of the person seeing, it is as impossible for two persons simultaneously to see the same object with their eyes, as to touch the same spot with their fingers; and every movement of the eye which brings a different portion of rays into contact with the organ, produces a different object of vision.[3] The object of vision being thus neither the rays alone nor the organ alone, but the organ as affected by the rays; and the sensation of colour being a purely organic affection, it follows that sight, like the other senses, gives us no immediate knowledge of an extra-organic world; though it is immediately cognisant of extension, and therefore of matter, as presented in the organism itself. Hence we have no immediate perception by sight of the *figure*, the *size*, or the *distance* of bodies; and we cannot in strict accuracy be said to *see* a distant body, such as the sun, at all; though in practice the direct perception becomes so intimately united with the indirect inference, that it is difficult to imagine that either can exist apart from the other. Admitting this view of the true object of sight, which may be regarded as established by physiological as well as psychological testimony,[4] we may notice some remarkable contrasts between the *presented object*, or that which we actually see, and the *represented object*, or that which we appear to see. The presented object is on the surface of the retina; the represented object appears without, and at a greater or less distance from the eye. The presented object is of such a size as can be contained within the spectator's visual organism; the represented object may be many times larger than his whole body. The presented object is a flat surface; the represented object is a solid body. The presented object is inverted; the represented object is erect. The presented object is double, there being a distinct image on the retina of each eye; the represented object is generally single, the two images being in normal vision united into one body. These and other apparent anomalies in the exercise of the senses will be discussed under the head of *acquired perceptions.*

Of Touch and Feeling.

Touch is regarded by many writers as the most objective and the most trustworthy of all our faculties. It has been described as the source of our knowledge of the existence of an external world, and of the real magnitudes, figures, and distances of objects; as the instructor of the other senses, and the corrector of their aberrations. It appears certain, however, that the sense of touch in itself is equally limited in its sphere with the rest of the senses, and that it can convey no other proper perception than that of the existence of its own organism as extended. The sensations of touch, considered by themselves, present no characteristics which can distinguish them from those of the other senses, as regards an immediate cognisance of the external world. Like smell, or sound, or light, they are affections of the nervous system, which may be produced by internal as well as external causes, and which directly indicate no other existence than that of the organized sentient being.[5] The fact is, that in the examination of this faculty, philosophers have often made a two-fold confusion between things in themselves distinct. In the first place, the sense of touch proper, in which the sentient subject is as passive as in any other state of sensation, is confounded with the faculty of locomotion, which originates in a voluntary act of the same subject. In the second place, the sense of touch having no special organ, but being common to all parts of the surface of the body, it has sometimes happened that perceptions have been assumed to be invariable and absolute, which, in truth, are relative to one part only of the organism, and assume a different character in relation to other parts. To mention only one eminent instance out of many, both these confusions occur in Bishop Berkeley's *Essay towards a New Theory of Vision.* That illustrious philosopher distinguishes between two kinds of magnitude, —the one tangible, which is perceived and measured by touch; the other visible, by the mediation of which the former is brought into view. The tangible magnitude he considers to be fixed and invariable, while the visible magnitude changes as we approach to or recede from the object. Hence he concludes that tangible and not visible figures are the objects of geometrical reasoning; the latter having no other use than words have, namely, as signs to suggest the former. Now, in the first place, it is obvious that mere touch, without the power of locomotion, can inform us of no other magnitude than that which corresponds to the touching organ. In point of fact, it informs us only of the extension of the organ itself; but under no possible hypothesis could it inform us of more than the magnitude of that part of a body with which we are actually in contact. In the second place, it has been proved by experiment that the same object will appear of different magnitudes when in contact with different parts of the human body, and consequently that the sense of touch, regarded by itself, is not only variable, but even self-contradictory in its testimony. Hence it follows that the sense of touch alone has no pre-eminence over the other senses as a criterion of truth in relation to a material world beyond our own organism; in fact, like the other senses, it is silent as to the existence of such a world. Touch, however, differs in some remarkable particulars from the other senses. There is no distinct organ appropriated to the tactual sensations alone; and the various parts of the body by which these may be communicated may also be the instruments of other classes of sensations, all of which have been confounded under the general name of "touch" or "feeling." The object of touch proper has no special name, like *sound, colour*, or *smell;* but in itself it is familiar to every one who has experienced the state of consciousness which results from the contact of his own body with another, when not sufficiently violent to rise into a positive sense of pleasure or pain. In this state there is a two-fold consciousness; that part of the bodily organism being known at the same time as *affected* and as *extended.* The former constitutes the *sensation*, the latter the *perception;* and in proportion as the former rises to a higher consciousness of pleasure or pain, the latter grows feebler, though never becoming wholly extinct. This double state, which has no appropriate name, may perhaps be distinguished in its twofold character by the name of *Tactual Impression.* In addition to this may be mentioned other modes of feeling communicated, partly at least, through the same organs, such as those of heat and cold, which have sometimes been regarded as the proper objects of the sense of touch, and the various kinds of pain and pleasure produced by external applications. It will be sufficient for our present purpose to notice, that all of them belong to the class commonly known as *secondary qualities of body;* that is to say, affections of the different parts of the nervous organism, which, as apprehended, have no resemblance to any property of inorganic matter, though generally caused by some unknown power by which that matter is capable of affecting our organs.

[5] See Destutt Tracy, *Elémens d'Idéologie*, p. i., chap. 7; or his follower, Brown, Lecture xxii. Both these authors, however, are wrong in denying an immediate tactual perception of our own organism, though right as regards an extra-organic world.

General Remarks on the Five Senses.

The psychological characteristics of the five senses in general, omitting those which properly belong to physiological inquiries, may be summed up as follows:—The proper function of each and all of them is a *sensation*, or affection of the nervous organism as *animated;* which affection, however, does not, and in all probability cannot, exist in consciousness without an accompanying intellectual cognition of the same organism as *extended* or *occupying space.* This cognition (the *perception* proper) is referred to the intellect rather than to the sense, chiefly for two reasons: Firstly, because it is not, like the sensation proper, limited in each case to a single form of sensibility, but appears as the common condition of consciousness in all. Secondly, because it is not in any case the consciousness of a single object as such, but of a relation either between the parts of the sensible object, viewed as out of each other, or between that object as a whole and the concomitant conditions under which it is presented to the sense. Thus, for example, the rays of light in contact with the retina may be perceived either as forming a visible surface, whose parts are related to each other, or as a luminous spot related to the surrounding obscurity; and even a smell or a sound, whether themselves perceived as extended or not, are at all events discerned in and by their relation to different parts of an extended organism.[1] The sensation and the perception are thus each the necessary condition of the other; and the union of the two is requisite to constitute a state of consciousness. But consciousness is not complete, even when these two elements are united. The consciousness of any mental state (whether of sensation or otherwise) never does, and probably never can take place, without the accompanying consciousness that something else preceded it. This *something* need not be distinctly known as a former state of consciousness (which would make a beginning of consciousness impossible), just as the space to which the object of perception is related need not be distinctly discerned as containing other objects; but every act of consciousness as such is accompanied by the conviction, indefinite it may be, of something having gone before, just as a coloured spot in sight is perceived as having something surrounding it.[2] In other words, every act of consciousness, as such, is presented as a *change in the state of our existence*, not as the beginning of that existence, and thus implies the continuous existence of a permanent self, presented in and through the several modes of consciousness, but not identified with any. We can have no knowledge of an abstract self apart from its successive states of consciousness, nor yet of any one of those states, save as a mode of the existence of one and the same indivisible self. The sensitive consciousness is thus revealed to us as composed of three elements; a permanent self, having a sensitive organism extended in space, and with successive affections of that organism taking place in time. None of these elements, apart from the rest, can be presented or represented in consciousness; and the distinction between sense and intelligence is thus verbal only, not real, constituting, like the concave and convex circumference of a circle, different sides of the same consciousness, but incapable in any act of thought of being considered apart from each other. In the words of Sir William Hamilton,—"It is manifestly impossible to discriminate with any rigour sense from intelligence. Sensitive apprehension is in truth only the recognition by intelligence of the phenomena presented in or through its organs.[3]

The *proper sensibles*—smell, taste, sound, colour, and tactual sensation—all belong to the class commonly called secondary qualities of body, which are in reality affections of the nervous organism, which have no resemblance to any attribute of inorganic bodies. It is true that, in their normal state, they are excited by the presence of such bodies; but that in themselves, as apprehended, they are states of the nervous organism, and not qualities of other bodies, is evident from the fact that they may be abnormally called into existence by any circumstance which produces the appropriate nervous action, even when the ordinary bodily correlative is not present. In fact, as Professor Müller has observed, "*external agencies can give rise to no kind of sensation which cannot also be produced by internal causes, exciting changes in the condition of our nerves.*"[1] Such is the case in the well-known phenomena of dreams, of spectral illusions, of ringing in the ears, of bitterness in the mouth, &c., to which may be added the several artificial means by which various sensations may be produced—light and colours by pressure on the optic nerves, ringing by a blow on the ear, and the sensations of all the senses by electricity.[2] Similar though less striking evidence to the same point is furnished by the familiar instances of the sensation remaining in the organism when the body is withdrawn, or the communication intercepted. Thus a luminous body, passing rapidly backwards and forwards before the eye, appears as a continuous line of light; a rapid succession of sounds will produce a continuous tone; the spectrum of a bright object may be distinctly seen after the eyes are shut, &c. It is manifest, therefore, that the senses cannot in any case furnish direct evidence of the existence or properties of an extra-organic world; for, even if we are compelled by a law of our constitution to suppose the existence of an external cause of our internal states, such a supposition is representative, not presentative,—suggested by, not contained in, the sensation; it gives us no knowledge of the nature of the cause which it suggests, and in some instances, as has been shown, is deceptive even in suggesting its existence.

---

[1] Notwithstanding the general opinion of philosophers to the contrary, I am inclined to think that some consciousness of extension is simultaneous with the earliest exercise of sensation. Of course I do not mean that this consciousness is distinct, and can be at that time separated by analysis from its concomitants; but this is equally the case with all the characteristics of sensation. I only mean that the element of locality is there from the beginning, at least as distinctly as anything else, and that it could be detected if the sensation in its original state could be reproduced in a mind sufficiently developed to be capable of analyzing it. In this respect it differs from the acquired perceptions properly so called, such as externality, distance, magnitude, &c., which may be chronologically as well as logically separated from the original sensation. So long as sensations are spoken of as affections of mind only, there is plausible ground for the opposite opinion; not so, however, when they are viewed in their true character, as affections, neither of mind alone nor of matter alone, but of an animated organism, *i.e.*, of mind and matter together. Professor Müller allows that there is a perception of the extension of the organism in sight, touch, taste, and even smell, though slightly, if at all, in hearing. It may be conjectured, however, that the compound action of the two ears in hearing will naturally give rise to some perception of extension, though this may become obliterated in acquired perception, from the attention being withdrawn from it to other sources of information. (See Baly's translation of Müller's *Elements of Physiology*, p. 1073, 1075, 1086.)

[2] Puisque réveillé de l'étourdissement on s'apperçoit de ses perceptions, il faut bien qu'on en ait eu immédiatement auparavant, quoiqu'on ne s'en soit point apperçu; car une perception ne sauroit venir naturellement, que d'une autre perception, comme un mouvement ne peut venir naturellement que d'un mouvement." (Leibnitz, *Monadologie*, sect. 23.) This position, which Leibnitz maintained on metaphysical and psychological grounds, is confirmed by the researches of physiology, which tend to show that consciousness has a physical as well as an intellectual growth; that impressions may be made on the organism which may leave perceptible traces in the subsequent development of consciousness, without having been themselves present to consciousness at all. (See Carpenter's *Human Physiology*, p. 818.) This may, perhaps, help to explain the apparent paradox, on the one hand, that consciousness must have had a beginning in time, and, on the other, that an absolutely first act of consciousness is inconceivable. Thus time is the universal form of consciousness as such.

[3] *Reid's Works*, p. 878.

What, then, it may be asked, is the nature of our sensations as thus described? Are they affections of mind, or of body, or of both? On the one hand, consciousness in all its modes seems manifestly to be a state of mind. On the other hand, sensitive consciousness appears with the concomitant condition of extension, which is an attribute of body. The general voice of modern philosophers has pronounced that sensations, as such, belong to mind, and not to body. This is asserted both by those who admit and by those who deny the existence of perceptible primary qualities of body in addition to the mental sensation.[3] And rightly, so long as by *body* is meant something distinct from our own organism; but wrongly, or at least inaccurately in language, so long as no distinction is made between body as brute matter and body as part of a sentient being. A dead body, though its eyes are open, has no sensation of colour: so far, sight is an affection of mind rather than of body. But a living man, if his eyes are put out, is equally deprived of the sensation: so far it appears to belong to body rather than to mind; for mind in its purest sense,—the abstract, immaterial, personal *ego*,—cannot be conceived as destroyed, or even as in any way diminished, by the deprivation of a bodily organ. But the above inaccuracy of language assumes more than a verbal importance, when it is made, as is sometimes the case, the foundation of theories of perception, as though the distinction which it indicates were strictly, not merely approximately, true. Thus it is argued that we can have no immediate perception of extension in space, "because it is not explained how the mind, which *alone* can have sensation or knowledge, and which certainly is not square itself, is to be made acquainted with the squareness of its own corporeal organ, or of the foreign body."[4] The whole force of the reasoning, and, at the same time, its whole fallacy, lies in the word *alone*. Mind is not *alone* capable of sensation; for it is sentient only in so far as it animates a bodily organism. That a disembodied spirit has consciousness we must indeed believe; at least it is impossible to conceive how spiritual existence can be otherwise manifested; but, at the same time, it is impossible to conceive such consciousness as at all resembling our own, at any rate in the particular phenomena which are conveyed by means of the senses. Sensation, then, is not an affection of mind alone, nor of matter alone, but of an animated organism, *i.e.*, of mind and matter united.[5] How this union is effected; whether the soul as a substance is one or many; whether it has or has not a local habitation; whether, in short, we have any knowledge at all of a pure immaterial being, apart from its modes of consciousness when embodied;—these and similar questions belong to the ontological branch of metaphysics. At present we are concerned only with the phenomena of sensation, and with the soul as the subject of those phenomena in and through its connection with the body. In this respect the soul cannot be assigned to any peculiar bodily organ as its seat, but, as manifesting its existence in sensation, must be regarded as present in all the sensitive organs alike.[6]

To the above account of sensation and perception an obvious objection presents itself, which it is necessary to consider before proceeding further. "The perception as it ought to be," it may be urged, "is very different from the perception as it is. We are told that we only perceive our own organism; we are conscious of actually perceiving things external to our organism. We do not see the image on the retina; we see the object at a distance from the eye. Even in hearing and smell, the object of which we are actually conscious is not presented as an affection of the nerves, but as situated in and proceeding from a distant body." The answer to this objection is to be found in the fact, that in the actual exercise of our senses, in their matured state, we never perform a pure act of perception, but one of perception united with something else. It is as certain as any fact of science can be, that the perception of distance is not originally conveyed by the eye, but is an inference of the understanding derived from certain concomitant visible phenomena, principally from the degree of distinctness of the colour and outline of the object. Yet of this inference we are never conscious in the exercise of our matured senses, but appear to see the distance of objects as immediately as their colour. The most ordinary judgments apparently derived from sense are instances of the same kind. When I say, "I see a horse," in reality I see nothing of the kind. Even granting for the moment that the external object is *seen*, it can be seen only as a coloured body of a certain figure. That the coloured body before me is a horse is not a perception of the sight, but a judgment of the understanding; a judgment which implies acts of memory, of comparison, of conception, &c. Yet we are not conscious of the data from which we make the inference, but refer the entire result to the act of sight alone. These instances sufficiently show the necessity of distinguishing between *original* and *acquired* perceptions; for which purpose we must first consider the operations of that faculty to which our intuitions of external objects as such properly belong.

[2] See Müller's *Elements of Physiology*, p. 1064; Carpenter's *Principles of Human Physiology*, p. 888; Abercrombie's *Intellectual Powers*, p. 61.

[3] See Descartes, *Principia*, iv. 197; Malebranche, *Recherche*, l. i., ch. x. *sqq.*; Locke, *Essay*, b. ii., ch. 8; Condillac, *Traité des Sensations*, p. iv., ch. 5; Berkeley, *Principles of Human Knowledge*, i. 3; Reid, *Inquiry*, ch. vi., sect. 4, 5, 6; Stewart, *Essays*, ii., chap. ii., sect. 2; Brown, *Lectures*, xxii. Leibnitz speaks more guardedly on this question,—"Il est vrai que la douleur ne ressemble pas aux mouvemens d'une épingle, mais elle peut ressembler fort bien aux mouvemens que cette épingle cause dans notre corps, et representer ces mouvemens dans l'ame, comme je ne doute nullement qu'elle ne fasse." (*Nouveaux Essais*, l. ii., ch. 8.)

[4] Brown, *Lectures*, xxii.

[5] In this respect the language of Aristotle is more accurate than that of the majority of modern philosophers,—Ἐπεὶ δ' οὔτε τῆς ψυχῆς ἴδιον τὸ αἰσθάνεσθαι οὔτε τοῦ σώματος (οὗ γὰρ ἡ δύναμις, τούτου καὶ ἡ ἐνέργεια· ἡ δὲ λεγομένη αἴσθησις, ὡς ἐνέργεια, κίνησίς τις διὰ τοῦ σώματος τῆς ψυχῆς ἐστί) φανερὸν ὡς οὔτε τῆς ψυχῆς τὸ παθος ἴδιον, οὔτ' ἄψυχον σῶμα δυνατὸν αἰσθάνεσθαι. (*De Somno*, chap. 1, sect. 5.)

[6] See Müller's *Elements of Physiology*, p. 1335. In the above remarks, and throughout this article, no notice has been taken of the different functions of the nerves and the sensorium in sensation. This question is confessedly one of the most difficult in physiology, and, in its proper place in that science, one of the most important. But in reference to the present remarks, this question is of little consequence. The visible image, or other sensible impression, is not itself transmitted to the sensorium; and the irritation of the interior nervous system can only serve to arouse the attention to the affection localized at the surface. The notion of a *seat of the soul*, in the literal sense of the term, is utterly meaningless to any but a materialist; and all that the minutest anatomy can hope to discover is the material *occasion* which acts as the immediate stimulant to consciousness. But the consciousness, once aroused, is as capable of acting in one part of the system as in another, and is, in fact, *present* wherever it acts. This is expressed with philosophical accuracy in the words of St Augustine:—"Ideo simplicior est corpore, quia non mole diffunditur per spatium loci, sed in unoquoque corpore, et in toto tota est, et in qualibet ejus parte tota est." (*De Trinitate*, vi. 6.)

OF THE LOCOMOTIVE FACULTY.

The locomotive faculty, which we have next to consider, differs from the senses, both in other respects, and especially in the circumstance that in its exercise, and partly also in its results, it is dependent upon the will of the person exercising it. By this it is not meant that the will is in all cases consciously exercised; that all motion is the result of a knowledge of two alternatives, and a deliberate preference of one of them. This is not always the case in the most undeniably voluntary acts performed in the maturity of our faculties. A man in the midst of a walk, when engaged in conversation or thought, is not distinctly conscious of each successive movement of his limbs; yet there can be no doubt that the acts are his own, as much as when he is attending to and conscious of the exertion, and that, in either case, it depends on himself to continue or discontinue the motion. How far the will itself is free or determined by antecedent causes, is a question which cannot be considered here; but, whatever theory we may adopt upon this point, as regards the actions of men or of brutes, there is an obvious difference between saying, "You may bring a horse to the water, but you cannot make him drink;" and saying, "You may fire a cannon in his ear, but you cannot make him hear," or "You may lay on the whip, but you cannot make him feel." This difference, whatever amount of liberty it may imply, is all that is insisted upon in distinguishing between the exercise of the locomotive faculty and that of the senses.

It is the locomotive faculty which first informs us immediately of the existence and properties of a material world exterior to our organism. This exterior world manifests itself in the form of *something resisting our volition;* and to this general head of *resistance* may be reduced the whole of those attributes which exterior bodies immediately exhibit in their relation to our organism; namely, gravity, cohesion, repulsion, and inertia. This consciousness of our locomotive energy being resisted by something external, though in practice accompanied by the sensation of touch, is so far distinct from that sensation that either may be conceived as taking place without the other. The sensation of touch is a consciousness of an irritation of the nerves spread over the surface of the skin; a consciousness which experience may teach us to connect with a pressure from without, but which may be, and sometimes is, also communicated from within, and which has no immediate relation to the will of the sentient person. The consciousness of resistance, on the other hand, implies a volition to move the limb, and this volition may be conceived as impeded externally without any accompanying organic feeling. The various qualities of the body, moreover, are manifested in proportion to the amount of volition exercised. A slight effort makes known to us the existence of a resisting body: a stronger or more continued effort is followed by a consciousness of a more vigorous resistance, or of a yielding on the part of the opposing body, either wholly or in a certain direction. Hence we obtain a knowledge of the attributes of hardness or softness, of mobility or immobility All these are different manifestations of a relation between self and not-self; between an organized body acted upon by the will, and a foreign body in antagonism to it. This consciousness of resistance to our voluntary motion is something very different from that of a mere inability to move, such as may take place when a stroke of paralysis destroys the power of the will over the bodily motions. We have in it, not the mere negative consciousness of will not followed by motion, but the positive consciousness of will followed by motion, and that motion resisted from without. In this relation both elements are equally *presented*, and one of them is the external body.

The manner in which the locomotive energy may be supposed originally to exert itself, and the foundation which by such exertion would be laid for the education of the sensitive consciousness, even before the latter is called into actual existence, has been graphically described by Professor Müller, in language which I will not attempt to weaken by alteration; though I may remark, in quoting it, that that eminent physiologist has hardly marked with sufficient accuracy the distinction between the sense of resistance and that of touch properly so called; and consequently has made some confusion between the objective and subjective, the presentative and the representative consciousness. "If we imagine a human being, in which—as in the fœtus in utero, for example—the sense of vision has never received any impressions, and in which sensations of touch merely have been excited by impressions made upon its body from without, it is evident that the first obscure idea excited would be no other than that of a sentient passive *self*, in contradistinction to something acting upon it.[1] The uterus, which compels the child to assume a determined position, and gives rise to sensations in it, is also the means of exciting in the sensorium of the child the consciousness of something thus distinct from itself and external to it. But how is the idea of two *exteriors*,—of that which the limbs of the child's body form in relation to its internal self and of the true exterior world,—developed? In a twofold manner: In the first place, the child governs the movement of its limbs, and thus perceives that they are instruments subject to the use and government of its internal *self;* while the resistance which it meets with around is not subject to its will, and therefore gives it the idea of an absolute exterior. Secondly, The child will perceive a difference in the sensations produced according as the parts of its own body touch each other, or as one part of the body only meets with resistance from without. In the first instance, where one arm, for example, touches the other, the resistance is afforded by a part of the child's own body, and the limb thus giving the resistance becomes the subject of sensation as well as the other. The two limbs are in this case external objects of perception and percipient at the same time. In the second instance, the resisting body will be represented to the mind as something external and foreign to the living body, and not subject to the internal *self.* Thus will arise in the mind of the child the idea of a resistance which one part of its own body can offer to another part of its own body, and at the same time the idea of a resistance offered to its body by an absolute *exterior*. In this way is gained the idea of an external world as the cause of sensations.[1] Though the sensations of the being actually inform him only of the states of himself, of his nerves, and of his skin, acted upon by external impressions,[2] yet henceforth the idea of the external cause becomes inseparably associated with the sensation of touch;[3] and such is the condition of sensation in the adult. If we lay our hand upon the table, we become conscious, on a little reflection, that we do not feel the table, but merely that part of the skin which the table touches;[4] but, without this reflection, we confound the sensation of the part of the skin which has received the impression with the idea of the resistance, and we maintain boldly that we feel the table itself, which is not the case. If the hand be now moved over a greater extent of the table's surface, the idea of a larger object than the hand can cover is obtained. If, to encompass the resisting object, the hand require to be moved in different directions and planes, the idea of surfaces applied to each other in different directions is conceived, and thus the notion of an external solid body occupying space is obtained."[5]

---

[1] Perhaps it would be more correct to say only, "a sentient passive self, modified in a certain manner." So far as touch alone, without motion, is concerned, it may be doubted whether there can be any consciousness of a something exterior to *self*. It may perhaps be possible to distinguish the one conscious self from its successive modifications; but the relation thus manifested can hardly be described as one of interior and exterior. The sentient self is on each occasion of sensation present in the organism, and has no conscious relation to anything beyond. There may, indeed, be a consciousness of a local relation between different parts of the body successively affected; but these, though exterior to each other, will not thus be recognised as exterior to the conscious self. The relation of interior to exterior can only exist between two bodies occupying space; and, in this case, can only arise when we become conscious of the double *non ego*, of the bodily organism in relation to some other body. This will be the consequent, not the antecedent, of locomotion.

From the consideration of the locomotive faculty, we should pass, by a natural transition, to that of the acquired perceptions, in which the information originally furnished by this faculty is transferred to other modes of consciousness. Before taking this step, however, it will be necessary to say a few words on another organ of sensation, which, in the opinion of some eminent authorities, is entitled to contest with the locomotive faculty the claim of giving rise to our knowledge of the properties of external matter.

OF THE MUSCULAR SENSE.

The motion of a limb, whether free or resisted, being accompanied by certain sensations arising from the contraction or relaxation of the muscles, it has been sometimes thought that to these sensations, and not to the motion which they accompany, is owing our earliest apprehension of the fact of external extension and resistance.[6] A few words on this question will be necessary to complete this portion of our inquiry.

In the first place, it is unquestionable that these muscular sensations exist, and that they are distinct from the proper impressions due to the five commonly acknowledged senses. The feeling of *fatigue*, for example, belongs, partly at least, to this class; but this feeling is only an increased degree of one which accompanies every muscular exertion, and which, in its more moderate forms, is pleasant instead of painful. When we move a limb after a sufficient rest, the motion is accompanied by a sensation similar to, though less intense than, that which ensues when it is moved after long previous exercise. To the same class belongs the sensation which accompanies the act of stretching, which is only another degree of the feeling of muscular tension.[7] In the second place, these sensations may in some cases be the means of indicating to us the fact of the motion; and such is probably the office which they perform in the earliest exercises of the locomotive faculty. As at that stage of our existence our other senses have not yet come into operation, or, at least, have not been developed to that degree which suffices for the perception of foreign bodies, it is clear that the fact of our limb being in motion must be made known to us by some feeling connected with the act itself, not by observation of it from any other centre. We cannot as yet *see* that our limb moves: we must therefore, in some manner, *feel* that it does so; and this, in point of fact, is effected by means of the muscular sensations of the limb itself.[8]

But this is not sufficient to convey a knowledge of external bodies. The muscular sensations, viewed by themselves, are, like all other sensations, merely the consciousness of a particular state of our organism, and do not, any more than other sensations, give us a direct perception of the cause from which they proceed. The muscular sensation that arises when our motion is resisted is not a consciousness of resistance, but of a state of our organism caused by resistance; and it is the state, and not the causation, that we immediately feel; the latter, as in the case of the other senses, being not *presented* in the sensitive act, but *represented* as a consequence of association. Hence, while we grant the existence and the importance of the muscular sensations, we are as far as ever from the knowledge of an extra-organic world. This knowledge depends, not on the relation in which that world stands to our *sensations*, but on that in which it stands to our *volitions*. We will in the first instance to move a limb; the sensation may inform us that the limb obeys our volition; but it is the motion, and not the sensation, which is resisted by the external body. The two are unlike in all their most important features. The sensation is chiefly, if not entirely, a passive state; the motion is an active energy. The sensation is in the organism; the motion is derived from the will. The sensation conveys an immediate knowledge of the *ego;* the motion, when resisted, conveys an immediate knowledge of the *non ego.* I am conscious at one time of a voluntary effort to move; I am conscious also (whether through the muscular sensation or otherwise) that I have overcome the inertia of the limb, and put it in motion; and I am conscious of the amount of effort necessary to effect this purpose. This consciousness contains, as its condition, a concomitant intellectual apprehension of *space*, without which, the effort to move could not be made or willed; and this apprehension appears to be original and inexplicable, as it is implied in the first consciousness of a power of locomotion, prior to its actual exercise. I next become conscious that the motion is resisted from without, and that an additional effort is needed to overcome the resistance and continue the motion. This is an immediate perception of a relation between *self* and *not-self*, between the resisted effort and the resisting object. In this the voluntary energy is the primary source of knowledge; the muscular sensation, the secondary, and possibly the contingent accompaniment. The language of Destutt Tracy,—"Il reste donc constant que le mouvement volontaire nous donne seul un vrai sentiment de resistance,"[1] can hardly be called exaggerated.

---

[1] Rather "as existing and resisting our volitions." To describe the external world merely as the *cause of sensations* is to make it no more than a hypothetical object, invented to account for certain states of the subject.

[2] True of the sensations proper, but not of the locomotive volition; and, in the case of the former, the impressions need not be *external.*

[3] How can it be *associated*, unless it has been first *given* without association; *i.e.*, in itself, and not merely in its effect? Otherwise there is a relation with only one related term.

[4] True of the mere feeling; but not of the consciousness that arises when we try to penetrate into the substance of the table, and find ourselves unable to do so.

[5] Müller's *Elements of Physiology*, p. 1080, Baly's translation. The notion of a solid body occupying space, may, however, arise from simpler data than those supposed in the last sentence. This will be considered hereafter, when we treat of the primary qualities of body.

[6] See Brown, Lecture xxii. In giving the prominent place to the muscular sensation, and taking but slight notice of the volition by which it is accompanied, Brown departs from the teaching of his master Destutt Tracy, and in the same degree vitiates the theory.

[7] See Brown, Lecture xxii.; and Mill, *Analysis of the Human Mind*, chap. i., sect. 7.

[8] It does not, however, follow that the muscular sensation is in this case the only possible evidence of the motion. On this point Sir William Hamilton observes:—"Supposing all muscular feeling abolished (the power of moving the muscles at will remaining, however, entire), I hold that the consciousness of the mental motive energy, and of the greater or less degree of such energy requisite, in different circumstances, to accomplish our intention, would of itself enable us always to perceive the fact, and in some degree to measure the amount, of any resistance to our voluntary movements, howbeit the concomitance of certain feelings with the different states of muscular tension renders this cognition not only easier, but, in fact, obtrudes it upon our attention." (*Reid's Works*, p. 864.)

OF THE PRIMARY AND SECONDARY QUALITIES OF BODY.

The theory of the action of our senses, and of their relation to the material world, would be incomplete without some notice of a famous distinction which has played an important part in various systems of philosophy,—the distinction between primary and secondary qualities of body. The history of this distinction, under various names, in ancient and modern times, has been given at considerable length in a learned note appended to Sir William Hamilton's edition of Reid's works, to which we must content ourselves with referring. Our limits will only allow a few remarks on the nature of the distinction itself, and its relation to the theory of perception which has been adopted in the preceding pages.

By modern philosophers the distinction between these two classes of qualities has been based, sometimes on a psychological, sometimes on a physical principle. In the former point of view, the primary qualities have been distinguished as those which cannot by any act of thought be separated from the conception of body, being essential to that conception itself, in whatever relation it may be viewed; while the secondary qualities are mere modifications of the primary, by which the bodies are enabled to produce certain sensations in us. In the latter point of view, the primary qualities are considered to be such as really exist, in the bodies themselves, in the same manner in which they are perceived by us; whereas the secondary qualities are but the occult causes of certain sensations, which, as experienced, bear no resemblance to the powers by which they are produced. Under the former class are comprehended extension and solidity, to which have sometimes been added figure, number, motion and rest,[2] hardness and softness, roughness and smoothness.[3]

Against the first of the above principles of distinction it has been objected that some secondary qualities, as well as the primary, are inseparable from the conception of body. Thus colour, of some kind or other, accompanies every perception, and even every imagination of extended substance; and of two contradictory qualities, one or other must be attributed to every object.[4] Against the second principle it may be objected that, even if we admit that in perception we are immediately conscious of the existence of a body as presented, still we know not what any of its qualities may be in themselves, out of relation to our faculties. Both mind and matter may be immediately present in an act of perception, yet the object perceived may be, like a chemical compound, the result of a relation between the two, and may resemble neither of the elements from which it is produced. We can never be certain how much of the perceived phenomena of a body depends on the constitution of our own faculties, and how much belongs to the absolute nature of the body irrespectively of its relation to us. To determine this point, it would be necessary that we should perceive it without our faculties.

Yet both the above principles of distinction are fundamentally sound, though, to free them from misapprehension, they require a somewhat different explanation and application from that which is usually given. The *body* which is directly perceived by the senses is not inanimate matter, but our own organism; and of this, as extended, we have an immediate consciousness in every act of perception. Hence the distinction between primary and secondary qualities as perceived by the senses, if it is tenable at all, must be tenable only in relation to certain qualities existing in our own organism. We can therefore no longer distinguish between attributes existing in bodies, and powers of affecting our sensitive organism; for the *body* in relation to which the distinction has to be made is not that which affects, but that which is affected. In this point of view, it is obvious that colour, for example, is a quality of body, as well as extension. Our visual organism is presented in the act of sight as *extended* and as *coloured.* We cannot say that the extension belongs to the inanimate, the colour to the animated body; for of the inanimate body the senses tell us nothing. Nor yet can we describe the one as an attribute of body *per se*, the other of body in relation to our senses; for the whole nervous organism, as such, exists for us only as it is perceived, and is perceived only as it is affected. Destroy or alter the faculty of sense, and the whole organism of sight, as it is perceived in sensation, exists no more, or exists in a different manner.

The true ground of distinction between primary and secondary qualities of body is, we think, to be found in the fact, that some attributes of body are presented in the exercise of all the senses alike, while others are peculiar to one sense only. In every act of sensation we are conscious of our own organism as extended or occupying space. In the act of sight we are conscious of it as coloured. The two impressions, when once acquired, may be inseparable from each other; but the first may be acquired without the second, as in the case of a man totally blind, who would have a knowledge of extension, but not of colour.[5] Hence the former class of attributes are essential to our conception of body, and indeed form that conception: the latter are accidental in so far as the conception of body may exist without them; though, when the association between the two has once been formed, it may not be possible to separate them by any subsequent act of thought.

[2] As by Locke, *Essay*, b. ii., chap. viii., sect. 9.

[3] As by Reid, *Inquiry*, chap. v., sect. 4; and by Stewart, *Essay*, b. ii., chap. ii., sect. 2.

[4] Sir W. Hamilton, *Reid's Works*, p. 839.

[5] Sir W. Hamilton asserts that "light and darkness, white and black, are, in this relation, all equally colours;" and this is true, when the sensation of both has been once given. But if objects are only discerned by difference, a man totally blind could not be said to have a consciousness of darkness as such, or to associate its idea with the positive impressions derived from the other senses. Ordinary blindness, however, is not a total privation of the sense of colour.

We are thus brought back to the old Aristotelian distinction between *common* and *proper sensibles*, which has been pointed out by Sir William Hamilton as in substance identical with the modern distinction between primary and secondary qualities. In this point of view, the secondary qualities of body may be easily indicated. To this class belong all the affections peculiar to certain parts of our sensitive organism, whether as the proper objects of the respective senses, or as the accidental accompaniments of certain sensations. "Such are the idiopathic affections of our several organs of sense, as colour, sound, flavour, savour, and tactual sensation; such are the feelings from heat, electricity, galvanism, &c.; nor need it be added, such are the muscular and cutaneous sensations which accompany the exercise of the locomotive faculty. Such, though less directly the result of foreign causes, are titillation, sneezing, horripilation, shuddering, the feeling of what is called setting the teeth on edge, &c., &c. Such, in fine, are all the various sensations of bodily pleasure and pain determined by the action of external stimuli."[1]

The primary qualities require somewhat more consideration to determine them. They are the universal attributes of body, common to every mode of its existence as an object of consciousness. Hence they are not, properly speaking, known by sense, but by intellect, having no special organ adapted to their perception, but being equally present in every exercise of the bodily senses. Hence, too, they cannot, in their pure form, be depicted to the sense or the imagination, but require, in every instance, to be united with one or other of the secondary qualities which are the proper objects of the several senses. Pure extension, for example, is not an object of sight or touch, but only visible or tangible extension; *i.e.*, extension combined with colour or tactual sensation. The perception of the primary qualities, in its original manifestation, is in fact an intellectual cognition of the relations between the several parts of our sensitive organism; and, as such, both implies a present consciousness of that organism as affected, and is implied by it. For, on the one hand, the consciousness of a relation implies the simultaneous consciousness of the objects related; and, on the other hand, the consciousness of an object as such implies so much of relation to other objects as is necessary to its distinct cognition. A coloured surface, for instance, can only be perceived as composed of several coloured points exterior to each other; and a coloured point can only be discerned as forming a portion of a coloured surface. The primary and secondary qualities are thus necessarily perceived in conjunction with each other; though the primary constitute the permanent element, implied in the cognition of body in general; the secondary constitute the variable element, implied in the cognition of body by this or that sense.

The primary qualities of body may be all included under the one general head of *relation to space.* This implies the twofold condition of,—1. *Solidity*, or occupation of space in the three dimensions of length, breadth, and thickness; 2. *Being contained in space*, or surrounded by space on every side.[2] Though the sensible affection, as confined to the surface of the organism, may appear at first sight to indicate two dimensions only, yet it is obvious, on a moment's reflection, that the intelligible relation of parts to parts which necessarily accompanies the affection, is only possible under the condition of a simultaneous immediate consciousness of solidity. Space, in all its dimensions, is the form of all our perceptions of sense: a surface, or even a visible point, can only be perceived as occupying a portion of space, and as surrounded by space on all sides of it. It is impossible to conceive a surface as having no space behind or before it, or as not breaking the continuity of that space, and thus occupying a part of it. The geometrical line which has length without breadth, and the geometrical surface which has length and breadth without thickness, are, as objects of perception, equally inconceivable with the geometrical point which has no magnitude;[3] though it is possible logically to distinguish between these various elements of body, and to ascertain the special properties of each. We have in this circumstance a further confirmation of the character which has throughout these pages been assigned to space, as an *à priori* condition of consciousness, manifested on the occasion of experience, but in no way to be evolved from it.

From the general attribute of solidity or occupation of space, in its two constituent features of *geometrical solidity* or trinal extension, and *physical solidity* or ultimate incompressibility, Sir W. Hamilton has deduced the three necessary relations of *number* or *divisibility*, *size* or *magnitude*, and *shape* or *figure;* and from the correlative attribute of being contained in space, those of *mobility* and *situation.* These may be all regarded as primary qualities of body, involved in, and deducible by analysis from, the conception of body in general as presented in every act of sensitive perception.

Those attributes which are immediately perceived as existing in extra-organic bodies are distinguished by Sir W. Hamilton under the name of *secundo-primary qualities.* These are not essential constituents of the conception of body in general, but attributes contingently observed to exist in bodies in relation to our organism. They are all contained under the general head of *resistance* or *pressure*, and are immediately discerned only by means of the locomotive faculty. To this general head belong the attributes of *weight*, *cohesion*, *inertia*, and *repulsion*, all of which are made known to us as different modes of resistance to our locomotive energy. It is by the apprehension of the secundo-primary, not by that of the primary qualities, that we immediately learn the existence and nature of an extra-organic world. We are conscious, to use the words of Sir W. Hamilton, "that our locomotive energy is resisted, and not resisted by aught in our organism itself. In the consciousness of being thus resisted is involved, as a correlative, the consciousness of a resisting something external to our organism. Both are therefore conjunctly apprehended."[4] For a more detailed exposition of this important subject, which our limits do not permit us to treat at greater length, the reader is referred to the dissertations of Sir William Hamilton.[5] It only remains for us to sum up briefly the substance of the above remarks.

By *primary qualities of body* must not be understood qualities of body *per se*, as it exists *out of relation to our faculties;* for of body in this sense we have not, and cannot have, any knowledge. The nearest approximation which we can make to a conception of body *per se* is that of body as it appears *in relation to all our faculties;* and, consequently, the primary qualities can only be directly given as existing in our own organism, which is the only body of which we are immediately cognisant in every act of exter nal perception. The secundo-primary and the secondary qualities are not in this sense qualities of body *per se*, being given only in certain special modes of cognition; the former as attributes of an extra-organic substance resisting our locomotive energy, the latter as affections of our organism in this or that particular state of sensation. The former are thus the essential constituents of our empirical notion of body, from whatever form of experience it may be derived; the latter are attributes superadded to that notion, as manifested by body in certain special relations only.

---

[2] Sir W. Hamilton, *Reid's Works*, p. 847.

[3] This is perfectly consistent with the fact, to be noticed hereafter, that the *actual perception* of solidity by sight is not original, but acquired.

[4] *Reid's Works*, p. 882.

[5] *Reid's Works*, notes D and D*.

But though the primary qualities of body as such are immediately given only as existing in our own organism, it is obvious that they are apprehended as forming the essential attributes of all matter alike, organic or otherwise; for the body which resists our locomotive energy can only do so as occupying a portion of space into which we attempt to penetrate, and thus as possessing the same primary qualities with the organism to which it is related. The secondary qualities, too, though immediately apprehended only as affections of our organism, are, in the later development of consciousness, necessarily associated with exterior objects. The nature of this association next claims our attention, as that which gives rise to the important phenomena of acquired perception.

OF THE ACQUIRED PERCEPTIONS.

The examination of the acquired perceptions should, in strict accuracy, be undertaken in connection with the representative, not with the presentative consciousness. They are not, properly speaking, *given* in the sensitive act to which they are supposed to belong, but *inferred* by the understanding, according to a law of association, from the presence of something else. But inasmuch as the inference is one which is never consciously performed; as it takes place by a necessary law of our mental constitution at a period too early to leave any trace in the memory; as, consequently, in the complex acts of our matured consciousness the inferred elements are not directly distinguishable from the data which suggest them; and as the explanation of the former is intimately connected with the preceding remarks on the latter, it will be better to sacrifice the strictly logical arrangement, in order to present in a more connected view the entire series of phenomena usually referred to the evidence of the senses.

It has been already observed that, in the exercise of our faculties in their mature state, no perception occurs pure and isolated, but is, in all cases, united with an act of judgment or inference. To ascertain by actual experience the relative proportions of these ingredients, so as to separate the independent acts of the senses from the results of their education, it would be necessary to have an exact recollection of our first impressions as they existed before the formation of habits. Nay, even this, were it possible, would be hardly sufficient; as it may be questioned whether the education of the senses does not in some respects precede even the first occasions of their exercise. From what has been said in treating of the locomotive faculty, it appears that the sense of sight, for example, can never be said to have existed in a wholly uneducated state; inasmuch as certain obscure notions of an external world already exist, and have made their influence felt, before the eyes of the child have come in contact with the light, or its acts been exposed to the observation of others. When, in the absence of experience of the simple, we attempt to supply its place by analysis of the compound, it must be borne in mind that the results at which we arrive will represent a theoretical rather than an actual process, and that some of the conclusions elicited by the theory will be only approximately true in practice. It must not be supposed, for instance, that the several stages through which the sense of sight is represented as passing, actually occur as distinct phenomena of vision during the unremembered days of infancy. When theory declares that the object which we really see is in the organ of sight, it does not follow that the infant has ever actually seen it there. The approximate truth, that the perception of distance is of gradual acquisition, may be ascertained by positive observation; but no observation can tell us whether the actual exercise of sight began with the first or with a later member of the series. The remark which we have before had occasion to make, that the distinctions of psychology represent the elements of consciousness rather than separate acts, is equally applicable here.

Of the acquired perceptions, those of vision are by far the most important; so much so, that it will be sufficient to notice a few of the principal of these, leaving the reader to apply our observations, *mutatis mutandis*, to the other senses. The principle which must guide him in making the application is that which we have more than once had occasion to repeat; namely, *that no sense, in its original state, informs us of anything more than certain states of our own organism.* In addition to this, it will be necessary to bear in mind another principle of no less importance; namely, *that all representation must be founded on a presentation;* in other words, *that nothing can be inferred in connection with one phenomenon of consciousness which has not been given in connection with another.* The examination of this principle belongs to a later stage of our inquiry. For the present we must content ourselves with taking it for granted.

Among the acquired perceptions of the sense of sight, the most important are the following:—1. The perception of an *external field of vision* distinct from the retina, and the consequent judgments concerning the *distance* and *magnitude* of objects in that field. 2. The perception of the *unity* of a visible object, which presents a separate image to each retina. 3. The perception of the object as *solid* or extended in three dimensions of space, and of its *figure* or boundary in each direction. 4. The perception of its *position*, which is the reverse of that of its image on the retina. A few remarks on each of these will, it is hoped, furnish sufficient information for the explanation of acquired perceptions in general.

I. *Field of vision.*—The true or perceived field of vision is the surface of the retina itself; and this may, in certain cases, be actually discerned as such. Thus, the sensation of darkness is the consciousness of the condition of the retina in a state of repose; and in this there is no perception of any field of vision exterior to the retina itself. The apparent or inferred field of vision is a space of greater or less extent, exterior to the eye, on which the images of the retina are projected by an act of the mind. In the majority of cases, we appear to perceive this field immediately; but many observations have been adduced to show that this apparent perception is not part of the original faculty of sight. An infant appears at first to have no perception by sight of the distance of objects, but stretches out its hands towards distant and near bodies alike. The youth who was couched by Cheselden saw at first all objects in one plane, and apparently touching the eye. It is true that the patient in this instance saw the objects as *on* not *in* the eye; and this may, perhaps, be the case with the infant also; but it must be remembered that the ideas of externality and distance are already partially acquired by the locomotive faculty before the sense of sight comes into exercise. From these approximate facts, joined to what we know of the theory of vision, we may conclude, with some probability, that a being destitute of the power of motion would, on first opening his eyes, discern nothing but the images existing on the surface of the retina.

But, when the knowledge of an external world has been once given by the locomotive faculty, the education of the sense of vision follows rapidly and imperceptibly. A certain image on the retina accompanies the perception of an object in contact with the hand. The object is pushed further off, and the size and outline of the image undergo a corresponding change. The hand is placed over the object, and its image takes the place of the other. It is placed over the eye, and the images vanish altogether. Certain sensations of sight are thus at first associated with certain perceptions of distance; then suggest those perceptions when the latter are not immediately present; and finally, as the process becomes more familiar, are substituted for them. Something similar to this takes place more perceptibly in some of the associations of ideas which are formed at a later period. In many cases, where the association is frequent, the antecedent is gradually forgotten, and the attention wholly fixed on the consequent. There is no original connection between the meaning of a word and its sound, or between the sound and the written characters by which it is represented to the eye; yet the sight of certain black figures on a white ground suggests to the child, first the sound, and, through the sound, the meaning. At a later stage the intermediate links of the chain are forgotten; the sound vanishes entirely; the form of the letter is scarcely, if at all, noticed; and the sight of the printed page plunges us at once into communion with the thoughts of the writer. Yet the mere visual perception remains as it was, one and the same to the man who can read and to the man who cannot. All beyond this is acquired by habit; and the process, when most familiar and most imperceptible, is in its successive steps precisely the same as in those early days when we painfully combined distinct letters into syllables, and distinct syllables into words, and distinct words into sentences. The principal difference which distinguishes this and similar operations from the acquired perceptions of sight is, that the associations are formed in the one case consciously, after the mind has acquired a power of reflecting on its own operations, and of acting in consequence of reflection; in the other, unconsciously, by an instinctive law of our constitution. Hence the latter may be described as a natural association common to all men; the former, as an artificial association peculiar to the educated. Yet our natural powers are not, as natural, necessarily born with us. It is natural for man to see distant objects; in the same way as it is natural for him to walk upright and to use his hands. Yet there was a time when he could not discern distances by the eye; just as there was a time when he crawled on all fours, and employed his hand for no other purpose than that of sucking its extremities.

The following remarks of Professor Müller are important, in illustration of the phenomenon in question:—"Several physiologists—as Tourtal, Volkmann, and Bartels—suppose the interpretation of the sensations of the retina, as objects forming part of the exterior world, to be a faculty of the sense of vision itself. But what, in the first place, constitutes the external world? Since, in the first acts of vision, the image of the individual's own body cannot be distinguished from those of other bodies, the referring of the sensations of vision to something external can be nothing else than the discrimination between the sensations of vision and the subject of them,—between the sensations and the sentient *self*. It is by the operations of the judgment that the objects of vision are recognised as exterior to the body of the individual. . . . It is said that the new-born infant perceives from the first that the objects of vision are external to its body and to its eye; but the infant perceives neither its own eye nor its body in the form of sensations of vision, and only learns by experience which of the images which it sees is its own body. We can therefore only say, that the new-born infant distinguishes the sensations from the sentient *self;* and in this sense only does it perceive the sensation as something external. In brutes, the co-operation of instinct renders this reaction of the sensorium under the impression of external objects much less indefinite; for the young animal soon applies itself to the nipple of the mother; so that its sensorium must be the seat of an innate impulse to attain to the image, which it sees, and which is an object, or something external to the sentient self, by appropriate movements. Though the new-born infant be at first unable to distinguish between the image of its own body and those of external objects, it will soon remark that certain images in the field of vision are constantly reappearing, and that these images move when its body is voluntarily moved. These are images of parts of its own body. All the other images in the field of vision either change quite independently of the body of the infant, or the changes which they undergo do not correspond with its voluntary movements. These are images of objects appertaining to the external world, which, now recognised as existing in a space external to the body of the individual, are henceforth continually presenting themselves in this space, which, according to the conception of the mind, is subject to the operations of vision. Of the eye, as the organ of vision, the new-born infant knows nothing."[1]

The field of vision being thus by association perceived as external to the eye, our judgment of the relative *distance* and *magnitude* of objects within that field is determined by similar associations. That of distance is an inference chiefly drawn, in the first instance, from the degrees of distinctness in the colour and outline of the objects, aided, perhaps, in the case of near objects, by the muscular sensations accompanying the convergence of the optic axes.[2] That of magnitude may be considered as partly original, partly acquired. Original, in so far as there is a difference in the size of the object actually perceived (*i.e.*, the image on the retina), dependent upon the visual angle made by the central rays of two pencils of light from the extreme points of a luminous body, intersecting after refraction within the eye: acquired, inasmuch as the inferred magnitude of the external object is the result of a combination of the size of its image with other phenomena, chiefly with those which give rise to our estimate of its distance. This is, in substance, the theory of distance and magnitude first proposed by Bishop Berkeley,—a theory which, while it has been amended and completed in some of its minor details by the discoveries of modern science, remains in its essential features unshaken.

II. *Single vision with two eyes.*—The above remarks are also applicable in a great degree to the phenomenon of single vision with two eyes; a phenomenon which many eminent physiologists have referred to a special provision in the structure of the visual apparatus,[3] but which is sufficiently proved by the observations and experiments of Professor Wheatstone to be an inference from the mental combination of the two images actually seen. To this combination it is necessary that the two images should fall on portions of the two retinæ which have been accustomed to act in concert; and the principle on which it mainly depends is doubtless the association of a single perception of resistance with the double image of the corresponding visible phenomena.[4]

III. *Solidity and Figure.*—The perceptions of solidity and figure are results of the same law of association. The former, as Professor Wheatstone's experiments show, is, like the unity of the object, the effect of the combination of the two visible images, and depends, as far as sight is concerned, upon the different perspective exhibited by the projection of each. The phenomena of the stereoscope present a now familiar illustration of this; two plane projections being, by means of this instrument, made to act upon the eye in the same manner that solid figures do in ordinary vision; and the two being, by an act of the mind, combined into the appearance of one external solid body.[1] The perception of resistance, however, has also some share in the origin of this association. Figure, like magnitude, is partly an original, partly an acquired perception. Plane figures, such as a square or a circle, can be depicted on the surface of the retina, and can thus be distinguished from each other by the original power of the sense of sight. Solid figures, such as a sphere or a cube, are discerned in a great measure by the simultaneous use of both eyes, though the accuracy of the discrimination is, no doubt, assisted by associations derived from touch assisted by motion.[2]

IV. *Erect vision.*—The explanation of the erect position of external objects has been attempted in various ways, none of which, however, can be considered as quite satisfactory.[3] It seems to be a law of the mind, in projecting images beyond the retina, to follow in some degree the course of the rays, and thus to produce an inverted impression when the image is projected beyond the point where the rays intersect. But to investigate this and similar points fully, it would be necessary to know the exact relations of mind and body to each other in the act of sensation. This is impossible, as we cannot trace the action of the mind apart from that of the organism. The explanation of many of the phenomena of sensation probably depend on some inscrutable condition of consciousness, which no examination of the mere nervous organism is able to reveal to us. "There is," says Mr Morell, "a perilous distance for the materialist to travel between the retina and the living soul. The eye does not see of itself, neither, if the optic nerve be severed, can any visual perception reach the mind. How, then, we may ask, can the image on the retina travel along the nerve, and impress the brain with its own form and hue? The moment we get beyond the mere *mechanism* of the case, our power of tracing the image is lost, and we can only detect at the other, or spiritual end of the process, a mental phenomenon, differing as widely as possible from the mere material substance without."[4]

The acquired perceptions of the other senses may be explained on the same principles. Such, for instance, are the judgments which we form of the direction and distance of an object by the hearing or the smell; these two senses having, like that of sight, both an original and an acquired field for their exercise. Cognate to the subject of acquired perceptions is that of acquired sensations. The feelings of pleasure and pain, which an object imparts through the senses, may be as much the result of practice and association as the information which we gain by the same means concerning its nature. Instances of this may be found in the artificial tastes which we gain by the constant use of objects which at first were considered as indifferent or disagreeable; and, again, in the strong feelings of dislike with which we often regard various sensations, solely in consequence of some early association. And hence it will often be the case that the different degrees of pleasure which the several senses are capable of affording to an educated man, will by no means correspond to those which they materially impart as vehicles of mere animal enjoyment. Thus the senses of sight and hearing, which are less intense than the other senses in the merely nervous affections which they are calculated to excite, are, notwithstanding, the vehicles of a mixed enjoyment (partly sensitive, partly intellectual) of a far higher order. But the pleasure which we enjoy from the sight of beautiful scenery, or from the hearing of music, is something very different from the natural sensation, or affection of the nervous organism. The natural sensation is limited to that amount of enjoyment of which the sense is susceptible at the moment of its exercise. When our eyes are gratified by a variety of visible objects, or our ears by a succession of sounds, the memory, and not the sensation, plays the principal part. We see the various objects, we hear the various sounds, *in succession;* though by an act of thought we imperceptibly combine them into a single whole. But the *discernment of relations* is in no case a work of sense; and beauty and deformity, harmony and discord, are almost entirely the result of *relations.* To estimate the merely sensual pleasure imparted by sight and hearing, we must suppose the eye to be limited to a succession of detached colours, and the ear to a succession of isolated sounds, with no consciousness of any relation between them, and no power of comparing the past with the present. This distinction between original and acquired sensations has been perhaps too much neglected in the various attempts that have been made to construct an exact philosophy of taste.

OF ATTENTION.

That sensation, as before observed, is neither a purely bodily nor a purely mental affection—that it belongs neither to the nervous organism alone, nor yet exclusively to the active self by which that organism is animated, but to that mysterious union of both, whose elements and laws philosophy has ever failed, and probably ever will fail, to penetrate—appears conspicuously when we come to examine two states of consciousness which appear to form the connecting links between the external and the internal affections, between the passive and the active elements of our nature—partaking of both, and identical with neither. These two are *attention* and *imagination.* Attention, in particular, partakes of this twofold character in a remarkable degree. To a hasty inspection it appears as if the operation of this faculty were at once the antecedent and the consequent of the sensible impression, as if the mind were at the same time active and passive in its production. It appears certain, on the one hand, that, in order to arouse the attention to any sensible phenomenon, that phenomenon must first be presented to consciousness; while, on the other hand, it has been argued, with some plausibility, that unless the attention be previously aroused, consciousness has no intimation of the existence of the phenomenon at all. All the physical conditions of sensation may exist in full perfection, without any corresponding impression being produced upon the mind. "When two persons," says Reid, "are engaged in interesting discourse, the clock strikes within their hearing, to which they give no attention. What is the consequence? The next minute they know not whether the clock struck or not. Yet their ears were not shut. The usual impression was made upon the organ of hearing, and upon the auditory nerve and brain; but, from inattention, the sound either was not perceived, or passed in the twinkling of an eye, without leaving the least vestige in the memory."[1] Of the two alternatives here offered to our choice, the latter is adopted by Dr Reid's successor as the more accurate explanation of the phenomenon. That attention is not necessary to the existence of a sensation in the consciousness seems at first sight manifest, both *à priori*, because a phenomenon must exist before the attention can be aroused to observe it, and *à posteriori*, from the very narrow limits within which experience testifies that our power over our own sensations is confined. When the mind is unoccupied, the slightest and most familiar sounds will make themselves heard as a matter of course. It is not necessary that the attention should be previously directed towards the object from which the sound proceeds; it is sufficient that it be not engaged with any other object. A louder or more unusual sound forces itself on the consciousness, however much the attention may be engaged elsewhere. The striking of a clock may be unheard during an interesting discourse; but the report of a gun, or any unwonted noise, will be heard in spite of it. These and other considerations may be urged in favour of the hypothesis so ably maintained by Dugald Stewart,—namely, that we are in all cases conscious of the sensation, but are not always able to recollect that we have been conscious. "The true state of the fact," says that distinguished philosopher, "I apprehend, is, that the mind may think and will, without attending to its thoughts and volitions, so as to be able afterwards to recollect them. Nor is this merely verbal criticism; for there is an important difference between consciousness and attention, which it is very necessary to keep in view, in order to think upon this subject with any degree of precision. The one is an involuntary state of the mind; the other is a voluntary act: the one has no immediate connection with the memory; but the other is so essentially subservient to it, that without some degree of it, the ideas and perceptions which pass through the mind seem to leave no trace behind them. When two persons are speaking to us at once, we can attend to either of them at pleasure without being much disturbed by the other. If we attempt to listen to both, we can understand neither. The fact seems to be, that when we attend constantly to one of the speakers, the words spoken by the other make no impression on the memory, in consequence of our not attending to them, and affect us as little as if they had not been uttered. This power, however, of the mind to attend to either speaker at pleasure, supposes that it is, at one and the same time, conscious of the sensations which both produce. Another well-known fact may be of use in illustrating the same distinction. A person who accidentally loses his sight never fails to improve gradually in the sensibility of his touch. Now there are only two ways of explaining this. The one is, that in consequence of the loss of the one sense, some change takes place in the physical constitution of the body, so as to improve a different organ of perception. The other, that the mind gradually acquires a power of attending to and remembering those slighter sensations of which it was formerly conscious, but which, from our habits of inattention, made no impression whatever on the memory. No one, surely, can hesitate for a moment in pronouncing which of these two suppositions is the more philosophical."[2]

---

[1] This explanation is of course inapplicable to the case of persons who have the sight of one eye only. Here, however, the same perception of solidity will be produced, partly by the associations suggested by resistance, and partly by the different perspective of the projection, consequent on changes in the position of the single eye.

[2] Molyneux proposed to Locke the question, whether a person born blind, who was able by touch to distinguish a cube from a sphere, would, on suddenly obtaining his sight, be able to distinguish them by the latter sense. (See Locke, *Essay*, b. ii., chap. ix.) Professor Müller finds it "difficult to conceive wherefore these two philosophers answered the problem in the negative." That figures, solid as well as plane, can be distinguished by sight alone, when the perception of an external field of vision has once been acquired, seems unquestionable; but the real problem is to determine whether each perception of sight can be at once identified with the corresponding perception of touch. This may in general be doubted, though this particular instance may possibly not be a case in point. (See Sir W. Hamilton, *Reid's Works*, p. 137.)

[3] Sir David Brewster's theory of the line of visible direction is objected to on physiological grounds by Dr Carpenter, *Human Physiology*, p. 916. That proposed by Professor Müller, and adopted by Dr Carpenter, may be briefly stated thus. Up and down, right and left, are relative terms; therefore the inversion of everything is equivalent to the inversion of nothing. This explanation, however, does not tell us why the inversion takes place, but only accounts for the fact of our not noticing it. The fact still remains unexplained, that the external object and the image on the retina are, *to the eye of a stranger*, in a position the reverse of each other. *Query*—Are they likewise so *in different stages of the vision of the person himself?* This we have as yet no means of determining.

[4] *Elements of Psychology*, p. 131.

But this ingenious reasoning is not quite so conclusive as at first sight it appears to be. It proves clearly that the attention cannot be directed to an object in contact with an organ of sense unless something intervenes to arouse it; but it assumes without proof that this something must itself be a phenomenon of consciousness. The question remains, Is the phenomenon of which we become fully conscious by attention the *same phenomenon* that it was before we attended to it? or has attention itself added an element which brings it within the sphere of consciousness? It seems at first sight a paradox to maintain that our consciousness can be stimulated by anything of which we are not conscious. Yet this apparent paradox is a fact which in some degree takes place at every moment of our lives. When we look at the smallest visible point of light, this is obviously compounded of parts so small as to be invisible; yet each of these contributes its share to the sum total of consciousness. When we see a distant forest, the indistinct impression of green is made up of the greenness of every individual leaf, not one of which could be singly discerned. The theory of *latent modifications of mind*, or, as they are called by Leibnitz, *obscure representations*, which is well calculated to explain many of the most curious phenomena of consciousness, has been almost entirely neglected by the philosophers of this country; yet it is one which, though in most of its details belonging to physiology rather than to psychology, must be assumed by the latter science as the basis of many of its researches. When the unpublished lectures of Sir W. Hamilton shall be given to the world, the English student of philosophy will have the means of seeing this question treated with the fulness and ability which its importance deserves.

But whether, in the widest sense of the term *consciousness*, it can or cannot be correctly described as prior to and independent of the act of attention, yet, in the narrower and more accurate sense, in which alone it can be the object of scientific analysis, attention becomes a necessary condition of its existence, or rather is identical with consciousness itself. Every phenomenon of consciousness proper, as before observed, must possess in some degree the attributes of *clearness* and *distinctness*, without which it can leave no trace in the memory, and cannot be compared with other phenomena of the same class. But to a clear or distinct consciousness it is necessary that an act of reflection should accompany the intuition; and to the act of reflection it is necessary that the phenomenon in question should have been observed with some degree of attention. The act of attention is therefore a necessary condition, possibly of the existence of a sensation in consciousness, but certainly of its recognition as such; and, in strict language, it would not be inaccurate to describe attention as consciousness in operation relatively to a definite object. This intimate union of the active with the passive functions of the human mind; this presence in every complete act of consciousness of a voluntary and personal factor—a permanent *self* in the midst of transitory modes,—exhibits man as in some degree the master of his own consciousness, and the author of the phenomena which it reveals to him. It is the exaggeration or exclusive consideration of this element which is the source of most of the extravagances of idealist metaphysics, as its neglect or suppression has given rise to most of the opposite extravagances of sensationalism.

[2] *Elements of the Philosophy of the Human Mind*, part ii., chap. ii.

OF IMAGINATION, MEMORY, AND HOPE.

In the act of attention the mind selects certain prominent features of an object of intuition, which thus become fixed in the memory, and capable of reproduction when the object is no longer present. The reproductive imagination is thus the sequel of attention, forming the second link in the chain of connection between the intuitive and the reflective consciousness.[1] Hence, in a strictly methodical arrangement, the treatment of attention and imagination should be postponed till after the complete examination of the phenomena of intuition. But the prominence which, in the majority of treatises on the subject, has been given to the sensible relations of these two cognate acts, may furnish both an excuse for the consideration of them in the present place, and an opportunity of pointing out some of the chief defects which may be noticed in the ordinary treatment of them. "Imagination," says Dr Reid, "when it is distinguished from conception, seems to me to signify one species of conception—to wit, the conception of visible objects."[2] In this he follows the language of Descartes,—"Imaginari nihil aliud est quam rei corporeæ figuram seu imaginem contemplari."[3] Mr Stewart, though differing in his language, virtually limits the office of the same faculty to the reproduction of sensible impressions, though he does not, like the two authors last cited, confine it to the impressions of sight. Under the name of *conception*, he defines it as "that power of the mind which enables it to form a notion of an absent object of perception, or of a sensation which it has formerly felt."[4] Of the proper sense of the term *conception* we shall have occasion to speak hereafter. For the present, it will be sufficient to observe that imagination, in the proper psychological sense of the term, should not be confined to the reproduction of the phenomena connected with the bodily senses. It should rather be defined as "the consciousness of an image in the mind, resembling and representing an object of possible intuition. Not the objects of sense alone, but the presentations of intuition, external or internal, desires, affections, volitions, thoughts, as well as sounds, or colours, or figures, —everything, in short, that can be experienced in consciousness as an individual thing, act, or state of mind, may remain as an image in the memory, or be reproduced in the mind at a future period. Or the detached portions of objects once perceived may be combined by the imagination in a manner in which they have never been presented in any actual experience. Thus, when the upper parts of a man and the lower parts of a horse have been perceived by the sense in separate objects, the image of a centaur may be formed as readily as that of a horse or a man. It is to this last "power of modifying our conceptions, by combining the parts of different ones together, so as to form new wholes of our own creation," that Mr Stewart would confine the term *imagination*. The distinction really lies not so much in the image obtained as in the manner of obtaining it; and, though worthy of notice on many accounts, should, I think, be expressed in different language.

Imagination is of two kinds, which, following the plan of classifying the phenomena of mind by the leading characteristics of each, may be distinguished as belonging to the intuitive and the reflective consciousness respectively. The first, in which the mind is comparatively passive, consists in the continuance, in a weaker form, of a sensible or otherwise intuitive impression, when the object which gave rise to it is no longer present.[5] This is the imagination which is described by Aristotle as a *kind of weak sensation*,[6] and as *sensitive imagination*.[7] When coupled with a consciousness of the past existence of the impression which it represents, it forms the *memory*, as distinguished from the *reminiscence* of Aristotle.[8] The other kind of imagination is more properly an act of thought,[9] and consists in constructing in the mind an individual image (whether actually resembling a former impression or not) in accordance with the attributes contained in a given general notion. In this instance, imagination coincides with a faculty to be hereafter described,—*conception*. It is, in fact, individualizing the contents of a concept or general notion, so as to depict them (which in their general form is impossible) to the intuitive consciousness. This kind of imagination may be simpler or more complex, according as the image is constructed immediately, from the data furnished by the given notion, or mediately, from a train of associations which that notion suggests. It includes under it as a species the *deliberative imagination* of Aristotle; and, when coupled with the conscious effort to recal a past impression, corresponds in some degree to the *reminiscence* of the same philosopher.[10]

Imagination, memory, and hope are psychologically one and the same faculty.[11] In imagination, the presence of the image is necessarily accompanied by a conviction of the *possible* existence of the corresponding object in an intuition.

---

[2] *Intellectual Powers*, Essay iv., chap. 1.

[3] *Meditatio Secunda*. The office of imagination in relation to two other senses is accurately described in the lines of Shelley—

"Music, when soft voices die,
Vibrates in the memory;
Odours, when sweet violets sicken,
Live within the sense they quicken."

[4] *Elements of the Philosophy of the Human Mind*, part i., chap. iii.

[5] Arist. *Anal. Post.* ii. 19. Ἐνούσης δ᾽ αἰσθήσεως τοῖς μὲν τῶν ζώων ἐγγίνεται μονὴ αἰσθήματος, τοῖς δ᾽ οὐκ ἐγγίνεται. Ὅσοις μὲν οὖν μὴ ἐγγίνεται, ἢ ὅλως ἢ περὶ ἃ μὴ ἐγγίνεται, οὐκ ἔστι τούτοις γνῶσις ἔξω τοῦ αἰσθάνεσθαι· ἐν οἷς δ᾽, ἔνεστι [μὴ] αἰσθανομένοις ἔχειν ἔτι ἐν τῇ ψυχῇ. The negative inserted by Trendelenburg appears indispensable to the sense.

[6] *Rhet.* i. 11.

[7] *De Anima*, iii. 11. Η μὲν οὖν αἰσθητικὴ φαντασία καὶ ἐν τοῖς ἄλλοις ζῴοις ὑπάρχει, ἡ δὲ βουλευτικὴ ἐν τοῖς λογιστικοῖς.

[8] Aristotle, *De Memoria*, c. 1. Τίνος μὲν οὖν τῶν τῆς ψυχῆς ἐστὶν ἡ μνήμη; φανερόν, ὅτι καὶ οὗπερ ἡ φαντασία· καὶ ἔστι μνημονευτὰ καθ᾽ αὑτὰ μὲν ὅσα ἐστὶ φανταστά.

[9] *De Memoria*, c. 2, 25. Διαφέρει δὲ τοῦ μνημονεύειν τὸ ἀναμιμνήσκεσθαι, οὐ μόνον κατὰ τὸν χρόνον, ἀλλ᾽ ὅτι τοῦ μὲν μνημονεύειν καὶ τῶν ἄλλων ζῴων μετέχει πολλά, τοῦ δ᾽ ἀναμιμνήσκεσθαι οὐδὲν, ὡς εἰπεῖν, τῶν γνωριζομένων ζῴων πλὴν ἄνθρωπος. Αἴτιον δ᾽ ὅτι τὸ ἀναμιμνήσκεσθαί ἐστιν οἷον συλλόγισμός τις.

[10] By reminiscence, Aristotle means the process of endeavouring to reproduce something formerly in the memory, indirectly, by means of associated ideas. Memory proper comes in at the conclusion of the process, though it may also exist without it. (See *De Memoria*, ii. 4.) In this point of view, it is obvious that memory is the result of a process of thought, and therefore should not have been identified with that retention or remembrance which in the same chapter is described as common to men and brutes. It would be more accurate to distinguish between *intuitive* and *reflective* remembrance, according as it is performed without or with the intervention of a concept; and of the latter the Aristotelian ἀνάμνησις is a special form.

[11] See Sir W. Hamilton, *Discussions*, p. 52.

Memory is the presence of the same image, accompanied by a conviction of the fact that the object represented has actually existed in a *past* intuition. Hope, in like manner, is the presence of the same image, together with an anticipation, more or less vivid, of the actual existence of the object in a *future* intuition. Imagination, memory, and hope are thus (whether formed by a reflective process or not), in their actual results partly *presentative*, partly *representative*. They are presentative of the image, which has its own distinct existence in consciousness, irrespectively of its relation to the object which it is supposed to represent. They are representative of the object, which that image resembles, and which, either in its present form or in its several elements, must have been presented in a past act of intuition. Thus there is combined an immediate consciousness of the present with a mediate consciousness of the past. An immediate or presentative consciousness of the past or the future, as such, is impossible.

Imagination being representative of an intuition, is, like intuition, only possible on the condition that its immediate object should be an *individual*. If we try to form in our minds the image of a triangle, it must be of some individual figure,—equilateral, isosceles, or scalene. It is impossible that it should, at the same time, be all of these, or none. It may bear more or less resemblance to the object which it represents; but it can attain to resemblance at all only by being, like the object itself, individual. I may recall to mind, with more or less vividness, the features of an absent friend, as I may paint his portrait with more or less accuracy; but the likeness in neither case ceases to be the individual representation of an individual man. On the other hand, my *notion of a man in general* can attain to universality only by surrendering resemblance; it becomes the indifferent representative of all mankind, only because it has no special likeness to any one in particular. This distinction must be carefully borne in mind in comparing imagination with the cognate process of conception.

OF INTERNAL INTUITION IN GENERAL.

Locke, as is well known, referred the origin of our ideas to two sources,—*sensation*, by which we acquire our knowledge of external objects; and *reflection*, by which we become acquainted with the internal operations of our own minds. The latter term is unfortunately chosen, as it naturally suggests the notion of a *turning back* of the mind upon an object previously existing; and thus represents the phenomena of consciousness as distinct from the act of reflecting upon them. Understood in this sense, reflection can have no other objects than the phenomena of sensation in some one of its modes; for sensation and reflection are the only recognised sources of knowledge; and if reflection implies a previously existing operation of mind, that operation can be none other than sensation. Interpreting Locke in this sense, Condillac and his followers were only carrying out the doctrine to its legitimate consequences when they maintained that sensation was the only original source of ideas, and furnished the whole material of our knowledge. But though the language of Locke is both unfortunate in its choice of terms and vacillating in the use of them, the general tenor of his philosophy demands a different interpretation of the term *reflection*, as synonymous with *internal consciousness;* that is to say, as a knowledge of the presence of certain inward phenomena of mind, which exist only as they are known, and are known only as they exist. Reflection is thus an original and independent source of ideas, not distinct from, but identical with, the acts that are its objects. It is, in fact, the consciousness of those states of the mind by which it is placed in relation to itself, as sensation is the consciousness of those states of the mind by which it is placed in relation to the material world. Both sensation and reflection thus denote original states of consciousness, which exist only in so far as we are conscious of them. For example, *I see, and I am conscious that I see.* These two assertions, logically distinct, are really one and inseparable. Sight is a state of consciousness; and I see only in so far as I am conscious of seeing. Here, then, is one source of ideas,—the consciousness of certain affections of our bodily senses in relation to external objects. Whatever comes from this source is classed by Locke under the general head of *ideas of sensation.* But again: I am angry, and I am conscious that I am angry; I fear, and I am conscious that I fear; I will, and I am conscious that I will. Here, too, are acts which exist only in so far as we are conscious of them, and which point to another and a distinct source of ideas,—the consciousness, that is to say, of internal phenomena taking place in the mind itself. Whatever comes from this source is classed by Locke under the general head of *ideas of reflection.* It is in this sense that he describes reflection as a source of ideas which every man has wholly in himself, and which, "though it be not sense, as having nothing to do with external objects, yet it is very like it, and might properly enough be called *internal sense.*"[1] And thus, also, in another passage, he says, "I cannot but confess that *external and internal sensation* are the only passages that I can find of knowledge to the understanding."[2] We may thus, retaining the substance of Locke's teaching, though slightly altering his language, divide the presentative consciousness into two kinds:—1. External intuition, which embraces the various phenomena of sensation and perception, together with that knowledge of the attributes of matter which is obtained through the locomotive faculty; and, 2. Internal intuition, which includes all those modes of consciousness in which we become immediately cognisant of the various states of our own mind, as well as the concomitant consciousness of our own personality as the one permanent subject of these successive states. The phenomena of external intuition have been described in the preceding pages. We have next to consider those of internal intuition; and here it will be most convenient to begin with the variable element, as exhibited in the several mental states of which we are successively conscious. The form of this consciousness, as has been already observed, is *time.* The phenomena which we are about to describe constitute the matter.

OF THE CLASSIFICATION OF INTERNAL INTUITIONS.

Internal intuition, in the widest sense of the term, includes among its modes the whole of the phenomena of consciousness; for consciousness in general denotes a state of the mind; and all states of the mind are objects of internal intuition. In this extended signification, the phenomena of sensation and those of thought are both included under this head; for sensation, though in respect of its object it is external to the conscious mind, is in itself an affection of which that mind is intuitively conscious; and thought, in like manner, though in respect of its object it is mediate and representative, is in itself an individual act of which we are immediately and presentatively conscious. Thus, for example, *colour*, the object of sight, is an affection of the nervous organism, and therefore external to the immaterial self, the subject of consciousness; but *sight*, as a species of sensation, is a state of the personal consciousness, and, as such, internal. So, again, when I think of any material object, such as a tree or a stone, the object of which I think is external to the mind, and represented by the notion which I form of it; but the act of thinking about it is an individual affection of the conscious self, having its own definite position in time, and thereby numerically distinguished from every other affection, however similar. I may think of the same tree on twenty successive occasions; but my several thoughts, however identical in their objects, are nevertheless twenty successive, distinct, and individual states of my own mind, and, as such, belong to the class of internal intuitions. But in the practical treatment of the subject it is not necessary to take into consideration either of the above classes of mental phenomena; for the distinction between an act of consciousness and its object, though logically valid, has psychologically no existence. In no actual operation of consciousness can the act be separated from the object, or the object from the act. By no mental abstraction can either of these correlatives be conceived apart from the other,—though they are conceived together, not as identical, but as related and logically distinguishable. A perception cannot be conceived except as the perception of some object; an object of perception cannot be conceived except as in relation to a perceiving mind. In treating, therefore, of the phenomena of sensitive perception in relation to their external objects, we have at the same time sufficiently exhibited their internal character as acts of mind. A similar remark may be made with respect to the operations of thought. These will be examined hereafter in relation to the objects which they represent, and to their manner of representing them; and this examination will, at the same time, necessarily include their presentative aspect as individual phenomena of consciousness. The perceptive and discursive faculties, which are thus excluded from our present consideration, embrace all those operations of consciousness which are usually referred to the head of *cognitive* or *intellectual powers*. There will still remain for consideration the various phenomena which in the same division are classified, not very accurately, as belonging to the *appetitive* or *active powers*;[1] and which may, perhaps, be more exactly comprised under the three appellations of,—1. *Emotions* or *passions*; 2. *Moral judgments*; 3. *Volitions*.[2] It is difficult to fix upon any positive mark which shall express the distinctive characteristic of this group of mental phenomena, viewed as constituting a single class; though they may, perhaps, be sufficiently distinguished from other states of mind by the negative criterion of attributes which they do not possess. The internal intuitions, as a class, may, in this way, be described as comprehending all those affections of mind which are neither directly caused by conditions of the nervous organism nor representative of an object distinct from themselves. The first criterion will distinguish them from the sensitive affections; the second, from the intellectual powers properly so called. An instance will perhaps explain the distinction more clearly than a definition. A man may be affected with fear at the sight of a lion. The emotion of fear may in one sense be said to be caused by an affection of the optic nerve—the sight,—and to have an object distinct from itself—the lion; but it is neither the immediate and necessary consequence of the one, nor is it representative of the other. It is quite possible for the man to see the lion without fearing him; and it is quite possible that he should fear him if he suspected that he was concealed near him, without any sensible intimation of his presence. And though the lion is the ultimate object of the mental affection, both when we think of him and when we are afraid of him, yet he is not represented in the mind by our fear as he is by our thought. An emotion, or other internal intuition, may accompany an act either of perception or of thought, though it is perfectly distinguishable from the one and the other. The pleasure which we experience at the sight of a beautiful prospect, and the desire which we have to see it, are both distinct from the sight itself,—just as the liking for mathematical studies, and the gratification arising from the solution of a problem, are distinct from the demonstrative process itself.

OF THE PASSIONS OR EMOTIONS.

Perhaps the nearest approach to a positive definition of the passions or emotions may be found in the language of Aristotle, who describes them as *those states of mind which are accompanied by pleasure or pain*;[3] but the definition requires some explanation before it can be accepted as satisfactory. A toothache is accompanied by pain; but a toothache is not an emotion. The pursuit and acquisition of knowledge is a source of pleasure; but neither the pursuit nor the acquisition can be classed among the emotions. But it is necessary to distinguish between the bodily sensation or the mental energy, considered in itself, and the feeling of liking or disliking by which it is accompanied. The bodily sensation is not pleasant or painful *per se*, but may be the one or the other, according to the degree in which it exists. The sensation of heat, for example, up to a certain point, is the pleasant feeling of warmth; beyond that point, it is the painful feeling of burning. The sensation of touch may be pleasant or painful or indifferent, according to the nature of the body with which we are in contact, or the degree of resistance which it offers. Light, within certain limits, is pleasant to the eye; increased beyond those limits, it is dazzling and painful. The sensation itself is in no case an emotion: the feeling of liking or disliking, which accompanies it, is so. The essence of the bodily sensation consists in its being a nervous affection of a particular kind. The accident, or emotion which in certain cases accompanies it, is, that that particular affection is agreeable or disagreeable. The same may be said of the mental energies likewise. The *desire* of knowledge and the *pleasure* which it imparts are emotions: the act of pursuit and the state of possession are not so. It is perfectly conceivable that men might be so constituted as to seek after knowledge, from a rational conviction that it is their duty to do so, without deriving the slightest gratification from the pursuit or the acquisition; just as they might take food, from a conviction of the duty of preserving life, without being actuated either directly by the appetite of hunger, or indirectly by the love of life. Under this explanation, we may, with tolerable accuracy, define the emotions or passions as *those states of mind which consist in the consciousness of being affected agreeably or disagreeably*; and consistently with this point of view, an eminent modern philosopher has observed that there are, strictly speaking, but two passions,—the one arising from the consciousness of pleasure, manifesting itself in the successive stages of *joy, love*, and *desire*; the other arising from the consciousness of pain, and exhibiting the successive forms of *grief, hate*, and *aversion*.[1] The various subdivisions of these two classes are, properly, not so much distinctions in the nature of the emotion itself, as in that of the objects upon which it is exercised.

---

[1] Of this classification Sir W. Hamilton observes:—"The division of the powers into those of the *understanding* and those of the *will* is very objectionable. It is taken from the peripatetic distinction of these into *gnostic* or *cognitive*, and *orectic* or *appetent*; but the original division is far preferable to the borrowed; for, in the first place, the term *understanding* usually and properly denotes only a part—the higher part—of the cognitive faculties, and is thus exclusive of sense, imagination, memory, &c., which it is now intended to include. In the second place, the term *will* is also usually and properly limited to our higher appetencies, or rational determinations, as opposed to our lower appetencies, or irrational desires, which last, however, it is here employed to comprehend. In the third place, both the original and borrowed divisions are improper, inasmuch as they either exclude or improperly include a third great class of mental phenomena—the phenomena of *feeling*. "The distribution of our powers into *speculative* and *active* is also very objectionable. Independently of the objection common to it with that into the powers of the understanding and the powers of the will—that the feel- ings are excluded or improperly included—it is liable to objections peculiar to itself. In the first place, *speculation* or theory is a certain kind or certain application of knowledge; therefore *speculation* is not a proper term by which to denote the cognitive operations in general. In the second place, *speculation* and *knowledge* are not opposed to *action*, but to *practice* or *doing*, or, as it is best expressed in German, *das Handeln*. *Speculative* powers ought not, therefore, to have been opposed to *active*. In the third place, the distinction of *active* powers is in itself vicious, because it does not distinguish, or distinguishes wrongly. *Active* is opposed to *inactive*; but it is not here intended to be said that the cognitive powers are inactive, but merely that the action of the powers of appetency is different in kind from the action of the powers of knowledge. The term *active* does not, therefore, express what was meant, or rather does express what was not meant. It is to be observed, however, that the English language is very deficient in terms requisite to denote the distinction in question." (*Reid's Works*, p. 511.) A somewhat similar criticism has been made by Brown, Lecture xvi., who uses the term *emotions* to denote the internal intuitions in general. For the classification approved by Sir W. Hamilton himself, see the next note.

[2] Sir W. Hamilton, in the advertisement to the second volume of *Stewart's Works*, observes that, "if we take the mental to the exclusion of material phenomena, that is, the phenomena manifested through the medium of self-consciousness or reflection, they naturally divide themselves into three categories or primary genera;—the phenomena of knowledge or cognition,—the phenomena of feeling, or of pleasure and pain,—and the phenomena of conation, or of will and desire." This division, which had previously been given by Kant in his *Kritik der Urtheilskraft*, though made on a somewhat different principle, coincides to a great extent with that given in the text. The phenomena of knowledge will include the external intuitions already treated of, together with the moral judgments and the operations of thought proper. The phenomena of feeling answer to the class of emotions, and those of conation in some degree to that of volitions. But in the present article the desires are classed with the feelings, and not, as in the above-mentioned arrangement, with the will.

[3] *Eth. Nic.* ii. 5. Λέγω δὲ πάθη μὲν ἐπιθυμίαν, ὀργήν, φόβον, θράσος, φθόνον, χαράν, φιλίαν, μῖσος, πόθον, ζῆλον, ἔλεον, ὅλως οἷς ἕπεται ἡδονὴ ἢ λύπη.

Hitherto we have used the words *passion* and *emotion* as synonymous. The above remarks will suggest, in stricter language, a distinction between them, which, though by no means accurately observed either in philosophical writings or in popular use, is yet in many cases imperfectly intimated by both. To distinguish, indeed, between these terms, in strict accordance either with philosophical or general usage, is out of the question; for scarcely any two writers or speakers are in all respects consistent with each other. Sometimes emotion is a species of passion; sometimes passion is a species of emotion; sometimes the two terms are used as exactly synonymous; and at others the word *passion* is used to designate a violent degree of emotion. A more serviceable, and therefore a better, distinction than any of these may, we think, be furnished by the characteristics of the phenomena themselves,—a distinction which, though not warranted by the etymology of the two words, yet appears to express with tolerable accuracy the difference imperfectly intimated in their popular use. Our internal as well as our external intuitions have both a subjective and an objective phase, inseparable from each other, but logically distinguishable. This distinction, which in the case of our external intuitions is expressed by the terms *sensation* and *perception*, may be marked in its internal aspect by the corresponding usage of *emotion* and *passion*. The mental phenomena of this class are composed of two principal ingredients,—a consciousness of being affected agreeably or disagreeably by a certain object, and a desire to obtain or avoid, to advance or impede, the object thus affecting us. This is equally the case, whether the object affecting us be a physical good, as in the feeling of hunger; a mental enjoyment, as in the desire of honour or knowledge; or the welfare of another, as in the benevolent affections. In all alike we may trace the fundamental distinction of consciousness, the distinction between myself affected and the object affecting me, whether that object be regarded as a reality separate from myself or not. The subjective feeling of pleasure or pain may, we think, be appropriately expressed by the term *emotion*; while the objective tendency to the thing by which that emotion is caused may be indicated, not improperly, by the term *passion*, which, in its ordinary signification, appears to denote those particular propensities of our nature which, in the language of Bishop Butler, have for their objects "external things themselves, distinct from the pleasure arising from them."[2] The passions, as thus described, may be excited by an object either perceived as present, or imagined as absent; the object being in the one case presented, in the other represented. When this representation is accompanied by a conviction of the possibility or impossibility of obtaining the object, the passion assumes the form of *hope* or *despair*,—terms which, in their widest sense, do not denote special passions, but general relations in which any particular passion may stand towards its own object. But the passion, as actually existing, whether directed towards a present or an absent object, is in every case an individual state of mind, intuitively discerned as now present in consciousness.[3]

The further subdivisions of the passions may be made on various principles, and from various points of view. The general features which have been above described as characteristic of this class of mental phenomena will, in their special manifestations, be subject to various modifications, according to the nature of the object upon which they are exercised, or the constitution and training of the subject in whom they exist. To attempt a complete enumeration of the complex modes of consciousness thus arising would be impossible: we must content ourselves with selecting some one principle of division, and pointing out a few of the most important and universal of the feelings comprehended under it. Perhaps, on the whole, the least objectionable principle of classification is that derived from the various classes of objects in relation to which the emotions of pleasure and pain, and the corresponding feelings of attraction or repulsion which constitute passion, may take place. In this point of view the passions may be divided, generally, into the two classes of *desires* and *affections*, according as the object to which they are related is a *thing* or a *person*,—regarded as a possession to be sought for or avoided, or as a moral agent, capable of mutual relations of sympathy or antipathy. Under the general head of desires may be specified the *appetites*, which take their rise from bodily conditions, and are common to men and brutes,—comprising the feelings of hunger, thirst, and sexual instinct; and the *desires*, as they are sometimes called in a special sense, such as the desire of knowledge, of society, of esteem, of power, and of superiority, together with the counter feelings of repugnance to the opposite class of objects.[4] The affections embrace our social, domestic, and religious feelings in general; the love of friends, of kindred, of God, and the special modifications of feeling arising from our particular relations with individuals among our fellow-men; such as respect, gratitude, compassion, anger, contempt, and so forth. The principles of self-love and benevolence, which are sometimes included in this enumeration, should be considered, not as original intuitions, but rather as derived conceptions, in which the several personal or social passions and their respective objects, together with their moral relations and observed consequences, are generalized into the comprehensive notions of a *regard for the welfare* of ourselves or of others.

[4] For the details of this classification, see Stewart's *Philosophy of the Active and Moral Powers.*

The complete treatment of the emotions and passions belongs to the province of moral philosophy. To the metaphysician they are important, chiefly in two points of view, *psychologically*, as individual phenomena of consciousness, perceived intuitively, and therefore capable of being conceived reflectively; and *ontologically*, as regards the light which they may be able to throw on the problem of the real existence of the subject or object to which they are related. In this latter point of view they will come again under our notice hereafter.

OF THE MORAL FACULTY.

Every passion, as we have seen, is ultimately related to an object regarded as the cause of agreeable or disagreeable emotions. But between the passion and its object there is always an intervening medium of communication,—the *action* by which the object is to be obtained or avoided. Pleasure and pain, so far as they are the objects of desire and aversion, do not properly lie in the things by which they are caused, but in the actions by which those things are brought into contact with the person affected. But the actions, and in some degree also the feelings which prompt them, may be exhibited in another point of view, not merely as pleasant or painful, but as *right* or *wrong*. The existence of these terms, or their equivalents, in every language, indicates a corresponding phenomenon in the universal consciousness of mankind, which no effort of ingenuity can explain away. Indeed, the very ingenuity of the various attempts that have been made to identify the conception of *right* with that of *expedient*, or *agreeable*, or any other quality, is itself a witness against them; for no such elaborate reasoning would be required, were it not necessary to silence or pervert the instinctive testimony of a too stubborn consciousness. That the terms *right* and *wrong* indicate a special class of mental phenomena, discernible in the contemplation of actions in themselves, and not merely inferred from observation of their consequences, is a truth guaranteed by the universal language of mankind, by the testimony of every man's own consciousness, and by the inconsistencies and mutual contradictions of its several antagonists. But what are these phenomena, and by what means are they discerned? Are they qualities of actions in themselves, or states of the mind which contemplates actions? Are they simple qualities, or complex; perceived intuitively, or conceived reflectively? Are they the objects of a special mental faculty, or are they discerned by the same faculty which perceives truth and falsehood in other cases? These doubts may be summed up, in the language of Stewart, in the two following questions, which, as he says, seem to exhaust the whole theory of morals:—"First, by what principle of our constitution are we led to form the notion of moral distinctions,—whether by that faculty which perceives the distinction between truth and falsehood in the other branches of human knowledge, or by a peculiar power of perception (called by some the moral sense) which is *pleased* with one set of qualities and *displeased* with another? Secondly, what is the proper object of moral approbation; or, in other words, what is the common quality or qualities belonging to all the different modes of virtue? Is it benevolence, or a rational self-love, or a disposition (resulting from the ascendant of reason over passion) to act suitably to the different relations in which we are placed?"[1]

The two alternatives proposed in the first of the above questions represent the antagonist views of the two schools of philosophy which made common cause with each other in protesting against the denial of all natural right and wrong, which characterized the philosophy of Hobbes. The first represents the opinion of Cudworth and his followers, who refer our knowledge of right and wrong to a decision of the *reason* or *understanding*. The second is the opinion of Hutcheson and those who with him maintain the existence of a faculty of *moral perception* or *sense*. The language in which the two theories are worded, though historically accurate, as representing the views of their respective authors, is in some degree defective in philosophical precision. On the one hand, there is no single faculty of mind which distinguishes between truth and falsehood in the various branches of knowledge. The understanding or reason, taken in its widest sense, to denote the reflective faculty in general, contributes only one element to the decision. Truth and falsehood depend upon the agreement or disagreement between the representations which we make of an object in thought, and the qualities presented by that object in intuition; and this agreement or disagreement can only be ascertained by the co-operation of the two faculties. How, for instance, do we know that it is true to conceive snow as white, and false to conceive it as black? The understanding furnishes the conception; but has the sight, therefore, nothing to do with the decision? Could we answer the question by the mere act of thought, without reference to the perception of a present, or the recollection of a past fact of intuition? If there were no moral intuition, truth and falsehood could have no place in moral thought; for the conception of right or wrong, even supposing that it could exist, would be related to no facts with which it could agree or disagree. Moral truth and falsehood, like all other truth and falsehood, must consist in the agreement or disagreement of thoughts with facts; and this may take place in two different ways, as regards the mental phenomenon or the extra-mental reality. For example: I may, owing to an inaptitude for mental analysis, have an inaccurate conception of the characteristics of a moral judgment which I have myself exercised. Hence will result a false representation of the phenomenon of moral approbation. Or I may have conceptions of right and wrong, perfectly in accordance with the facts of my own consciousness, but at variance with some higher standard of right and wrong *per se*. The latter is an ontological falsehood, the criterion of which we are not yet in a position to determine. The former is a psychological falsehood, which can only be corrected by comparing the thought with the intuition to which it is related. But in neither case can the act of thought guarantee its own accuracy; else would every conception be equally true, for the sole reason that it is conceived. On the other hand, Hutcheson and his followers, as Stewart has observed, while rightly admitting the existence of a moral intuitive faculty (whether it be called *sense* or not is unimportant), unfortunately, in their description of its operation, were too much misled by a false analogy derived from the perception by the bodily senses of the secondary qualities of matter. It is no necessary part of the theory of a moral sense that it should be represented as perceiving qualities only in so far as they are *pleasing* or *displeasing*. It is true that the exercise of our bodily senses produces pleasure as well as information; but the perception of a fact is logically distinguishable from the sensation of an affection; and, however much in practice they may be united, either may be conceived to exist independently of the other. If, in like manner, we distinguish between the *moral perception* of an act as right or wrong, and the accompanying *moral sensation* of the pleasing or displeasing manner in which we are affected by those qualities, the hypothesis of a moral sense may be freed from most of the excrescences which have hitherto disfigured it in the systems of its advocates, and have afforded the chief handle to the criticisms of its antagonists.

---

[1] *Philosophy of the Active and Moral Powers*, b. ii., chap. v.

An illustrious critic of this hypothesis[1] has remarked with truth, that in our perception of the moral character of an act, whether done by ourselves or by others, we may trace the united action of a *moral judgment* and a *moral sentiment.* Our *feeling of indignation* at an act of treachery may be more or less vivid, according to our proximity to the time and place at which the act was committed, or to our relation to the doer or the sufferer. Our *condemnatory judgment* is independent of the accidents of time, place, or circumstance; we pronounce the action to be evil with the same assurance, whether it was done yesterday, or ten years, or a thousand years ago; whether the victim was our dearest friend or a complete stranger. Of these two elements of moral consciousness, the judgment is the superior, the permanent, the essential factor; the sentiment is the inferior, the fluctuating, the accidental one. The sentiment, he adds, may be due to a moral sense; but the judgment, which is derived from the universal and necessary ideas of good and evil, can belong to no other faculty than the reason.

The above analysis, though true so far as it goes, is, like that which it criticises, incomplete. The moral judgment itself may be further divided into two constituent parts; the one, an individual fact, present now and here; the other, a general law, valid always and everywhere. That this particular act of my own, at the moment of being committed, is wrong, is a fact presented immediately by the judgment of conscience. That all acts of the same kind, whensoever or by whomsoever committed, are necessarily wrong, is a judgment formed by the reason through the medium of the general notions of acts of a certain class, and of right and wrong. The latter, as an universal and necessary truth, may be referred to the same faculty, and formed under the same conditions, as other truths of the same kind. The former, as the *presentative condition of moral thought*, must be allowed to possess that chronological priority which in other cases is admitted to exist in individual facts, as compared with universal notions.

A more accurate theory of the nature and origin of moral judgment than is contained either in the moral reason of Cudworth, or in the moral sense of Hutcheson, or even in M. Cousin's union of the two, may, we think, be proposed in accordance with what has been said in the preceding pages of the complex nature of consciousness in general. It has been before observed, that every mode of consciousness, to be known as such, must possess a certain degree of clearness and distinctness, and that this is the product of the combined action of the presentative and representative faculties. The distinctions of language are doing their work; the task of education is going on; the phenomena of consciousness are assuming shape and consistency, before we are capable of discerning the various transitory conditions of our minds, or of distinguishing them one from another. A conscious act of pure moral sense, like a conscious act of pure physical sense, if it ever takes place at all, takes place at a period of which we have no remembrance, and of which we can give no account. To have a clear notion of moral obligation as such, we must have reflected upon it; and to reflect upon it, we must have obscurely experienced various acts in relation to it, and others distinct from it. At what time the notions of *good, bad,* and *indifferent,* first clearly presented themselves to the mind, it is as impossible to say, as it is to determine when we first distinctly recognised as such, and severed from each other, the visible phenomena of *white, black,* and *grey.* All that we can hope to do is, by subsequent analysis of the compound phenomenon, to detect in its composition an intuitive and a reflective element, growing by side from the first dawn of intelligence, and contributing their respective shares to the gradual development of their mutual product. Our mental, no less than our bodily constitution, testifies that we are the work of One whose judgments are unsearchable and his ways past finding out. The results alone we know; the creative process we can but darkly conjecture. "As thou knowest not what is the way of the spirit, nor how the bones do grow in the womb of her that is with child; even so, thou knowest not the works of God who maketh all."

The preceding remarks have in some degree furnished by anticipation the answer to an objection which a distinguished author has recently urged against the theory of a moral sense as usually understood. "The judgment of man," it has been said, "concerning actions as good or bad cannot be expressed or formed without reference to language, to social relations, to acknowledged rights; and the apprehension of these implies the agency of the understanding in a manner quite different from the perceptions of the bodily senses."[2] If there is any truth in the view which has been taken, in the preceding pages, of the operations of the bodily senses, it appears that the perceptions of these also are not so independent of the agency of the understanding as is usually supposed; and that there is at least sufficient analogy between our physical and moral intuitions to justify the metaphorical use of the term *sense,* to denote the mode of action of the latter. But there still remains a point in which the ordinary theory needs correction. It is commonly said, that by the operation of the moral sense we perceive immediately the character of acts, whether done by ourselves or by others. The assertion that we are immediately conscious of the morality of another person's actions, appears to be an error of the same kind in relation to our moral perceptions, as the assertion that we are immediately conscious of the past in memory is in relation to our bodily senses. To be directly conscious that this act, now being committed, or about to be committed, is right or wrong, I must be directly conscious of two things: of a law of obligation, commanding a certain person to act in a certain way, and of the course now before that person, as agreeing or disagreeing with such law. But I cannot be directly conscious of a law of obligation as it exists in another person's mind: I can only infer its existence by *representing* his mind as similarly constituted to my own. If man were not a free agent, his acts, whether beneficial or hurtful in their physical results, could have no moral character as right or wrong. But I cannot be immediately conscious of the free agency of any other person than myself; and, were it not for the direct testimony of my own consciousness to my own freedom, I could regard human actions only as necessary links in the endless chain of phenomenal cause and effect. It is obvious, therefore, that the intuitive perception of moral qualities cannot extend beyond our own actions, in which alone we are directly conscious of a law of obligation and of a voluntary obedience or disobedience to it. The actions of other men may be known presentatively in their material aspect as beneficial or hurtful; for this is a relation external to the mind of the agent. They cannot be presentatively known in their moral aspect as good or evil; for this is an internal relation, existing in the hidden depths of another's consciousness.

---

[1] M. Cousin. See his review of Hutcheson's system. *Cours de* 1819, Leçon 14.

[2] Whewell, Preface to Butler's Three Sermons.

The substance of the above remarks may be briefly summed up as follows:—Moral consciousness, in the only form in which it can be distinctly recognised in the mind, consists, like all other consciousness, of a presentative and a representative element; the one being necessary to its first formation, the other to its completeness and recognition as what it is. Neither reason alone, nor sense alone, can account for the existence of the moral judgment as a fact of consciousness, whether we regard it in its subjective aspect, as an emotion, pleasant or painful, analogous to sensation proper, or in its objective aspect, analogous to perception proper, as exhibiting a voluntary act in relation to a law. The presentative element must be referred to a special faculty of moral intuition or sense,—in one word, to avoid more objectionable phrases, to *conscience*,—whose object, like that of all intuitions, is an individual phenomenon now present:—a special faculty, we say, in the only point of view in which the mind can be said to have distinct faculties at all, namely, on the ground of a difference of which we are conscious in the corresponding objects. The representative element, on the other hand, in common with all other general notions, may be referred to the single faculty of the *understanding*.

Up to this point the moral problem is properly psychological; its purpose being only to determine what are the characteristic features and origin of the moral judgment, regarded as a fact of consciousness. The second question which Stewart proposes as completing the theory of morals,—"What is the proper object of moral approbation? or what is the common quality or qualities belonging to the different modes of virtue?"—is one which belongs not to psychology, but to moral philosophy, which, in this point of view, may be considered as a branch of ontology; its office being to inquire into the nature of virtue, regarded, not as a mental perception, but as an extra-mental reality. The moral decisions of conscience cannot by themselves be the ultimate criterion of right and wrong; for if so, whose conscience is to be taken as the standard? If the individual conscience is ever mistaken in its judgments; if crimes can ever be committed which seem no crimes to the perpetrator, there must be a standard of right and wrong *per se*, by which our moral intuitions and our moral conceptions must both, in ultimate appeal, be tested. To ask what this standard is, though the most important of all questions in speculative morals, would be out of place here; the only legitimate office of the psychological inquirer being to analyse and exhibit the characteristic features of the mental phenomenon of moral approbation.

OF VOLITION.

The correlative terms, *will* and *volition*, are usually distinguished, in the language of philosophy, as applying, the one to the general faculty, the other to the special acts in which it manifests itself. A volition is an act of the will; and our several volitions are classified as proceeding from one and the same faculty. *Will*, then, like *sense* and *reason*, does not indicate a special phenomenon of consciousness; but is a general name for the power from which special phenomena proceed, and which itself exists in consciousness only as it is manifested in operation. The examination, therefore, of this portion of our consciousness must be attempted in relation to the internal acts, which, in the usual language of philosophy, are denominated *volitions*.

That volition is not identical with desire, and cannot properly be classed with the phenomena of emotion, was one of the earliest results of psychological analysis, and is, indeed, obvious to the consciousness of every man who has experienced the two, however much they may have been confounded together by the perversity of a few unscrupulous system-makers. A man may be thirsty, and yet refuse to drink; his desire drawing him one way, and his will determining him in the other.[1] Desires are not under our own control; they arise naturally and necessarily on the occasion of the presence of objects which affect us agreeably or disagreeably. We cannot help being so constituted as to derive pleasure from certain objects; we cannot help feeling attracted to pleasant objects, for the pleasure constitutes the attraction. But we can help yielding to the attraction of desire when felt; and we can help putting ourselves in the way of feeling it. Desire may be vicious as well as action; but only in so far as either is combined with volition. I may place myself in the way of desirable objects, and, in so doing, my act is voluntary. I may give my attention to thoughts calculated to excite desire, and the attention is a voluntary act; but in the mere fact that an object, when present, no matter how its presence is procured, raises a corresponding emotion in the mind, there is no volition, and consequently no moral character. Hence it has long been established as a canon in morals by the soundest writers on the question, that virtue and vice depend, not in the existence of desires, but on their relation to the will.[2]

But volition must be further distinguished, both from the judgment which precedes, and from the external act which follows it.[3] For example, a man determines to take a walk for the benefit of his health. The feeling that health is desirable is not voluntary: the conviction that walking is beneficial to health is not voluntary. The one is an emotion, which by his constitution he cannot help having: the other is a relation between natural cause and effect, which he cannot make other than it is, and cannot judge to be other than he knows it to be. But, while conscious that health is desirable, and while conscious that walking promotes health, he is also (and this forms a distinct phenomenon) conscious that it is in his own power to take or not to take the means necessary to the end. We cannot at present inquire how far this consciousness of power answers to any corresponding reality in the nature of things. We are not yet in a condition to examine the paradox maintained by some philosophers, that consciousness deludes us with a fallacious appearance of liberty. We are concerned only with the mental phenomenon that a man does, in certain states of consciousness, feel possessed of a power of choosing between two alternatives, which in certain other states he does not feel. But again: Suppose that the man determines to walk, but finds himself, by a sudden stroke of paralysis, deprived of the use of his limbs: here again we must distinguish between the fact of determination, which is always in our own power, and the fact of bodily motion, which may or may not be in our own power, according to circumstances. The power of locomotion (I do not now speak of that of muscular effort) is not, properly speaking, a fact of consciousness at all; that is to say, it is not a fact whose existence is identical with our knowledge of its existence. We may suppose the case of a man whose limbs have become paralysed without his being aware of it. The conscious portion of the effort to move is the same as before, but the physical sequence is interrupted. Or we may suppose the act of motion to take place as a consequence of volition, without the person being conscious of the relation between the volition and the act. The latter supposition, indeed, is actually true in all cases; for motion is the remote, not the immediate, consequence of volition; and between the one and the other there is an intervening nervous and muscular action, of which we not only are not conscious in the act of moving, but which we may pass a whole lifetime without discovering.

[3] Cousin, *Cours de* 1819, Leçon xxiii. *Cours de* 1829, Leçon xxv.

Some philosophers of no small eminence, especially in this country, have maintained that we are not directly conscious of mind or self, but only of its several modifications.[1] It is in relation to the phenomena of volition that the error of this theory is most manifest. If, in the mental state which corresponds to the judgment, *I will*, there is no consciousness of *I*, but only of *will*, it is impossible to place the essential feature of volition, as has been done above, in *the consciousness of myself having power over my own determinations*. *Will*, and not *I*, being the primary fact of consciousness, the causative power of volition must be sought in the relation between will and some subsequent phenomenon; and so sought, it will assuredly never be found.[2] It cannot be found where Locke sought it,—in the relation between the determination of the will and the consequent motion of the limb; for the determination is not the immediate antecedent of the motion, but only of the intervening nervous and muscular action. I cannot, therefore, be immediately conscious of my power to move a limb, when I am not immediately conscious of my power to produce the antecedent phenomena. Nor yet can the causative power be found where Maine de Biran sought it,—in the relation of the will to the action of the nerves and muscles; for this relation may at any time be interrupted by purely physical causes, such as a stroke of paralysis; and in that case no exertion of the will can produce the desired effect. We can escape from this difficulty—the stronghold of scepticism and necessitarianism—by one path only, and that is by a more accurate analysis of the purely mental state, which will discover an immediate consciousness of power in *myself determining my own volitions.*

The essential characteristic of volition, as presented to the mind, consists in *the consciousness of a power of choosing between two alternative determinations*. But, by a natural association, as in the case of the acquired perceptions, we are led to connect the volition with its most striking, not with its most immediate consequence, and thus to believe that we have an immediate consciousness of our power to move the limbs of the body. The latter act is indeed voluntary, as being the foreseen, though remote, consequence of a volition; the remoteness of the consequence not affecting the moral responsibility; just as a man who shoots another is guilty of murder, though his immediate act is not to inflict the wound, but to pull the trigger. But the connection between volition and its remote consequences is not *presented* in consciousness, but *inferred*. The importance of the will as an element of consciousness, and its influence upon the other phenomena, may be in some degree estimated by comparing the characteristics of consciousness in its ordinary state with those which it presents during a *dream*. In the latter state the functions of volition, properly so called, are altogether suspended.[3] We may seem to ourselves to act as well as to suffer; but the action is not accompanied by a consciousness, at the moment of its performance, of a power to act otherwise. In other words, our actions during a dream are *spontaneous*, but not *voluntary*, being never presented to the consciousness in the form of a choice between two alternatives. Hence our inability during sleep to break off or change the direction of the train of ideas which is passing through the mind. Hence, too, the absence of all power of reflecting upon those ideas; and the natural consequence, that fancies the most absurd, and events the most improbable, are never at the time discerned as being so. It is impossible to compare the events of a dream with the natural course of things; for to do so we must make a voluntary effort to recal the latter to mind;—we must will to withdraw our attention from the phenomenon before us, and to fix it upon the remembrance of our past experience. It may be conjectured, with all the probability of which conjectures on such points are susceptible, that if man were, as so many philosophers have maintained, a necessary agent, determined even in his volitions by antecedent phenomena, his waking state would resemble that of a dream: he would be astonished at nothing. Astonishment, as Plato and Aristotle have said, is the commencement of philosophy.[4] When we examine, compare, judge, and pronounce sentence upon the phenomena of our own consciousness, we assert our right to a place distinct from, and superior to, that of a mere link in the chain of phenomena; we exercise the privilege of our conscious existence as beings above phenomena; though the being and the phenomenon are manifested together as parts of one and the same complex act of consciousness.

We may notice, in conclusion, the light that is thrown, by the phenomena of dreaming, on some of those remarkable cases of passive subjection to another person, which, under the names of Mesmerism, Hypnotism, or Electro-Biology, have of late years excited so much public attention, and given rise to such strange and unfounded theories of physical or hyperphysical agency. These states exhibit, in their ordinary features, little more than the mental phenomena of sleep without the accompanying bodily conditions. The mental phenomena of sleep exhibit two principal characteristics:—1. They show the power of the mind to produce, by its internal agency, sensible phenomena, having all the vividness and apparent reality of those communicated by impressions from without. 2. They show that the mind, under certain circumstances, may be so completely under the influence of a leading idea as to follow passively the train of associations suggested, without the slightest power of judging of their truth or falsehood, probability or absurdity. The principal difference between these phenomena and those of the above-mentioned states consists in the circumstance that the leading suggestion is, in the latter case, conveyed from without, by the operator, instead of from within, by the patient's own mind. Is there any necessary law of connection between the mental state of

[2] Cousin, *Fragments Philosophiques*, Preface de la prémière edition.

[3] Stewart, in one of the most interesting chapters of his *Elements of the Philosophy of the Human Mind*, argues that the power of volition itself is not suspended during sleep, but only the influence of the will over the thoughts and actions. But he has not sufficiently distinguished between merely *spontaneous* acts and those which may properly be called *voluntary*. We are conscious in a dream of making an effort; but we are not conscious at the moment that it is in our power not to make it. Thus, though the active function of the mind is retained, the essential feature of volition has disappeared. This remark, however, applies only to the conscious exercise of volition in determining our own mental states. It is probable that spontaneity itself is but a lower form of volition; and attention, in which some amount of volition is always implied, seems to be a necessary condition of all consciousness, sleeping or waking. At any rate, it is necessary to recollection; and thus the phenomena of dreaming would, without some co-operation of the voluntary energy, either not take place at all, or be to the waking man as though they had never been.

Psychology.

suspended volition and the bodily state of suspended susceptibility to external impressions? If, by any artificial means, the former of these states can be produced without the latter (and this is partially the case, even without artifice, in reverie and absence of mind), we have a link to connect these psychological marvels with the most familiar facts of our everyday experience.[1]

OF THE CONSCIOUSNESS OF PERSONALITY.

The universal language of mankind has established a distinction between the capacities of mind and matter, which philosophy has often, but in vain, attempted to explain away. We speak of the *properties* of material agents, of the *faculties* of the human mind.[2] It is a *property* of fire to burn, of metals to conduct electricity, of a tree to bear fruit after its kind. Sensibility, memory, reason, are *faculties* of the mind. Yet the attributes of mind, as well as those of body, are known only by their effects. I know that I have a power of thinking, only because I actually think,—as I know that fire is capable of burning, only because it actually burns. What, then, is the distinction between the nature of intelligent and unintelligent beings, to the existence of which our language instinctively bears witness? The foundation of the distinction is to be found in the *consciousness of self*. Whatever variety of phenomena may succeed one another within the field of consciousness, in all alike I am directly conscious of the existence of one and the same indivisible self, the centre and the possessor of each and all. Let system-makers say what they will, the unsophisticated sense of mankind refuses to acknowledge that mind is but a bundle of states of consciousness, as matter is (possibly) a bundle of sensible qualities. There may be no material substratum distinct from the attributes of extension, figure, colour, hardness, &c. Matter may be merely a name for the aggregate of these, for we have no immediate consciousness of anything beyond them; but, unless our whole consciousness is a delusion and a lie, *self* is something more than the aggregate of sensations, thoughts, volitions, &c. Our whole consciousness is manifested as a relation between a permanent and a changeable element,—a conscious self, affected in various manners. The notion of a state of consciousness, with no one to be conscious of it, is as absurd as the opposite fiction of a conscious self with nothing to be conscious of. If the latter has given rise to the extravagances of rational psychology, the former is the basis of a not less extravagant reaction, which in its logical consequences leads to the consistent denial of personality, of freedom, of responsibility; nay, of the very conceptions of substance and cause, the foundations of all philosophy.

Consciousness is given to us as a relation; and no effort of analysis can separate the two correlatives; for analysis is itself an act of consciousness, and contains the same relation. We cannot conceive either factor of consciousness apart from the other; but, on the other hand, we cannot annihilate either in conceiving their product. We cannot analyse the judgment *I will*, and set an abstract *I* on the one side, and an abstract *will* on the other; but neither can we conceive the entire judgment, save as the product of two constituent elements. Whatever may be the variety of phenomena of consciousness,—sensations, volitions, thoughts, imaginations,—of all we are immediately conscious as affections of one and the same self. It is not by any subsequent effort of reflection that I combine together sight and hearing, thought and volition, into a factitious unity or compounded whole: in each case I am immediately conscious of *myself* seeing and hearing, thinking and willing. This personality, like all other simple and immediate presentations, is indefinable; but it is so because it is superior to definition. It can be analysed into no simpler elements; for it is itself one element of a product which defies analysis. It can be made no clearer by description or comparison; for it is revealed to us in all the clearness of an original intuition, of which description and comparison can furnish only faint and partial resemblances.

Relation is the law of consciousness, and relation is the end of philosophy; for philosophy is only the articulate expression of consciousness. *Cogito, ergo sum*, may indicate a legitimate passage from thought to being, from psychology to ontology; but the thought and the being alike are manifested only in the form of relation. Whether that dualism, which in another country has become a byeword for unphilosophical thinking, may be made the basis of a sounder philosophy than the mutilated and shapeless fragment which aspires to the name of unity, is a question which is probably reserved for a future generation to answer. This much, however, appears to be proved by experience as well as testified by reason, that it is hopeless to attempt to found philosophy on the annihilation of consciousness.

We have now described the principal phenomena of the intuitive consciousness, in which are presented to us individual states of the mind in relation either to itself or to the material world. We have next to describe the phenomena of the reflective consciousness, in which the several intuitions, external or internal, are represented under general notions, and thus become objects of thought.

OF REPRESENTATIVE OR REFLECTIVE CONSCIOUSNESS.

The term *representation* has been used by philosophers in various senses. In the Leibnitzian and subsequent philosophies of Germany, this word, or its German equivalent *Vorstellung*,[3] is employed to denote any cognitive act, including even those obscure cognitions, as they are termed by Leibnitz, which do not amount to a conscious apprehension of an object as such. Thus Kant includes under the common genus of *representation* the successive subclasses of representation with consciousness, or *perception;* which is divided into subjective perception, or *sensation*, and objective perception, or *cognition;* the latter containing under it immediate cognition, or *intuition*, and mediate cognition, or *conception*.[4] On the other hand, Sir William Hamilton, distinguishing between *presentative* and *representative knowledge*, and rightly referring the perceptions of the senses to the former class, uses the term *representation* to denote exclusively the cognition of individual objects by means of images resembling them.[5] Representation, thus distinguished, is synonymous with imagination, and does not include the operations of thought properly so called, which have for their immediate object general notions or concepts. In the present article it has been found convenient to adopt an intermediate course. Kant's extension of the term *representation*, to include the intuitions of sense, involves, even on his own theory of sensitive perception, at least an unnecessary ambiguity of language. The intuition, on that theory, is representative of nothing that can possibly come within the sphere of consciousness, but of an unknown and unknowable *thing in itself*, or absolute reality out of all relation to human faculties. Concepts, on the contrary, are representative of intuitions, from which they are originally derived, and whose place they

Psychology.

occupy in the processes of thought. But it is obvious that, in the analysis of consciousness, the thing in itself, being *ex hypothesi* unknown and unknowable, may be dropped out of our reckoning altogether. The intuition, or consciousness of an individual object, being the commencement of our knowledge and the point beyond which it cannot penetrate, may be more accurately described as a state of *presentative consciousness*, of which thought, or *representative consciousness*, is the reflective sequel. On the other hand, Sir W. Hamilton, by confining the term *representation* to those modes of consciousness in which there is an actual and adequate imagination of an object, has perhaps narrowed the term too much from its original meaning, and restricted it to a sense which, however convenient in the controversy concerning perception, is, out of that controversy, unnecessary and likely to mislead. The general notion of *man* is representative of many individuals in their common qualities, and of any one individual, so far as those qualities are concerned, as much as the image which the mind forms of James or John is representative of the proper characteristics of that person. The notion is generalized from the individuals, and must be ultimately verified by reference to them; and, though not resembling the individuals, and therefore incapable by itself of being depicted in the imagination, it becomes their substitute in the act of thought, just as the written word, which likewise bears no resemblance to the sound of speech, becomes the substitute and representative of the word spoken. In one respect, indeed, the thought proper may be called *representative* in a stricter sense than the imagination; for the imaginative consciousness, though representative, is presentative also, and, so far, has more affinity to sense than to thought. It is presentative of the image, which is itself an intuition, as well as representative of the object of sense. But the concept, so far as its object is concerned, is purely representative. It presents nothing on which the mind can rest as an adequate object of consciousness,—nothing which is not in its nature obviously incomplete and relative,—nothing, in short, but the fact of thinking at a particular time, and the sign in which the thought is exhibited.

Representative consciousness, like presentative, cannot be considered as forming a complete act by itself. The phenomena of intuition by themselves present nothing but a confused impression of diversity, until they are classified and distinguished from each other under separate general notions; and the notion, on the other hand, though in the ordinary exercise of thought it may be employed apart from the consciousness of the object which it represents, can only be so separated by being associated with a further representation of itself, such as is furnished by the symbols of language. Pure thought, if by that expression is meant the consciousness of general notions and of nothing else, is an operation which may perhaps be possible to higher intelligences, but which never takes place in the human mind. Our only choice lies between notions as exemplified in individual objects, and notions as represented in signs spoken or unspoken; for the sign, the clothing of our thought, accompanies our silent meditations as well as our audible utterances: εὐφήμον στόμα φροντίδος[1] is not a mere poetical metaphor, but the literal statement of a philosophical fact. Thinking, as Plato has observed,[2] is but the conversation of the soul with herself; and the instrument employed is the echo of that which forms the medium of communication with others. To this it may be added, that the notion, as represented in language, is but the substitute for the notion embodied in intuition, and derives all the conditions of its validity from the possibility of the latter; for language, though indispensable as an instrument of thought, lends itself with equal facility to every combination, and thus furnishes no criterion by which we can judge between sense and nonsense—between the conceivable and the inconceivable. *A round square*, or *a bilinear figure*, is, as a form of speech, quite as possible as *a straight line* or *an equilateral triangle*. The mere juxtaposition of the words does not indicate the possibility or impossibility of the corresponding conception, until we attempt to construct, by intuition, an individual object in accordance with it. Language, like algebra, furnishes a system of signs, which we are able to employ in various relations without at the moment being conscious of the original signification assigned to each. But what our thoughts thus gain in flexibility they lose in distinctness, and the logical and algebraical perfections are thus in an inverse ratio to each other. It therefore becomes necessary, at the end of the process, and even occasionally during the intermediate stages, to submit the result to the test to which each step has been tacitly assumed to conform; namely, the possible co-existence of the several groups of attributes in corresponding objects of intuition.[3]

From this use of language in thought arises the distinction, originally pointed out by Leibnitz, between *intuitive* and *symbolical* cognition. In the former we deal with the notions themselves, as exemplified in an individual object of intuition, real or imaginary. In the latter we deal with the same notions as represented by their symbols in language. The latter, however, is rather a substitute for consciousness than an act of consciousness itself. It implies a consciousness, indeed, of the act of thinking, but not immediately of the object about which we think.[4] Like the bank-note, it is the representative of value without having an intrinsic value of its own; and, like the bank-note, its real worth depends on the possibility of its being at any time changed for the current coin of the realm. But, as in practice the note is treated as if it were the money which it represents, so it will be convenient, in the following remarks, to treat symbolical knowledge as if it were itself the complete consciousness to which, if valid, it may be at any time reduced. We shall therefore treat both of intuitive and symbolical reflection under the general name of Representative Consciousness or Thought.

[2] *Theætetus*, p. 190. "Εγωγε τὸ δοξάζειν λέγειν καλῶ· καὶ τὴν δόξαν λόγον εἰρημένον, οὐ μέντοι πρὸς ἄλλον οὐδὲ φωνῇ, ἀλλὰ σιγῇ πρὸς αὑτόν.

[3] "Plerumque, præsertim in analysi longiore, non totam simul naturam rei intuemur, sed rerum loco signis utimur, quorum explicationem in præsenti aliqua cogitatione compendii causa solemus prætermittere, scientes aut credentes nos eam habere in potestate: ita cum chiliogonum, sec polygonum mille æqualium laterum cogito, non semper naturam lateris, et æqualitatis, et millenarii (seu cubi a denario) considero, sed vocabulis istis (quorum sensus obscure saltem atque imperfecte menti obversatur) in animo utor loco idearum, quas de iis habeo, quoniam memini me significationem istorum vocabulorum habere, explicationem autem nunc judico necessariam non esse; qualem cogitationem *cœcam*, vel etiam symbolicam appellare soleo, qua et in algebra, et in arithmetica utimur, imo fere ubique." (Leibnitz, *Meditationes de Cognitione Veritate et Ideis.*)

[4] Cognitio quæ ipso idearum intuitu absolvitur, dicitur *intuitiva*, seu, rem intuitive cognoscere dicimur, quatenus ideæ ejus, quam habemus, nobis sumus conscii. E. gr. Dum arborem præsentem intueor, mihique conscius sum eorum quæ in eadem obtutu comprehendo, intuitivam arboris habeo cognitionem. Si triangulum mihi vi imaginationis tanquam in tabula delineatum, vel asserem triangularem representem, atque hujus figuræ mihi conscius sim; triangulum intuitive cognosco. Quodsi cognitio nostra terminatur actu quo verbis tantum enunciamus quæ in ideis continentur, vel aliis signis eadem repræsentamus, ideas vero ipsas verbis aut signis indigitatas non intuemur, *cognitio symbolica* est. Ita cognitionem symbolicam habeo trianguli, si cogito ipsum esse figuram tribus lineis terminatam, trianguli vero ideam nullam, multo minus linearum quibus terminatur, ac numeri ternarii earundem, ideas intueor. Similiter cognitionem chiliogoni symbolicam habeo, si verbis tacite quasi loquens mihi ipsi indigito, chiliogonum esse figuram mille lateribus terminatam, laterum vero singulorum, ac numeri millenarii, ipsiusque chiliogoni ideam nullam intueor. Quod etiam signis aliis uti possimus ad res nobis repræsentandas, præter verba, vel sola arithmetica loquitur, ubi singularibus utimur notis numericis ad numeros quoscumque repræsentandos. Habes igitur hic signa numerorum quæ sunt a verbis, quibus enunciantur, diversa. Luculentiora exempla analysis recentiorum quam algebram vulgo dicimus suppeditat, ubi formulis ex literis atque signis aliis compositis notiones rerum exhibemus." (Wolf, *Psychologia Empirica*, sect. 286, 289.

OF THE FORM AND MATTER OF THOUGHT.

The form of consciousness in general has been explained as consisting in *relation to a conscious subject*. The form of representative consciousness in particular must be ascertained by observing in what manner the subject, as a thinker, moulds into thought the raw materials furnished by intuition. The conditions under which this is done constitute the *laws of thought;* and the feature by which these laws are manifested in the product will be the *form of thought*. The former of these terms is strictly used with reference to an act of thought; the latter, with reference to its product. Conceiving, judging, and reasoning are carried on under certain *laws*. Concepts, judgments, and reasonings exhibit certain *forms*. To ascertain what these are, we must endeavour to analyse the complex act of consciousness, and to separate those elements which appear to be contributed by the reflective act of the conscious subject.

The office of thought consists in arranging the confused materials presented to it in such a manner as to constitute *an object*. This is done by *limitation* and *difference*. The object, as such, must contain a definite portion of the materials, and a portion only. Without the first of these conditions, there would be no contents out of which the object could be constructed: without the second, there would be no distinct representation of an actual object, but a confused and imperfect consciousness of the universe of all possible objects. An oak, for example, to be discerned as an oak, and as nothing else, must have certain constitutive features of its own; and these must in thought be separated from those of the surrounding objects. These two conditions of all thought, expressed in the most general terms, are the well-known logical laws of identity and contradiction, *A is A*, and *A is not not-A;* that is to say, every object, to be conceived as such, must be conceived as having a contents of its own, and as distinct from all others. But these two conditions necessarily involve a third. The object which I distinguish and that from which I distinguish it must constitute between them the universe of all that is conceivable; for the distinction is not between two definite objects of thought, but between the object of which I think and all those of which I do not think. *Not-A* implies the exclusion of A only, and of nothing else, and thus denotes the universe of all conceivable objects with that one exception. This relation, in its most general expression, constitutes a third law of thought,—that of excluded middle: *every possible object is either A or not-A*. (*Principium exclusi medii inter duo contradictoria*.) These three principles of identity, contradiction, and excluded middle, constitute the laws of *thought as thought*, and are the foundation of pure or formal logic.

Every complete act of consciousness is a compound of intuition and thought; and the portion which is due to the act of thought as such, conducted under the above laws, will be the *form of the representative consciousness*. Now, by the act of thought, the confused materials presented to the intuitive faculties are contemplated in three points of view: as a single object, as distinguished from other objects, and as forming, in conjunction with those others, a complete class or universe of all that is conceivable. We have thus the three *forms* (or, as they are called by Kant, *categories*[1]) of *unity*, *plurality*, and *totality;* conditions essential to the possibility of thought in general, and which may therefore be regarded as *à priori* elements of reflective consciousness, derived from the constitution of the understanding itself, and manifested in relation to all its products. They are thus distinguished from the *matter*, or empirical contents, by which one object of thought is distinguished from another. The matter of thought is derived from the intuitive faculties, and consists in the several *presented phenomena* which form the special characteristics of each object, as a man, a house, a tree, &c. In order to exhibit this distinction more completely, it will be necessary to notice in detail the different operations into which thought is ordinarily divided.

OF THE SEVERAL OPERATIONS OF THOUGHT.

The ordinary division of the representative faculties into conception, or simple apprehension, judgment, and reasoning, is properly a logical rather than a psychological division, and relates to the products of thought rather than to the powers or operations by which those products are generated. Viewed as products of thought, projected, as it were, out of the thinking mind, and embodied in language, the concept, the judgment, and the syllogism are expressed in different forms of speech, are susceptible of different relations one with another, and are subject to different logical rules and tests of validity. For logical purposes, therefore, they may properly be regarded as distinct objects, though susceptible of treatment upon common principles; just as the different works of the same artist, though the result of the same productive power, may be arranged in different classes and criticised from different points of view. But the logical division of products does not necessarily imply a corresponding psychological division of faculties. The same faculty, operating by the same laws, may produce different results according to the nature of the objects submitted to it; just as the same artist may produce different works out of different materials. It is necessary, therefore, before we transplant our logical divisions into the field of psychology, to inquire upon what principles the latter science is justified in distinguishing at all between various powers of the human mind.

The only natural and necessary principle of distinction between objects is the numerical diversity of individuals. All other divisions are, to a certain extent, arbitrary and artificial, and subservient to the special purposes of this or that branch of study. The naturalist may class the man and the ape together, on account of certain points of similarity in their physical structure; the moralist will place them as widely as the poles asunder, as rational and irrational, responsible and irresponsible agents. But no possible system of arrangement can make Socrates the same individual as Plato, or regard an act performed to-day as numerically one with a similar act performed three days ago. Numerically, not only intellectual operations of various kinds, but every single act of each kind, is distinct from every other. An act of reasoning which I perform today is *numerically* distinct from any similar act performed yesterday; though both may be governed by the same laws, and applied to the same objects. But in the classification of acts as *specifically* the same or different, much must depend on the purpose which we have in view, and on the utility of certain relations for certain ends. A distinction which is useful for the purposes of logic may be worthless or injurious as regards psychology.

---

[1] Besides these three, which are classified as categories of quantity, Kant enumerates nine others, viz., three of quality,—reality, negation, and limitation; three of relation,—inherence and subsistence, causality and dependence, and community or reciprocal action; and three of modality,—possibility or impossibility, existence or non-existence, and necessity or contingence. But the Kantian categories are not deduced from an analysis of the act of thought, but generalized from the forms of the proposition, which latter are assumed without examination, as they are given in the ordinary logic. A psychological deduction, or a preliminary criticism of the logical forms themselves, might have considerably reduced the number. Thus the categories of quality are fundamentally identical with those of quantity,—reality, or rather affirmation and negation, being implied in identity and diversity, and limitation in their mutual exclusion. The remaining categories are, to say the least, founded on a very questionable theory in logic; and the two most important—those of substance and cause—present features which distinguish them from mere forms of thought. But these will have to be examined hereafter.

The distinction between various faculties of the internal consciousness, if made at all, must be made on a principle exactly the reverse of that by which a similar distinction is made with respect to the external senses. The bodily organs of sensation are given as locally and numerically distinct from each other, and thus furnish a pre-existing basis for the classification of their several operations. Seeing and hearing are not only distinct phenomena of consciousness, but are performed by means of distinct organs; and the faculty of seeing is at any rate so far distinct from that of hearing, that a man may be blind without being deaf, and deaf without being blind. But as regards the internal consciousness, we have no other ground for discriminating between different faculties than that which is furnished by the mental characteristics of the corresponding acts. We do not classify the acts from an acknowledged diversity of the faculties; but we attempt to classify the faculties from some admitted or supposed diversity in the acts. The acts, therefore, must, on independent grounds, be determined to be identical or distinct in species, before we can unite or separate them as related to the same or different mental powers.

The distinction between the various reflective faculties is therefore not so much to be considered with regard to its truth or falsehood as with regard to its convenience or inconvenience. The theory of distinct mental organs corresponding to distinct acts of thought is untenable on any hypothesis but that of the crudest materialism. No soberminded pyschologist ever intends to represent the mental faculties as substantially and numerically distinct portions of the mind; but, as *entia rationis*, they may furnish more or less convenient heads of classification, to connect or distinguish the similar or dissimilar mental acts or states of which we are successively conscious. In this point of view, the phenomena of conception, judgment, and reasoning, viewed merely as acts of thought, without reference to the diversity of the data from which the act commences and with which it deals, appear to furnish far more prominent features of similarity than of difference. They are effected by the same means; they are governed by the same laws; they are confined within the same limits; they admit of the same distinctions of material and formal validity. The pyschological analysis of any one may be applied, almost in the same words, to the others; and, so far as thought alone is concerned, the same mental qualities are manifested in the right performance of each. In a psychological point of view, to enumerate separate mental faculties and operations, as giving rise to the various products of thought, is, to say the least, to encumber the science with unnecessary and perplexing distinctions. It will be sufficient to refer them to the single faculty of *thought* or *reflection*, the operation of which is, in all cases, *comparison*. The unit of thought is always a judgment, based on a comparison of objects; and the several operations of thought are, in ultimate analysis, nothing more than judgments derived from different data. In order to exhibit this in special instances, it will be convenient to adopt provisionally the logical classification, and to examine the phenomena of thought under the several heads of conception, judgment, and reasoning.

OF CONCEPTION.

The ultimate object of all complete consciousness, intuitive or reflective, is, as has been already stated, an *individual;* that is to say, an object occupying a definite position in time, or space, or both. It is not, however, necessary that the individual so presented to consciousness should be discerned as such by any distinctive features. We must distinguish between an individual act of consciousness and an individual object viewed out of relation to that act. The conditions of time and space are sufficient to distinguish *the act* from every other act, and the object *at the moment of perception* from every other object; but they are not parts of *the object itself;* and they furnish no marks by which that object may be *permanently* distinguished from others. The same object may occupy different places at different times; or different objects may successively occupy the same place. Hence, in addition to these conditions, which serve only for the intuitive cognition of a single individual at a particular moment, it is necessary to select others, which may serve as marks for the reflective cognition of an individual, as such, when different objects are compared together. In any given intuition we may or may not be conscious of marks sufficient for this purpose. I may see, for example, at a distance, three men standing together. They are unquestionably three individual men, each occupying his own position in space; and this at the moment is sufficient to distinguish them from each other. But I may be unable, on account of the distance, to discern any distinctive features belonging to the objects themselves. I discern them as three men, and that is all. I cannot say whether they are fair or dark, tall or short, acquaintances or strangers. I can distinguish them by nothing but their relative positions; and these may at any moment be changed without my being able to discover it. In other words, I perceive in the individuals only such qualities as are characteristic of a class.

The above example may serve to illustrate the process of *imperfect or intuitive generalization,* which consists in directing the attention, voluntarily or involuntarily, to the common features of several objects presented to us, neglecting or not perceiving those qualities which are peculiar to each.[1] It is not a distinct cognition of the class as a class, nor of the individuals as individuals; but a confused perception of both together. To form a complete cognition of the individual, I must, by the aid of imagination, supply those distinctive features which I am unable clearly to perceive. To form a complete cognition of the class, I must separate the common attributes from their connection with a definite time and place. But how are attributes, apart from their juxtaposition in space, to be so connected together as to constitute a single object? The head and trunk and limbs of an individual man are connected together by continuity in space, and by that continuity constitute a whole of intuition, whether distinctly recognised in that relation or not. How are the attributes of mankind in general to be separated from their position in space, and yet so united together as to constitute a whole of thought? To effect this, we must call in the aid of language. The word is to thought what space is to perception. It constitutes the connecting link between various attributes,—the frame, as it were, in which they are set,—and thus furnishes the means by which the features characteristic of a class may be viewed apart from the individuals in which they are intuitively perceived, and combined into a complex notion or concept. Conception is thus, in the operations of thought, the counterpart of perception in those of sense. In the latter we are conscious of objects as extended; *i.e.*, as possessing parts related to each other by juxtaposition in space. In the former we are conscious of notions as embodied in words, and as composed of subordinate notions, which are themselves also expressed by similar symbols.

---

[1] " *Si in cognitione intuitiva acquiescimus, prima intellectus operatio absolvitur, dum in ideis duorum vel plurium individuorum simul nobis occurrentibus ad ea successive attentionem dirigimus quæ in iisdem eadem sunt.* Dum enim attentionem nostram successive dirigimus ad ea quæ in ideis duorum vel plurium individuorum simul nobis occurrentibus eadem sunt; magis nobis conscii sumus quod jam in pluribus eadem percipiamus, quam quod percipiamus alia, atque adeo operatione intellectus ea a subjectis, quibus insunt, quasi separamus. Distincte igitur percipimus quæ ad genus vel speciem illarum rerum pertinent, consequenter genera et species nobis distincte repræsentamus. Quare cum generum et specierum repræsentatio sit notio, distincta autem notio intellectus operatio sit eaque prima; si in cognitione intuitiva acquiescimus, prima mentis operatio absolvitur, dum in ideis duorum vel plurium individuorum simul nobis occurentibus ad ea successive attentionem dirigimus, quæ in iisdem eadem sunt. Hoc modo patet, quomodo nobis genera et species rerum in universali repræsentare debeamus. Quod alius non detur modus in cognitione intuitiva genera et species rerum repræsentandi, ex eo intelligitur, quod universalia, seu genera et species non existant nisi in singularibus, et ad notionem entis in universali non pertineant nisi determinationes intrinsicæ pluribus singularibus seu individuis communes. Ponamus e. gr. duas arbores, cerasum atque prunum, oculis nostris una objici, ita ut utramque uno intuitu comprehendere valeamus. Quodsi jam attentionem nostram ad folia utriusque arboris simul dirigimus, nobis conscii sumus nos in utraque percipere folia, et magis quidem conscii sumus, quam quod alia vel in iisdem

Conception, apart from intuition, is only possible under the form of symbolical cognition, in which the notions are contemplated in their signs. In this form it consists in the enumeration, by means of verbal or other symbols, of the different parts constituting a given notion.[1] Conception, intuitive as well as symbolical, is thus in all cases a judgment. In intuitive conception we judge that an object now present to the mind exemplifies a given notion: we pronounce, for example, that this is a man. In symbolical conception we pronounce that the notion comprehends such and such subordinate notions as its constituent parts. But symbolical cognition supposes intuitive cognition, actual or possible, as its condition. The existence of a class is possible if the existence of individual members is possible; for the universal has no existence apart from the individual. A class really exists, if individuals exist possessing the attributes of that class: a class may imaginably exist, if we can imagine the existence of individuals possessing the corresponding attributes. But where neither perception nor imagination is possible—where the attributes are such that we cannot, either by observation or by construction, manual or mental, combine them into an individual unity of representation—the class is inconceivable, and the words by which it is represented, however separately intelligible, are, in their combination, utterly unmeaning.

Hence, as a general rule: *Conception is only possible within the limits of possible intuition*,—that is to say, those notions only are conceivable whose objects as individuals can be presented to intuition in themselves or represented in their images. It is not necessary that the intuition should in all cases actually take place; it is sufficient if, from our intuitive knowledge of the several attributes, we know that there is no incompatibility between them which renders their union in one representation impossible. I conceive a chiliogon when I define it as a regular figure of a thousand sides; but I cannot distinctly represent in the imagination a thousand sides at once; nor do I think it necessary to draw the figure in order to convince myself by actual experience of the possibility of the intuition. But I know that the property of inclosing space contains nothing incompatible with the number of a thousand sides; and that therefore the corresponding figure could be constructed, if necessary. Under this conviction, the symbolical takes the place of the intuitive cognition; and we are enabled, by the aid of language, to think of the figure in certain relations without actually constructing it.[2] In speaking of *possible intuition* as the test of conceivability, we do not mean merely the intuition of the bodily senses. Fear, or anger, or volition, or moral approbation, or any individual state of the internal consciousness, is as much an object of intuition as a sound, or a colour, or an odour; and is equally capable of being represented in an image or conceived under a general notion. Neither do we make any difference between the real and the imaginary, between the mentally and the physically possible. A centaur is as conceivable as a horse or a man, whether the actual existence of such a creature is physically possible or not. I may imagine or conceive a stone remaining suspended in air or water, or mounting upwards instead of falling downwards, though consistently with the natural law of gravitation it can do nothing but sink to the ground.

---

arboribus vel extra eas una percipiamus. Quodsi jam porro attentionem nostram promovemus ad surculos in utraque arbore simul, eorundem eodem prorsus modo conscii nobis sumus. Et idem tenendum est de ramis atque truncis. Hac ratione absque omni vocabulorum vel aliorum signorum usu, ea nobis distincte repræsentamus, quæ arboribus communia sunt, atque adeo notionem hujus generis ingrediuntur, quod arboris nomine indigitamus. Atque ita simul intelligimus, quid sit mente separare ea, quæ individuis communia sunt. Neque vero utilitate sua caret nosse, quomodo in cognitione intuitiva prima intellectus operatio sese exerat, quoniam notionibus generum atque specierum claritas affunditur, si cognitio intuitiva cum symbolica conjungatur." (Wolf, *Psychologia Empirica*, sect. 326.)

[1] "*In cognitione symbolica prima mentis operatio absolvitur recensione vocabulorum, vel aliorum signorum, quibus ea indigitantur, quæ notionem rei distinctam ingrediuntur.* Etenim in cognitione symbolica tantummodo verbis enunciamus quæ in ideis continentur, vel aliis signis eadem repræsentamus, ideas vero ipsas verbis aut signis aliis indigitatas non intuemur. Quare cum in cognitione intuitiva prima mentis operatio absolvatur, si attentionem successive in idea rei ad ea dirigimus quæ notionem distinctam generis vel speciei ingrediuntur, singula autem hæc enunciabilia sint, adeoque vocabulis vel signis aliis indigitari possint; in cognitione symbolica prima mentis operatio absolvi debet recensione vocabulorum, vel repræsentatione aliorum signorum, quibus ea denotantur quæ notionem rei distinctam ingrediuntur. Ita prima mentis operatio in cognitione symbolica arboris absolvitur, si dicimus vegetabile, quod ex trunco, ramis, surculis et foliis constat: etenim sigillatim recensemus verba quibus ea indigitantur quæ in arboribus tanquam communia distinguimus, consequenter quæ notionem arboris in genere, quatenus distincta est, ingrediuntur. Non autem jam nobis quæstio est, utrum notio distincta sit completa atque determinata, atque oratione ista talis notio significetur, ut hæc definitionis loco inservire possit. Sufficit enim hic ea sigillatim enunciari quæ mente ab idea rei separantur, dum distincte nobis genus vel speciem repræsentare conamur. Pendet enim cognitio symbolica ab intuitiva, quam supponit et ad quam refertur. Quicquid igitur huic deest, idem etiam illi deesse debet." (Wolf, *Psychologia Empirica*, sect. 328.)

[2] "Quoniam vocabula sunt signa nostrarum perceptionum, vel rerum per eas repræsentatarum, dum verba recensemus quibus ea indigitantur quæ notionem rei distinctam ingrediuntur, ea singula ad perceptiones rerum in cognitione intuitiva locum habentes referre tenemur, etsi ad notionem eidem respondentem non attendamus, quod eadem ex crebro usu satis intelligere arbitremur. Quamobrem *operatio intellectus prima in cognitione symbolica præsupponit operationem ejusdem primam in intuitiva*. Hæc probe notanda sunt, ne demus sine mente sonos, nobisque persuadeamus nos notionem rei habere, dum vocabula recensere valemus, etsi *cognitionem symbolicam ad intuitivam reducere* minime valeamus: quæ reductio in eo consistit, ut ideam alicujus individui in nobis excitemus, sive sensuum, sive imaginationis ope, ac attentio nostra successive ad ea dirigatur quæ in re percepta insunt, atque deinde vocabula ad eadem referantur, prout singulis, vi significatus quem obtinent alias, subinde etiam vi etymologiæ ac compositionis, denotandis apta deprehenduntur, quatenus scilicet in etymologia vel compositione ratio denominandi latet, ad rem vocabulo denotatam manducens, nisi ipsimet vocabula ad ea significanda in cognitione intuitiva transtulerimus, atque hujus facti meminerimus." (Wolf, *Psychologia Empirica*, sect. 329.)

Conception without an accompanying intuition is only possible, as we have already observed, by means of symbols; but the thought which accompanies every complete intuition, and by which various presented attributes are regarded as constituting a whole, is an act of precisely the same kind, and may therefore properly be called by the same name. Conception may thus be distinguished as of two kinds:—*Symbolical Conception,* in which a general notion, represented in language, is regarded as composed of other subordinate notions similarly represented; and *Intuitive Conception,* in which an individual object, present to sense or imagination, is regarded as a whole composed of certain presented parts. By this the object is *thought under a concept;* being thereby separated from the surrounding objects of intuition, and regarded as a whole by itself.[1] The former kind of conception is based on the latter, and derives its validity from it. It is in the latter, therefore, that the form and laws of conception will be most clearly exhibited. We must therefore analyse the complex act of intuitive conception, in order to detect, in the whole so conceived, the part contributed by the reflective faculty, and the laws under which it operates.

It has been already observed that intuition and thought, the presentative and the representative consciousness, can be distinguished from each other, as actual states of mind, only logically, not really. To the recognition of either, as a fact of consciousness, the presence of both is indispensable. To discern the element contributed by conception to the cognition of an object of consciousness as such, we may revert, for the moment, to the supposition of a being susceptible of a diversity of intuitions, but with no power of discerning wherein that diversity consists. In other words, we must suppose him divested of the faculty of *comparison.* In the exercise of sight, for example, he might at any moment be dimly conscious that he saw something; he might also be dimly conscious that he had seen something before; but he would not be conscious whether the two objects were the same or different in species; for this implies a reflective cognition of each under a separate notion. By the act of conception I discern a particular object as such; and this implies at the same time a consciousness of its difference from something else. The act of reflection has thus added a new element to the phenomena of intuition, namely, a consciousness of their relation to each other. The mere presence of an object affecting the organ of sight does not in itself imply that any other object accompanies or has preceded it; but the recognition of it as this object rather than that, does so. Conception, whether intuitive or symbolical (for the latter is but the substitute for the former), thus implies the cognition of objects under separate notions, and this cognition constitutes the common or formal feature of the act of conceiving, being unaffected by any diversity in the nature of the objects conceived. To ascertain the laws of conception, we must therefore ask what this cognition of objects in all cases supposes: in other words, what are the relations implied in the knowledge of an object as such. In the first place, the object is *discerned,* or separated from all others; and this separation implies two relations,—*identity* and *diversity.* The consciousness of identity is at the same time the consciousness of difference; I discern a thing by knowing it as what it is, and by distinguishing it from what it is not. In the second place, the cognisance of this relation between objects implies also their *mutual relation to a common consciousness.* I am conscious of the distinction of one thing from another, by including both as modes of one continuous conscious existence. Without this, memory would be impossible, and without memory there could be no comparison. We have thus the three forms of unity, plurality, and totality, manifested as the necessary relations with which the mind, in the act of conception, invests the materials furnished by intuition. To conceive any object A as such, I must distinguish it from all that is not A, and I must regard A and *not*-A as constituting between them the universe of my consciousness. These requirements are expressed by the three laws of identity, contradiction, and excluded middle, which may thus be regarded as the universal or formal conditions of every act of conception as such, in contradistinction from the special or material conditions which are necessary to the conception of this or that particular class of objects only.

From the above exhibition of the laws and forms of thought in general, as manifested in the act of conception, it will be easy to deduce, in a somewhat amended enumeration, those special forms which have been treated by logical writers as distinctive of the concept proper.[2] The concept is necessarily conceived as *one,* as *one of many,* and as *constituting with the many an universe of the conceivable.* From the last of these three conditions it follows, that the concept must possess a generic or universal feature, by which it is characterized as a concept in general, or a member of the conceivable universe. From the second it follows, that it must also possess a differential or peculiar feature, by which it is distinguished from all others. And from the first it follows, that these two features must be united into a single whole. Hence every concept, as such, must possess in some degree the attributes of *distinctness,* as having complex contents, capable of analysis into genus and difference: of *clearness,* as being by one portion of its contents distinguishable from other notions; and of *relation to a possible object of intuition,* inasmuch as the unity of a complex notion depends, not on a mere juxtaposition of terms, but upon its being the representative of one object.[3] These three forms may be otherwise denominated (for the difference is merely verbal) *comprehension, limitation,* and *extension.* As having complex contents, every concept *comprehends* certain attributes; as distinguishable from others, it is *limited* by its specific difference; and, as representative of a class of possible objects, it has a certain field over which it is *extended.* The forms of the concept proper may thus be indifferently enumerated, as distinctness, clearness, and relation to an object; or as comprehension, limitation, and extension.

We have thus exhibited the general laws of thought in their relation to those objects with reference to which the thinking act is usually distinguished as conception. But though no conception is possible, except in conformity with these laws, it must not, therefore, be concluded that conception is possible in all cases in which they are not transgressed. An object may be inconceivable in two ways,—*essentially* or *formally*, because the attempt to conceive it involves a violation of the laws of thought; and *accidentally* or *materially*, because of the absence of certain preliminary conditions, whose existence must be presupposed before thought comes into operation. By the laws of thought, a concept must have distinctive contents; it must not comprehend two contradictory elements; and it must be contained under one or the other of the contradictory notions which constitute the universe of thought. Where these conditions are not observed, the object is formally or essentially inconceivable. Thus pure Nothing which has no contents, and also the indefinite notions indicated by the terms Being, Thing, Existence in general, which have no definite contents, are formally inconceivable, as violating the law of identity: they are not an A as distinguished from a *not*-A. So, again, we are formally unable to conceive the same surface as both black and *not*-black, which involves a violation of the law of contradiction; nor yet can we conceive it as neither one nor the other; for this is prohibited by the law of excluded middle. But the accidental or material inconceivability of objects depends on other conditions. The materials of thought are furnished by the phenomena of the senses or of some other intuitive faculty; and hence, when the intuition is wanting, conception is impossible, as having no data upon which to operate. Thus, a blind man can form no conception of colours, and a deaf man can form no conception of sounds,—not because sounds and colours are in themselves inconceivable, but because the preliminary intuition, which should furnish the materials of the conception, is deficient. And so likewise any man, though in the full possession of his senses, is unable to form a conception of a colour which he has never seen, or of a sound which he has never heard, or of a savour which he has never tasted; or, at least, he can form only such an imperfect conception as may be furnished by its supposed likeness to some object of his actual experience,—a conception necessarily defective, as not containing the specific difference which characterizes the object as such, and which actual experience alone can furnish. Objects accidentally inconceivable may be divided into two classes:—those which are deficient in the *matter* of the intuition, and those which are deficient in the *form;* for it must be remembered that the form of intuition becomes part of the matter of thought; and that both these classes are therefore, so far as conception is concerned, inconceivable *materially* or *accidentally*. The form of intuition is to be found in the general conditions of space and time, which are common to all external or internal intuitions respectively, as such: the matter is to be found in the special affections of this or that mode of external or internal sense, by which one object is distinguished from another. Upon the necessary relations of space and time are founded the two sciences of geometry and arithmetic; and a notion which violates the principles of either of these may be classified as inconceivable from a defect in the form of intuition. Thus it is impossible to conceive a figure bounded by two straight lines, or an odd number which is the sum of two even ones; because the two straight lines cannot be perceived or imagined as occupying such a position in space as is necessary before we can include them under the general concept of a figure; and the two even numbers cannot occupy such a succession in time as is necessary to the formation of the concept of an odd number. These notions are not, as some writers have supposed,[1] logically self-contradictory, and therefore formally inconceivable; they are not inadmissible in their general character as thoughts, but in their special character as thoughts about figures or numbers. In one respect they differ considerably from the other class of materially inconceivable objects, in which the impossibility arises only from a deficiency in actual experience of the matter of intuition, such as has been supposed in the case of an unknown colour or sound. The latter may become conceivable by a mere extension of experience, without any change in our bodily or mental constitution. The former, being dependent on the subjective conditions of intuition, could not become conceivable without a change in the constitution of our intuitive faculties. This difference will be more fully examined when we come to treat of the distinction between necessary and contingent truths.

---

[1] "The understanding, thought proper, notion, concept, &c., may coincide or not with imagination, representation proper, image, &c. The two faculties do not coincide in a general notion; for we cannot represent man or horse in an actual image without individualizing the universal; and thus contradiction emerges. But in the individual, say Socrates or Bucephalus, they do coincide; for I see no valid ground why we should not *think,* in the strict sense of the word, or *conceive* the individuals which we *represent.*" (Sir W. Hamilton, *Discussions,* p. 13.) We may go even beyond this, and regard conception as coinciding, not merely with the *imagination,* but with one element of the *perception* of an individual object. For the combination of individual parts into a whole is a cognition of *relations,* and, as such, is properly an act of the understanding, operating by means of concepts.

[2] See Kant, *Logik,* sect 2. Fries, *System der Logik,* sect. 20. The former places the form of a concept in its universality; the latter adopts the same view, subdividing universality into extension and comprehension.

[3] Arist. *Metaph.* vi. 12. Ἐπὶ μὲν γὰρ τοῦ ἄνθρωπος καὶ λευκὸν πολλὰ μέν ἐστιν, ὅταν μὴ ὑπάρχῃ θατέρῳ θάτερον, ἓν δέ, ὅταν ὑπάρχῃ καὶ πάθῃ τι τὸ ὑποκείμενον ὁ ἄνθρωπος· τότε γὰρ ἓν γίγνεται καὶ ἔστιν ὁ λευκὸς ἄνθρωπος. *Ibid.* vii. 6. Ὁ δ᾽ ὁρισμὸς λόγος ἐστὶν εἷς οὐ συνδέσμῳ καθάπερ ἡ Ἰλιάς, ἀλλὰ τῷ ἑνὸς εἶναι.

Before concluding this part of our subject, it will be necessary to say a few words on the controverted question of the processes usually regarded as subsidiary to conception, namely, abstraction and generalization. The account usually given of these processes by writers on logic cannot be regarded as accurately exhibiting the psychological phenomena connected with the passage from intuition to thought; and the question derives additional interest from the controversy which has been raised by philosophers of eminence concerning the reality of the processes themselves.

The ordinary logical account is to the following effect:—We examine, it is said, a number of individual objects, agreeing in some features and differing in others: we *abstract* or separate the points in which they agree from those in which they differ; and we *generalize*, or construct a common notion, represented by a common name, out of the features of similarity so separated from the rest; which common notion becomes thus indifferently applicable to all the individuals from which it was derived. The process, as thus described, appears to presuppose the very act of conception to which it is represented as giving rise. If, for example, I am to form a general notion of *man* by examining the individuals Peter, James, and John, and by separating the accidents of complexion, stature, expression of countenance, &c., from the human form which is common to all, it is obvious that I must previously have formed general notions of the parts so separated from each other. Before I can say, this man has blue eyes and that man has black; and the colour of the eyes may therefore be set aside as accidental; I must have discerned, by means of concepts, the eyes as such from other features, and the colours blue and black from other visible qualities. If these concepts, according to the above theory, are formed by means of a previous abstraction, the same difficulty is repeated. Conception supposes abstraction, and abstraction again supposes conception, and the explanation thus runs in a constantly recurring circle.

The error of the theory consists in supposing that the individual is discerned *as such* before the universal. In the confused consciousness, if it can be called consciousness at all, which alone would be possible in an act of sensation unaccompanied by thought, we could not be said to discern either likenesses or differences. We should not be able to distinguish one individual from another, or to compare them together as like or unlike. As soon as thought is awakened, the general notion is perceived in and along with the individual which is discerned under it; and it is impossible to distinguish an individual as such from others, without at the same time being conscious of the notion which that individual exemplifies. Indeed, properly speaking, every collection of individual attributes is potentially the representative of a class; for there is nothing in the attributes themselves to prevent their being exhibited by more than one object. In one sense, indeed, it might be said that our cognition of the class is prior to that of the individual. For, in the development of consciousness by the aid of language, resemblances are noticed earlier than differences; and even the names distinctive of individuals are at first associated only with their generic features. Children, says Aristotle, at first call all men *father*, and all women *mother*, but afterwards they distinguish one person from another.[1] By the aid of language, our first abstractions are in fact given to us already made, as we learn to give the same name to various individuals presented to us under slight and at first unnoticed circumstances of distinction. The name is thus applied to different objects long before we learn to analyse the growing powers of speech and thought, to ask what we mean by each several instance of its application, and to correct and fix the signification of words at first used vaguely and obscurely.

---

[1] Among others may be mentioned Leibnitz, *Théodicée*, sect. ii., p. 480, ed. Erdmann; Stewart, *Elements*, part ii., ch. i.; and Whately, *Logic*, appendix on Ambiguous Terms, *v. Impossibility*.

The nature of the general notion or concept itself has been no less a point of controversy among philosophers than the process by which it is formed. According to Locke,[2] the general idea of a triangle is an imperfect idea, "wherein some parts of several different and inconsistent ideas are put together." As limited to no particular kind of triangle, but including all, it must be "neither oblique nor rectangular, neither equilateral, equicrural, nor scalenon; but all and none of these at once." The general idea, as thus described, Berkeley easily perceived to be self-contradictory, and the doctrine suicidal. "I have a faculty," he says, "of imagining or representing to myself the ideas of those particular things I have perceived, and of variously compounding and dividing them. I can imagine a man with two heads, or the upper parts of a man joined to the body of a horse. I can consider the hand, the eye, the nose, each by itself, abstracted or separated from the rest of the body. But then, whatever hand or eye I imagine, it must have some particular shape and colour. Likewise, the idea of man that I frame to myself must be either of a white, or a black, or a tawny, a straight, or a crooked, a tall, or a low, or a middle-sized man. To be plain, I own myself able to abstract *in one sense*, as when I consider some particular parts or qualities separated from others, with which, though they are united in some object, yet it is possible they may really exist without them. But I deny that I can abstract one from another, or conceive separately, those qualities which it is impossible should exist so separated; or that I can frame a general notion by abstracting from particulars in the manner aforesaid."[3] On these grounds, the bishop maintains that things, names, and notions, are in their own nature particular, and are only rendered universal by the relation which they bear to the particulars represented by them.

The remarks which have been made above, on the distinction between intuitive and symbolical knowledge, and on the office of language in promoting distinctness of intuition as well as of conception, may assist in placing this controversy on a more satisfactory footing. The error of Locke, as Berkeley clearly perceived, consisted in regarding abstraction as a positive act of thought, instead of the mere negation of thought. Abstraction is nothing more than non-attention to certain parts of an object: we do not positively think of the triangle as neither equilateral, nor isosceles, nor scalene; but we think of the figure as composed of three sides, without asking the question whether those sides are equal or unequal. On the other hand, Berkeley, in maintaining that all notions are in their own nature particular, has overlooked the fact, that thought, and, through thought, language, is necessary to distinguish the particular as particular, no less than the universal as universal; and that we are thus enabled, both in intuitive and in symbolical cognition, to discern generic attributes, and to constitute them an object of conception, without being conscious of the particulars by which they are accompanied. I see a man at a distance, and I know him to be a man; here is intuition and conception combined. But I am not near enough to discern either his stature or his complexion; and though, if my attention is called to the point, I cannot help admitting that he must be of a certain size and a certain colour; yet the visible object presents neither the one nor the other; and it is not necessary that my attention should be called to them at all. It is true that the visible object, as a surface, is coloured; but this colour does not enter into my notion of the thing represented. The faint blue tint that marks a distant object is not included in my conception of the object as a man, and my sight is too feeble to enable me to supply any other. Here, then, is a distinct cognition of generic attributes as such,—attributes which are indeed perceived as existing in an individual, but which contain no distinctive feature by which the individual can be recognised as such. The abstraction becomes still greater when the conception is purely symbolical; as we are thus enabled to think of the attributes without being at the moment conscious of their coexistence in any individual whatever. Berkeley mistakes the test of conception for the act of conception itself. Conception is not identical with imagination; though the latter process is so far the test of the former, that nothing can be conceived as constituting a class, which is absolutely and in its own nature incapable of being imagined as existing in an individual.

The length to which our remarks have run on the subject of conception will enable us to be more brief in our treatment of the remaining operations of thought, which are nothing more than the same faculty of comparison applied to different objects.

OF JUDGMENT.

Judgment, in the limited sense in which it is distinguishable from consciousness in general, is an act of comparison between two given concepts, as regards their relation to a common object. Omitting those judgments which involve merely the enumeration of the attributes comprehended in a concept (the *analytical* or *explicative judgments* of Kant), which may be more properly classified as acts of conception; and confining ourselves to those in which the contents of the given concepts are distinct from each other (the *synthetical* or *ampliative judgments* of Kant), we may distinguish the form from the matter of judgments,—the part contributed by the act of judging itself, from the preexisting materials on which it operates,—as follows. The concepts being distinct from each other in contents, their relation to a common object cannot be ascertained by any mere examination of those contents: this relation, therefore, as well as the concepts themselves, must be given prior to and out of the act of comparison. In other words, the relation between the two concepts must be given in an act of intuition, pure or empirical, imaginary or real, before we can decide by an act of judgment that such a relation does or does not exist. For example: in order to form the judgment "two straight lines cannot inclose a space," I must not only know the meaning of the terms employed, but I must also, by the aid of imagination, construct a representation in my mind of two actual straight lines and their actual positions in space. I must perceive that these two straight lines are incapable of inclosing a space, before I pronounce the universal judgment concerning straight lines in general. Here the relation between the two

Psychology

concepts is presented in a *pure* or *à priori intuition*,—*i.e.*, in an intuition containing no adventitious element external to the mind itself. Again, in order to form the judgment "gold is heavy," supposing that my conception of gold does not in itself include the attribute of weight, I cannot, by merely thinking of gold as a hard, yellow, shining body, determine what effect it will produce when laid upon the hand. I must actually place an individual piece of gold upon my hand, and ascertain by experience the fact of its pressure. Here the relation between the two concepts is presented in a *mixed* or *empirical intuition ; i.e.*, in an intuition caused by the presence of a body external to the mind itself. The examination of these constituent elements will enable us to distinguish between the matter and the form of thought as exhibited in the act of judgment.

If I poise a piece of gold in my hand, in order to ascertain whether it is heavy, the presented phenomena belong to distinct acts of sensation. The evidence of sight attests the presence of a round, yellow, shining body; the evidence of touch, or rather of muscular pressure, attests its weight. To unite these attributes, as belonging to one and the same thing, is an act, not of sensation, but of thought. The mere sensation, aided by the concepts, presents us with three things—the body which is seen, the pressure which is felt, and a certain temporal and local juxtaposition of the two. To combine the presented attributes as belonging to one thing; to pronounce that it is *the gold* which is heavy, is an act of thought, constituting a judgment. Here, then, we have one form of judgment, expressed in the copula "gold *is* heavy:" this indicates the identification of two concepts as related to a common object; an identification usually known as the *quality* of the judgment.

The same is the case with the *quantity* of judgments. I see a number of balls lying on a table, and pronounce at once that they are all white; I see another collection, and assert in like manner that some are white and some black. Here the senses, even when aided by the concepts in distinguishing the balls as such, yet present to us only individual objects. *This*, *this*, and *this* are within their province; but they know nothing of *all* or *some*. It is by an act of thought that the several individuals are regarded as constituting a whole, and a judgment pronounced concerning that whole or a portion of it.

A third form of the judgment, as indeed of all thinking, is *limitation*. In predicating one notion of another, I at the same time necessarily exclude everything to which that predicate is opposed, and thereby limit the subject to one alone of those contradictory determinations which make up the universe of thought. In asserting, for example, that gold is heavy, I as much exclude it from the class of imponderables as I include it within that of bodies possessing weight. The canon that *predication is limitation* is now, indeed, universally admitted as an axiom in philosophy;[1] and the various metaphysical systems of modern Germany, since the days of Kant, may be briefly described as so many attempts to evade the consequences of this principle by constructing a philosophy of the unlimited on a basis independent of logical predication.

Psychology.

These three forms of the judgment,[2] like those of the concept, may be regarded as special manifestations of the three conditions of thought in general—unity, plurality, and totality. As *one*, the judgment possesses *quality*, exhibited in its copula, by which, as a connecting link, it is constituted a single act of thought. As *one out of many possible judgments*, it is *limited* by its predicate; and as *a whole composed of parts*, it represents an object of thought, which, whether it be one individual or many, contains in itself the several attributes indicated by the terms. This relation to an object is expressed by the *quantity* of the judgment, whereby one, some, or all of the members of a class are pointed out as an object possessing various attributes and combining them into a whole.

The three highest laws of thought are likewise operative in the act of judging, as in that of conceiving. This may be shown by ascertaining what are the universal conditions under which the judgment, *as a thought*, is possible. Of course we have nothing to do with the material conditions under which this or that judgment is possible *as a fact*. The latter conditions are special, not general, and apply to this or that particular judgment in its relation to its objects; not to all possible judgments in their relation to the thinking subject. As far as the laws of thought are concerned, it is indifferent whether we assert that the earth goes round the sun, or the sun round the earth; the latter proposition being logically as valid as the former, however incompatible with the facts of astronomy. The universal conditions of the possibility of any judgment as a thought may be ascertained by the following question:—Given any concept A, under what conditions may another concept B be predicable of it? The particular objects signified by A and B are supposed to be unknown; the question of the logical validity of the thought being thus kept free from all admixture of material elements. In the first place, the concept B must have definite contents: it is to be a predicate limiting A. It is therefore a portion, and a portion only, of the universe of possible concepts distinct from A. This is expressed by the law of excluded middle. Every concept distinct from A is either B or *not*-B. In the second place, the concept B must contain no attribute logically incompatible with A. This is expressed by the law of contradiction. In the third place, the concepts A and B, when united in a judgment, must be regarded as representing one and the same object; that which is A is also B. This is expressed by the law of identity. A in becoming B remains identical with itself. This apparent paradox of identity in diversity constituted one of the earliest puzzles in metaphysics, and gave rise to a scepticism which, refusing to admit without explanation the laws of thought themselves, consistently denied the possibility of uniting two notions in a judgment.[3] Whether the doubt thus suggested can be satisfied by ontology, is a question which cannot be considered at present. In a psychological point of view, it is sufficient to say that such is the form which thought necessarily assumes. The office of psychology is to exhibit the laws of thought as they actually exist; it cannot undertake to vindicate them, or to explain why the human mind is constituted as it is.

---

[1] See, for example, among others, Fichte, *Ueber den Grund unseres Glaubens an eine göttliche Weltregierung*, p. 16 (*Werke*, v., p. 187): *Gerichtliche Verantwortung*, p. 47 (*Werke*, v., p. 265); *Bestimmung des Menschen* (*Werke*, ii., p. 304). Hegel, *Logik*, p. i., b. ii., chap. 2.; p. ii. chap. 2 (*Werke*, iv., p. 26; v., p. 70).

[2] Kant (*Kritik der r. V. Transc. Anal.*, B. i., Abschn. 2; *Logik*, sect. 20) admits four forms of the judgment,—quantity, quality, relation, and modality. The two first have been admitted above. That of relation, under which head Kant classes the division of judgments into categorical, hypothetical, and disjunctive, is based on a very questionable position of the ordinary logic. If, as appears to be the case, hypothetical and disjunctive judgments, so far as they are judgments at all, are reducible to categoricals, relation, instead of being a special form of judgment, becomes a term equivalent to judgment in general. As regards modality, it may perhaps be more accurately referred to the matter than to the form of the judgment. The only judgments necessary *as thoughts* are those in which the subject logically contains the predicate: the only judgments impossible *as thoughts* are those in which the one term contradicts the other. These, as analytical judgments, have been above classed under the head of conception. All other judgments, *as thoughts*, are contingent, and become necessary or impossible only as thoughts about this or that particular object. It is not logic nor metaphysics, but geometry, which tells us that the angles of a triangle *must be* equal to two right angles.

[3] Plato, *Theæt.*, p. 201. Ἐγὼ γὰρ αὖ ἐδόκουν ἀκούειν τινῶν ὅτι τὰ μὲν πρῶτα οἱονπερεὶ στοιχεῖα, ἐξ ὧν ἡμεῖς τε συγκείμεθα καὶ τἄλλα, λόγον οὐκ ἔχοι· αὐτὸ γὰρ καθ᾽ αὑτὸ ἕκαστον ὀνομάσαι μόνον εἴη, προσειπεῖν δὲ οὐδὲν ἄλλο δυνατόν, οὔθ᾽ ὡς ἔστιν οὔθ ὡς οὐκ ἔστιν. *Sophist.* p. 251. Εὐθὺς γὰρ ἀντιλαβέσθαι παντὶ πρόχειρον ὡς ἀδύνατον τά τε πολλὰ ἓν καὶ τὸ ἓν πολλὰ εἶναι, καὶ δή που χαίρουσιν οὐκ ἐῶντες

OF REASONING.

The third operation of thought, reasoning, is likewise an act of comparison between two concepts; and only differs from judgment in that the two concepts are not compared together directly in themselves, but indirectly by means of their mutual relation to a third. As the concept furnishes the materials for the act of judging, so the judgment furnishes the materials for the act of reasoning. The matter of the syllogism thus appears in the several propositions of which it is composed, and which vary in every different instance; its form appears in the manner in which those propositions are, in the act of reasoning, connected together as premises and conclusion. This connection consists in the recognition of a relation of identity or contradiction between the terms given in the antecedent and those connected by the reasoning act itself in the consequent. The forms and laws of reasoning may thus be ascertained by the following question:—"Given two judgments (no matter what may be their material signification), what relations must exist between them, to warrant us in inferring a third judgment as their consequent?"

In the first place, the premises and the conclusion must stand to each other in the relation of condition and conditioned. As the predicate of a judgment limits and determines the subject, so the premises of a syllogism must limit and determine the conclusion. *Limitation* is thus a form of reasoning, as of all thinking, and exhibits, as has been shown in the case of judgment, the operation of the law of excluded middle. The conclusion, to be determined, must be one of two contradictory possibilities. In other words, the premises must be so related to each other as to necessitate *some conclusion.* If the connection between A and B, as exhibited in the premises, be such that, *as far as those premises are concerned*, we are not necessitated to infer that A is either B or *not*-B, there is no determination of a conclusion, and consequently no reasoning.

In the second place, since the concepts A and B are not compared together directly, but through the medium of a third, it is necessary that this third concept should be successively compared with each of the others. This comparison results in a relation either of identity or contradiction; the subjects of the two concepts being pronounced identical whenever the premise is affirmative, and contradictory whenever it is negative; and a similar relation being consequently inferred to exist between the concepts compared together in the conclusion. Hence the reasoning in all affirmative syllogisms is governed by the law of identity, and in all negative syllogisms by that of contradiction. Thus, when we reason "All C is (some) B; all A is (some) C: therefore all A is (some) B; the law which determines the conclusion is, that whatever is identical with a portion of C is identical with a portion of that which is identical with all C. Here is the principle of identity: "Every portion of a concept is identical with itself." Again, when we reason "No C is (any) B; all A is (some) C: therefore no A is (any) B,"[1] the law which determines the conclusion is, that whatever is identical with a portion of C cannot be identical with that which is contradictory to all C. Here is the principle of contradiction: "No portion of a concept can contradict itself." The forms which the syllogism exhibits, as exemplifying the above laws, are those of *mood* and *figure*, affirmative or negative, which determine what relations of identity or contradiction in the premises of a syllogism may legitimately determine a similar relation in the conclusion. Here, again, we see a special exemplification of the three general forms of unity, plurality, and totality; the middle term, in its twofold capacity of self-identity and double comparison, constituting the syllogism both a single thought and a whole composed of parts; while the determination of a definite conclusion and the exclusion of others indicates its limited character as one thought out of many.[2]

The further examination of the syllogistic forms belongs to the province of logic. Before dismissing this portion of our subject, however, it may be necessary to say a few words in defence of the character which throughout the preceding pages has been assigned to the general laws of thought;—that of identical judgments, in which the predicate expresses the same notion that is already given in the subject. The reader who remembers the contemptuous chapter of Locke on Trifling Propositions,[3] or the equally contemptuous observations of Stewart on the Aristotelian Logic,[4] may be astonished to find these despised propositions elevated to the character of laws of mind, and placed at the head of all thought. In truth, however, the position thus assigned to them is not only justified by the analysis of the act of thought, but is a necessary consequence even of the doctrines of Locke himself. Supposing that the act of thinking is governed by general laws at all (and that it is so, is manifest from the inability to conceive absurdities), such laws can clearly impart nothing in the way of instruction or the discovery of new truths. A new truth is in its very nature partial: it is new only because it is partial, because it is the discovery of the particular attributes of some particular thing or class of things. In a psychological point of view, the determination of the laws of thought (be their character as judgments what it may) is as much a new truth as any other, being the discovery of a particular fact in the constitution of the human mind. But when we consider the same laws logically, in their application to the products of thought, how is it possible for any new truth to be determined by them? As general laws, they have no special relation to this object of thought rather than that; and it is upon such special relations that the

ἀγαθὸν λέγειν ἄνθρωπον, ἀλλὰ τὸ μὲν ἀγαθὸν ἀγαθόν, τὸν δὲ ἄνθρωπον ἄνθρωπον. Arist. *Metaph.* iv. 29. Διὸ Ἀντισθένης ᾤετο εὐήθως μηθὲν ἀξιῶν λέγεσθαι πλὴν τῷ οἰκείω λόγῳ ἓν ἐφ' ἑνός, Simplicius *in Arist. Phys.* f. 20. (Scholia ed. Brandis, p. 330.) Οἱ δὲ ἐκ τῆς Ἐρετρίας οὕτω τὴν ἀπορίαν ἐφοβήθησαν ὡς λέγειν μηδὲν κατὰ μηδενὸς κατηγορεῖσθαι, ἀλλ αὐτὸ καθ' αὐτὸ ἕκαστον λέγεσθαι, οἷον ὁ ἄνθρωπος ἄνθρωπος καὶ τὸ λευκὸν λευκόν. (Cf. Zeller, *Philosophie der Griechen*, ii., p. 115.)

[1] In expressing the quantity of the predicate in our propositions, we have adopted the rule laid down by Sir W. Hamilton as the basis of a new analytic of logical forms, viz., *to state explicitly what is thought implicitly.* The particular instances selected, however, only express the rules of the ordinary logic, which tell us that the predicate is distributed always in negative propositions, and never in affirmative; *i.e.*, that it is actually thought as universal in the one case and particular in the other.

[2] In the Kantian logic, which adopts the ordinary classification of syllogisms, the categorical syllogisms are referred to a modified form of the laws of identity and contradiction, which Kant treats as one law; while hypothetical syllogisms are regarded as dependent on the principle of sufficient reason, and disjunctives on that of excluded middle. But Kant too hastily accepted the ordinary logical classification. If, as I believe to be the case, all hypothetical and disjunctive reasonings, so far as they are reasonings at all, may be reduced to the categorical form, it follows that all syllogisms will depend on the laws of identity and contradiction, and, in a subordinate manner, on that of excluded middle. The principle of sufficient reason, in its logical form, is, properly speaking, not a law of thought, but only a statement that all thought must be governed by some law or other.

[3] *Essay*, b. iv., chap. viii.

[4] *Elements*, part ii., chap. iii.

discovery of every new truth must depend. Material knowledge arises from the observation of differences; the essential feature of laws of thought must be abstraction from all differences.[1] A necessary law of all thinking, which shall at the same time ascertain the definite properties of a definite class of things, is a contradiction in terms; for it is optional, and therefore contingent, whether we shall apply our thoughts to that particular class of things or not. But if all men have been thinking, some on this thing, some on that, but all under one code of laws, what marvel if, when their attention is called to those laws, they should recognise them as what they have all along virtually acknowledged. Herein lies at once the explanation and the justification of the so-called frivolity of principles of this kind. They can determine only the general attributes common to all objects of thought as such; and, as every object of thought is such from the moment we are able to think of it at all, these attributes must constitute the very identical judgments which logic has been so much decried for offering. To this it may be added, that Locke, who denies the existence of innate ideas, and maintains that man cannot by any power of thought invent or frame a new simple idea,[2] is the very last philosopher who should have condemned the laws of thought as conveying no instruction. For if the principles of pure thought are competent to add anything to the matter already given, the act of thought can in so far invent or frame a new idea; and this brings us back of necessity to the theory of innate ideas. If, on the other hand, the reflective faculty can only modify the materials already given to it, it follows that identical judgments are not mere verbal frivolities, but fundamental laws of the human mind.

OF THE ASSOCIATION OF IDEAS.[3]

The laws of thought, properly so called, indicate the necessary conditions under which one thought suggests another, as involved in it *à priori*, and in its own nature, irrespectively of the particular experience of individual thinkers. These conditions may be reduced to the two relations of identity and contradiction; and the principles in which these relations are expressed may be called necessary or *à priori* laws of thought as thought. We have now to consider another connection, by virtue of which one thought accidentally suggests another, as associated with it in the past experience of this or that individual thinker. The conditions under which this suggestion most frequently takes place may be exhibited as the general conditions of the phenomenon usually known as the association of ideas; and the laws in which these conditions are expressed may be called contingent or empirical laws of thought in its accidental relations. The phrase *association of ideas* seems to be now so completely established in philosophical language, that it is hardly possible to put it aside in favour of a more accurate expression; but in retaining it, we must, to avoid misapprehension, point out that it is in many respects defective. In the first place, the term *association* expresses only a very limited portion of the phenomena,—those, namely, in which the elements associated together are consciously distinguished from each other, and equally correlative; whereas in many of the most important phenomena of this class the combined elements are so completely fused together that the constituent ingredients can with difficulty, if at all, be detected in the compound; and in others the relation is almost entirely on one side,—the first element suggesting the second far more strongly than the second suggests the first. In the second place, to speak of the associated objects as *ideas* naturally tends to limit the relation to modes of cognition, to the exclusion of desires and feelings.[4] On this account it would be better to describe the phenomena in question, in more general language, as those of *related modes of consciousness*,—a phrase which is indifferently applicable to equal and unequal correlatives, and to all the states of mind which are capable of connection among themselves and with each other.

In one sense, indeed, our whole consciousness may be said to be dependent, not indeed on the *association*, which term implies a previous separate existence of the objects associated, but on the *coexistence* or *relation* of ideas or modes of consciousness to each other. For consciousness is only possible as an apprehension of differences; and this apprehension is only possible by the simultaneous cognition of the objects distinguished from each other. I can perceive, for example, a particular colour only by its contrast to some other colour or to a surrounding darkness. I can be conscious of a state of pleasure or pain only by its contrast to some other mental state preceding it; and this contrast implies a juxtaposition of the two states at the moment of the transition from one to the other. Consciousness is only realized under the condition of space or time; and space and time can only be discerned by means of the relation between objects contiguous in the one or successive in the other. These general relations, as the conditions of all consciousness, have been already noticed in the preceding pages, and need not be again examined here.

Nor yet is it necessary to dwell on those special relations which are necessary to the existence of any particular mode of consciousness as such, and do not merely regulate its subsequent reproduction. Our *complex ideas*, as they are called (and all ideas are in some degree complex), are instances of this class of relations. My perception of a horse, for example, is compounded of a certain colour, shape, and arrangement of parts,—all which are simultaneously presented to the eye, and form the conditions of my cognition of the horse as such. This, again, is not a case of suggestion or association, since none of the ideas thus given in combination can be regarded as the cause or antecedent condition of the rest.

Nor, again, should we include under the head of association the logical consequence of one notion from another,—a consequence intrinsic and essential to the thoughts themselves, and not dependent on the experience of a particular thinker. These consequences are all reducible to the relations of identity and contradiction, and imply, not the suggestion of one notion by another, but the analysis of a notion already given into the parts which it implicitly contains, and which are virtually given along with it. Under this class will come those relations which Sir William Hamilton has specified as *logical* or *objective* trains of thought,—in which "thoughts, though denoted by a single and separate expression, implicitly contain a second; which second the process of thinking explicates, but does not determine to succeed."[5] Such is the case with all terms which in their signification are essentially relative to each other. The thought of a parent is relative to that of a child; that of a greater to a less; that of a cause to an effect. But then the term *parent*, in itself, means parent of a child; the term *greater* means greater than a less; the term *cause* means cause of an effect. Hence, as Sir W.

---

[1] See Kant, *Logik*, Einleitung, vii.

[2] *Essay*, b. i., chaps. ii., iii., iv.; b. ii., chap. ii.

[3] For the history of the doctrine of mental association, on which our limits will not allow us to enter, the reader is referred once for all to the admirable note of Sir William Hamilton, *Reid's Works*, p. 889. The illustrious writer has triumphantly vindicated the claims of Aristotle to be regarded as the earliest, and, even to this day, the most accurate and complete expositor of the whole theory, and has supplied some interesting facts in its later history from authors almost unknown to ordinary readers.

[4] See the criticisms of Reid, *Intellectual Powers*, Essay iv., chap. iv.; of Sir James Mackintosh, *Dissertation* (*ante*, vol. i., p. 381); and of Sir William Hamilton, *Reid's Works*, p. 907.

[5] *Reid's Works*, p. 911.

Hamilton observes, it is improper to say of such terms that they are *associated* or mutually *suggestive*, since the thought of both is already given in the thought of each.

These being discarded, there remain to be considered those relations of thought which, in the language of Sir W. Hamilton, are distinguished as indicating a *psychological* or *subjective* consecution,—a connection, that is to say, established between two phenomena of consciousness, owing to some accidental juxtaposition in the mind of the person connecting them. Phenomena of this class belong entirely to the reproductive or representative consciousness; for, though the suggesting antecedent may be an intuition presented from without, the suggested consequent, not being given with it, is called up by the action of the mind itself; and thus the connection between the two is an act of representation or thought. The phenomena of association, in this limited sense, may be comprehended under two principal classes:—1. Those of direct remembrance or memory, in which the occurrence of any mode of consciousness at a certain time suggests the fact of the same mode having been experienced at a previous time. 2. Those of indirect remembrance or reminiscence, in which the occurrence of any mode of consciousness at a particular time suggests the recollection of a different mode of consciousness, which at some previous time was experienced along with it. Hence arise the two general laws, distinguished by Sir W. Hamilton[1] as those of repetition and redintegration; namely, *Thoughts coidentical in modification, but differing in time, tend to suggest each other*: and, *Thoughts once coidentical in time, are, however different as mental modes, again suggestive of each other, and that in the mutual order which they originally held.* The first of these laws must be extended to include not merely total identity of the mental modification, but also that partial identity which is the basis of resemblance or analogy. Thus, for example, I may see a man, and recognise him as the same person whom I met a few days ago. Here there is a complete identity of two mental modifications, differing only in point of time, as earlier and later. But again, I may see, not the man himself, but his portrait; and this may remind me of the original. Here there is a partial identity of the mental modifications; the man and the picture being in certain features the same, however different in other respects. Or again, the metaphorical use of the term *man*, as applied to the figures on a chess-board, or to the cairn on the top of a mountain, may suggest the object from which the metaphor was derived. Here, however little there may be of visible resemblance between the objects, there is still one point in which they are identical, namely, that both are denoted by the same word.[2] The second law is of still wider application. Not only homogeneous modes of consciousness, —two cognitions, two feelings, two desires,—but heterogeneous modes,—a cognition and a feeling, or a feeling and a desire, which have at any past time been associated together,—may on future occasions mutually suggest each other. The sight of a place may recal to mind an event which has taken place there, and the feeling of joy or sorrow which that event occasioned to ourselves.[3] The sight of the surgeon who has performed a painful operation upon us may recal vividly an image of the agony which we suffered at his hands, and create a feeling of dislike at his presence.[4] The food which we have tasted during illness, or the syrup in which a bitter medicine was administered, may ever afterwards convey to the mind an impression, in some cases almost amounting to an actual repetition, of the suffering which we felt, or the bitterness which we tasted.[5]

But the above laws, being the most universal principles of association in general, are not sufficient to account for the special instances included under each. They explain why certain associations of ideas *may* take place; but they do not tell us why this particular association actually takes place in preference to others of the same kind. Any two modes of consciousness which have once been coexistent in experience have a tendency to suggest one another; but this does not explain why the tendency is realized in certain instances and not in others. To account for these special phenomena, we must have recourse to a third law,—that of preference. *Thoughts are suggested, not merely by force of the general subjective relation subsisting between themselves; they are also suggested in proportion to the relation of interest (from whatever source) in which these stand to the individual mind.*[6] The grounds of this predominant interest may be of various kinds. Sometimes the frequent occurrence of certain experiences may impress the association which they convey indelibly on the mind, and serve to recal it on the slightest occasion. At other times the intensity of the feeling connected with the occurence may atone for its comparative rarity, and an event which has occurred but once in a lifetime may haunt the memory incessantly during the remainder of our existence. In some instances, in which the repetition is frequent and the suggested consequent of greater practical importance than the antecedent which suggested it, the latter disappears entirely from the consciousness, and the result of association becomes transformed apparently into that of immediate apprehension. A striking instance is furnished by those phenomena of the senses which have been already described under the name of Acquired Perceptions; such as the apprehension of the distance and unity of objects by the eye, in which the immediate and proper objects of sight, the rays in contact with the two retinæ, have been dropped out of consciousness, and the distant luminous body is to all appearance directly visible. Something similar to this may be observed in less familiar instances, in which we are conscious of the existence of a train of suggested thoughts remotely connected with each other, but overlook the intermediate and less important links. Such for example, is the often-quoted instance mentioned by Hobbes.[1] "In a discourse of our present civil war, what could seem more impertinent than to ask, as one did, what was the value of a Roman penny? Yet the coherence to me was manifest enough. For the thought of the war introduced the thought of the delivering up the king to his enemies; the thought of that brought in the thought of the delivering up of Christ; and that again the thought of the thirty pence which was the price of that treason." It is probable, as Stewart has remarked upon this passage,[2] that had the speaker himself been interrogated about the connection of his ideas, he would have found himself at first at a loss for an answer.

---

[1] *Reid's Works*, p. 912. The latter of these laws has been usually regarded by modern philosophers as the sole general law of association. See, for example, Hobbes, *Leviathan*, chap. iii.; Leibnitz, *Nouveaux Essais*, l. ii., chap. xxxiii.; Mill, *Analysis of the Human Mind*, chap. iii. The former law may perhaps have been hinted at by Aristotle, but its distinct recognition and enunciation are due to Sir W. Hamilton.

[2] In some cases the association may depend on mere identity of name, without any other point of similarity or analogy. Thus Alexander the Great may suggest Alexander the Coppersmith. On the influence of language as a principle of association, see Hobbes, *Human Nature*, chap. v.; Stewart, *Elements*, chap. v., part. i., sect. 2.; Mill, *Analysis of the Human Mind*, chap. iii. Not only identity of names, but even of letters, is noticed by Stewart, as in the case of ideas in poetry suggested by alliteration.

[3] This is beautifully described by Shelley in a passage from which we can only quote a small portion:—

"You are not here! the quaint witch Memory sees
In vacant chairs your absent images,
And points where once you sat, and now should be,
But are not.—I demand if ever we
Shall meet as then we met;—and she replies,
Veiling in awe her second-sighted eyes,—
'I know the past alone—but summon home
My sister Hope, she speaks of all to come.'
But I, an old diviner, who know well
Every false verse of that sweet oracle,
Turned to the sad enchantress once again,
And sought a respite from my gentle pain,
In acting every passage o'er and o'er
Of our communion."

[4] See the anecdote narrated by Locke, *Essay*, b. ii., chap. xxxiii., sect. 14.

[5] See the instance mentioned by Vives, quoted by Sir W. Hamilton, *Reid's Works*, p. 893.

[6] Sir W. Hamilton, *Reid's Works*, p. 913.

The three above-mentioned laws, of repetition, redintegration, and preference, will, in many cases, act in combination with each other; ideas, once associated by similarity, being afterwards farther connected by the fact of that juxtaposition, and acquiring a preferential claim by the frequency of the recurrence. Thus the sight of the picture of a man may suggest the original; and afterwards the thought of the man may suggest the thought of his picture, as having been seen at a former time in connection with it. Here the elements of similarity and diversity are combined together in the same association, as identical modifications of thought at diverse times, and again as diverse modifications of thought at the same time.[3] To the two first laws may also be reduced the four heads of association enumerated by Aristotle; viz., Proximity in Time, Similarity, Contrast, and Coadjacence.[4]

The phenomena of mental association, if in modern times they have been too much neglected by some philosophers, have unquestionably been exalted to an extravagant degree of importance by others. If Locke, on the one hand, appeals to this principle chiefly to explain some extravagances and prejudices of individual minds, later writers have, on the other hand, made far more than sufficient amends, by attributing to the power of association results which it is utterly incapable of producing or explaining. According to Hartley and his follower Priestley, "Not only all our intellectual pleasures and pains, but all the phenomena of memory, imagination, volition, reasoning, and every other mental affection and operation, are only different modes or cases of the association of ideas; so that nothing is requisite to make any man whatever he is, but a sentient principle, with this single property."[5] In a like spirit, Sir James Mackintosh, in language in which some allowance must perhaps be made for the rhetoric of a public lecture, affirmed that the law of association was the basis of all true psychology; and that Hartley, by his exposition of this principle, stood in the same relation to Hobbes as Newton to Kepler; the law of association being that to the mind which gravitation is to matter.[6] Condillac, a few years before Hartley, had testified to the same effect, asserting that all the operations of the mind are engendered from perception alone, and that the investigation of this process was of more value than all the rules of the logicians.[7] Accordingly, in Hartley's theory, as well as in that of Condillac, not only our desires and affections, and the phenomena of memory and imagination, but even the universal laws of thought, and the necessary principles of mathematical reasoning, and the immutable judgments of the moral faculty, and the self-determinations of the will, are derived with equal readiness from this prolific law acting on the material furnished by the senses. Association in psychology becomes, like the adverb in grammar, entitled to the appellation of the universal recipient, in which is swallowed up every mode of consciousness, and every faculty of the mind.[8] That the foundation is not always able to bear the weight of superstructure placed upon it, may be suspected at the outset from the amount of transformation which, in the systems of Condillac and Hartley, the sensible materials have to undergo, during the process of association, and of association only. Like "compound medicines," to use the simile of Hartley himself, "the several tastes and flavours of the separate ingredients are lost and overpowered by the complex one of the whole mass; so that this has a taste and flavour of its own, which appears to be simple and original, and like that of a natural body."[9] Thus the sensation of bodily pain becomes by association the emotion of fear; the pleasure of sucking, and other sensible enjoyments bestowed by the same person, become the affection of the child for its mother; and the restraint imposed upon actions by prohibition and punishment is gradually metamorphosed into the ideas of right, wrong, and obligation. The advocates of this kind of mental chemistry appear to have overlooked the fact that ideas have not, like chemical substances, a distinct existence and properties of their own, but exist and operate only as modes of the conscious mind. Consequently, the changes effected, even granting in all cases the assumed affiliation of consequent on antecedent, must be due to a transforming power or natural faculty of the mind itself, not to a mere working of sensible impressions in combination with each other. But this admission amounts to a confession that sensation is not the source of the derived ideas, but only furnishes the occasion on which the mind exercises a power of its own, thereby framing additional ideas, or elements of ideas, which sensation does not contain and cannot supply. To this it must be added, that the power of associating ideas at all implies a consciousness of their difference from, and mutual relation to, each other; and that thus association presupposes thought, instead of thought being the offspring of association.[10] But the failure of Hartley's theory is most conspicuous in reference to the phenomenon which we have next to consider,—the existence, namely, in consciousness of *necessary truths.*

[2] *Elements*, part ii., chap. ii.

[3] An ingenious, though quaint illustration of this is given by Coleridge, *Biographia Literaria*, chap. vii.:—"Seeing a mackerel, it may happen that I immediately think of gooseberries, because I at the same time ate mackerel with gooseberries as the sauce. The first syllable of the latter word being that which had coexisted with the image of the bird so called, I may then think of a goose. In the next moment the image of a swan may arise before me, though I had never seen the two birds together. In the first two instances, I am conscious that their coexistence in time was the circumstance that enabled me to recollect them; and equally conscious am I that the latter was recalled to me by the joint operation of likeness and contrast. So it is with cause and effect; so too with order."

[4] See Sir W. Hamilton's note, *Reid's Works*, p. 899, where the classification of Aristotle is examined and compared with those of Hume and others.

[5] See Priestley, *Hartley's Theory*, Introductory Essays, p. xxiv.

[6] Lecture delivered at Lincoln's Inn; quoted by Coleridge, *Biographia Literaria*, chap. v. In his Preliminary Dissertation, *ante*, vol. i., p. 378, Sir James's judgment of Hartley is more discriminating.

[7] *Origine des Connoissances Humaines*, section seconde. This work was published about three years before Hartley's *Observations on Man*. The theory of the latter, however, seems to have been formed independently, and is far more complete and elaborate, as regards association, than that of the former. Some remarks in comparison of the two will be found in Sir James Mackintosh's Dissertation, *ante*, vol i., p. 380.

[8] "Adverbium Stoici πανδέκτην vocant; nam omnia in se capit, quasi collata per satyram concessa sibi rerum varia potestate." *Charisii Ars Grammatica*, lib. ii., De Adverbio.

[9] Hartley, *Observations on Man*, prop. xii., cor. 1.

[10] In the above remarks we have considered Hartley's system only with reference to the doctrine of association, omitting the mechanical hypothesis of vibrations, on which that doctrine is founded. A valuable criticism of the whole theory will be found in Coleridge's *Biographia Literaria* chaps. vi. and vii.

OF NECESSARY TRUTHS.

It is a fact of consciousness to which all experience bears witness, and which it is the duty of the philosopher to admit and account for, instead of disguising or mutilating it to suit the demands of a system, that there are certain truths which, when once acquired, no matter how, it is impossible, by any effort of thought, to conceive as reversed or reversible. Such, to take the simplest instances, are the truths of arithmetic and geometry. By no possible effort of thought can we conceive that twice two can make any other number than four, or that two straight lines can inclose a space, or that the angles of a triangle can be greater or less than two right angles; nor yet can we conceive it possible that, by any future change in the constitution of things, even by an exertion of Omnipotence, these facts can hereafter become other than they are, or that they are otherwise in any remote part of the universe. It is this characteristic of a certain class of judgments, which the theory of association altogether fails to explain; for it does not appear in those instances in which, according to that theory, we ought to expect it. Probably no man, even of those acquainted with geometry, reads Euclid every day; and many pass several days together without thinking of mathematical relations at all. Consequently, the conviction that day and night must succeed one another once in every twenty-four hours, ought, as far as it depends on association, to be more fixed and certain than that the angles of a triangle are equal to two right angles, or that seventeen and eight make twenty-five. Whereas, in point of fact, while the two latter propositions are conceived as possessing an eternal and absolute necessity, which no exertion of power can change,[1] the former is regarded as one out of many possible arrangements, which has no other necessity than the will of the Creator, which might be changed at any moment by an exertion of the same will that produced it, which does not hold good in other parts of the universe, nor even in certain regions of our own globe. Again, on the theory of association, our conviction of the truth of mathematical propositions should be more certain in proportion to the number of instances in which we have seen them verified. That two and two make four, or that two straight lines do not inclose a space, should be admitted at first with doubt and hesitation, and asserted with more confidence as our experience of its truth increases. Here, again, the fact is at variance with the theory. A single enunciation of an axiom, or a single demonstration of a theorem, in mathematics, is as valid as a thousand; and the conviction once gained is gained with an absolute certainty which no subsequent evidence can increase.

The judgments which appear to possess this character of absolute necessity in thought, which no theory of mere association can explain, may be classified under the following four heads.—1. Logical judgments, in which the predicate is identical with the whole or a part of the attributes comprehended in the subject; as that every triangle must have three angles, that the sums of equal things must themselves be equal, or that all men must be animals. 2. Mathematical judgments, which express a necessary relation between two distinct notions concerning quantity, continuous or discrete; as that two straight lines cannot inclose a space, that the angles of every triangle must be equal to two right angles, or that seven and five must make twelve. 3. Moral judgments, which state the immutable obligation of certain laws of conduct, whether actually observed in practice or not; as that ingratitude or treachery must at all times and in all persons be worthy of condemnation. 4. Metaphysical judgments, expressing an apparently necessary relation between the known and the unknown, between the sensible phenomenon and the supersensible reality; as that every attribute belongs to some substance, and that every change is brought about by some cause. The necessity in all these four classes of judgments is essentially different from that manifestation of the laws of nature which is sometimes distinguished by the name of physical necessity. The laws of nature, if by *nature* is meant unconscious agents only, express nothing more than an observed fact in its highest generalization; and of that fact we can only say that it is so, and that it might have been otherwise. This is the case even with those phenomena whose relations may be exhibited by mathematical formulæ; for though the mathematical portion of the reasoning may have an *à priori* necessity, its application to the facts in question is empirical, and, as far as thought is concerned, contingent. Thus, that a body in motion, attracted by a force varying inversely as the square of the distance, will describe a conic section, is a matter of demonstration; but that the earth is such a body, acted upon by forces of this description, is a matter of fact, which might have been otherwise, had the Creator been pleased so to appoint. Necessity is the result of law; and law implies an agent whose working is regulated thereby.[2] But it is a law only to that which works under it; to an observer, who sees the results of the law without being subject to its influence, it is no more than a fact of experience. The laws of nature may be a sufficient reason why certain phenomena must take place in a certain way; but they furnish no reason at all why I must think so. As it is optional with me to study the phenomena in question, it is optional with me to become acquainted with their laws; and I can become acquainted with them as facts only. To know a law as such, I must know it as an obligation binding upon myself as a thinker; and this alone can give rise to a necessity of thought. When I speak of the alternations of day and night as consequent on a *law* of nature, I mean no more than that the alternations have invariably been observed to take place; and when I resolve such alternations into the *law* of the earth's rotation, I mean only that the earth does revolve on her axis once in twenty-four hours. *My belief* in the continuance of the observed order of natural phenomena may perhaps be explained by some law of my mental constitution; but, as thus explained, it is a law of mind and not of matter.

Of the four classes of judgments above distinguished as necessary in thought, the first, or logical judgments, do not require much explanation. Any notion, however, empirical in its origin, must, when once acquired, be analysed in accordance with the general laws of thought; and the result will exhibit that formal necessity which implies no more than the harmony of a thought with itself. Judgments of this character, affirmative and negative, are only particular instances of the two great laws of identity and contradiction, and have been already sufficiently explained in our previous remarks on the operations and laws of thought. Thus the axiom, that the sums of equal things are equal, may be expressed, representing the first pair of equals by A, and the second by B, in the form of the identical judgment, $A+B=A+B$. The analysis of a complex notion into its constituent parts, as in the assertion that all men are animals, or that every triangle has three angles, is only a special application of the identical judgment "A is A;" or, "any particular specimen of a class has the general attributes of the class to which it belongs."

---

[1] Le Clerc (*Logica*, p. ii., cap. iii.) enters into a defence of the canons of logic against certain theologians who maintained that the Divine power could make two contradictory judgments simultaneously true. But even this intrepid assertion of apparent absurdity does not amount to maintaining that *we can conceive* such an exertion of power; and this is all with which, as psychologists, we are concerned.

[2] "All things that are have some operation not violent or casual. That which doth assign unto each thing the kind, that which doth moderate the force and power, that which doth appoint the form and measure, of working, the same we term a law." (Hooker, *E. P.* i. 2.)

Mathematical judgments may be divided into two kinds,—indemonstrable or axiomatic judgments, whose necessity is self-evident; and demonstrable judgments, whose necessity depends on some previous assumption. The necessity of the latter is derived from that of the former, so that the indemonstrable judgments alone require a special examination. Under this class are comprehended the axioms of geometry, properly so called;[1] viz., the original assumptions concerning magnitudes in space as such, and the propositions belonging to the fundamental operations of arithmetic,—addition, and subtraction.[2] The necessity of these judgments results from the existence in the mind of the *à priori* forms of intuition,—space and time. The axioms of geometry are self-evident statements concerning magnitudes in space; such as that two straight lines cannot inclose a space. Their self-evidence or necessity is to be explained by the circumstance that the presented intuition, as well as the representative thought, is derived from within, not from without. For geometrical propositions are primarily necessary, not as truths relating to objects without the mind, but as thoughts relating to objects within; their necessity, as regards real objects, is only secondary and hypothetical. If there exist anywhere in the world two perfect straight lines, those lines cannot inclose a space; but if such lines exist nowhere but in my imagination, it is equally true that I cannot think of them as invested with the contrary attribute. This necessity of thought is dependent on a corresponding necessity of intuition. The object of which pure geometry treats is not dependent on sensation, but sensation on it: it is a condition under which alone sensible experience is possible; and therefore its characteristics must accompany all our thoughts concerning any possible object of such experience; for, however much we may abstract from the attributes of this or that particular phenomenon of experience, we are clearly incompetent to deprive it of those conditions under which alone, from the constitution of our minds, experience itself is possible. We can perceive only as we are permitted by the laws of our perceptive faculties, as we can think only in accordance with the laws of the understanding. If, then, by a law of my perceptive faculty, I am compelled to regard all objects as existing in space, the attributes which are once presented to me as the properties of a given portion of space, such as the pair of straight lines now present to my sight or imagination, must necessarily be thought as existing in all space and at all times. For to imagine a portion of space in which such properties are not found, would not be to imagine merely a different combination of sensible phenomena, such as continually takes place without any change in the laws of sensibility:—it would be to imagine myself as perceiving under other conditions than those to which, by a law of my being, I am subjected. But a condition, though potentially existing in the original constitution of the mind, is actually manifested only in conjunction with that of which it is the condition. Space, therefore, and its laws are first made known to consciousness on the occasion of an actual phenomenon of sense. Hence the twofold character of geometrical principles: empirical, as suggested in and through an act of experience; necessary, as relating to the conditions under which alone such experience is possible to human faculties.

Arithmetic is related to time as geometry to space, and the necessity of its propositions may be explained upon similar principles. The two sciences, however, present some important features of distinction. Most of the propositions of geometry are deductive: it contains very few axioms, properly so called, and its processes consist in the demonstration of a multitude of dependent propositions from the combination of these axioms with certain logical principles of thought in general. On the other hand, the fundamental operations of arithmetic,—addition and subtraction,—present to us a vast number of independent judgments, every one of which is derived immediately from intuition, and cannot, by any reasoning process, be deduced from any of the preceding ones.[3] Pure geometry cannot advance a step without demonstration, and its processes are therefore all reducible to the syllogistic form. Pure arithmetic contains no demonstration; and it is only when its calculus is applied to the solution of particular problems that reasoning takes place, and the laws of the syllogism become applicable. It is not reasoning which tells us that two and two make four; nor, when we have gained this proposition, can we in any way deduce from it that two and four make six. We must have recourse, in each separate case, to the senses or the imagination, and by counting up an individual succession corresponding to each term, intuitively perceive the resulting sum. The intuition thus serves nearly the same purpose as the figure in a geometrical demonstration; with the exception that, in the latter case, the construction is adopted to furnish premises to a proposed conclusion; while in the former, it gives us a judgment which we have no immediate intention of applying to any further use.

The intuition in the case of arithmetic is furnished by the consciousness of successive states of our own mind. Setting aside all other characteristics of those states, save that of their succession in time, we have the immediate consciousness of *one*, *two*, *three*, *four*, &c. A purely natural arithmetic would consist in carrying on this series, with no other relation between its members but that of succession, until the memory became unable to continue the process. The artificial methods by which calculation is facilitated and extended, such as that of a scale of notation, in which the series recommences after a certain number of members, vastly increase the utility of the calculus, but do not affect its psychological basis. To construct the science of arithmetic in all its essential features, it is only necessary that we should be conscious of a succession in time, and should be able to give names to the several members of the series; and since in every act of consciousness we are subject to the condition of succession, it is impossible in any form of consciousness to represent to ourselves the facts of arithmetic as other than they are.

The necessity of propositions in geometry and arithmetic is thus derived from their relation to the universal forms of intuition, space, and time. We can suppose the possibility of beings existing, whose consciousness has no relation to space or time at all. This is no more than to admit the possible existence of intelligent beings otherwise constituted than ourselves, and consequently incomprehensible by us. But to suppose the existence of geometrical figures or arithmetical numbers such as those with which we are now acquainted, is to suppose the existence of space and time as we are now conscious of them, and therefore relatively to beings whose mental constitution is so far similar to our own. Such a supposition necessarily carries with it all the mathematical relations in which space and time, as given to us, are necessarily thought. For mathematical judgments strictly relate only to objects of thought as existing in my mind, not to distinct realities existing in relation to my mind. They therefore imply no other existence than that of a thinking subject, modified in a certain manner. Destroy this subject, or change its modification, and we cannot say, as in other cases, that the object may possibly exist still without the subject, or may exist in a new relation to a new subject; for the object exists only in and through that particular modification of the subject, and, on any other supposition, is annihilated altogether. Thus it is impossible to suppose that a triangle can, in relation to any intelligence whatever, have more or less than two right angles, or that two and two should not be equal to four; though it is quite possible to suppose the existence of intelligent beings destitute of the idea of a triangle or of the number two. This is *necessary matter* in the strict sense of the term; a relation which our minds are incapable of reversing, not merely positively, in our own acts of thought, but also negatively, by supposing others who can do so.

---

[1] Under this head are included the tenth, eleventh, and twelfth *axioms*, as they are called in the modern editions of Euclid (*postulates* is Euclid's own term), with several other geometrical assumptions employed in the subsequent demonstrations, though not distinctly expressed. The remaining *axioms* of the modern editions (the *common notions* of Euclid himself) are logical, not geometrical principles, and depend solely on the laws of thought.

[2] "Though in some things, as in numbers, besides adding and subtracting, men name other operations, as *multiplying* and *dividing*, yet are they the same; for multiplication is but adding together of things equal; and division but subtracting of one thing as often as we can." (Hobbes, *Leviathan*, p. i., chap. v.)

[3] Subtraction may be demonstrated from addition, if all the results of the latter are supposed to be given, or *vice versa*; though it is simpler to regard subtraction as an independent process of *denumeration*, as is done by Condillac, *Langue des Calculs*, chap. i. But no result of either can be derived from a preceding result of the same operation.

A somewhat similar consideration will explain the necessity of moral judgments also. The fact of duty, whether in conformity or not with an absolute standard of morality, is in each case intuitively presented to me as an act in relation to a law of whose obligation on myself I am immediately conscious. It thus essentially differs from the phenomena of external nature, whose laws I do not intuitively perceive, but only infer them from the observed recurrence of certain facts. The moral sense, like the intuitions of space and time, is thus an *à priori* condition of my mind, not determined by experience as it is, but determining beforehand what experience ought to be; and, though manifested in consciousness on the occasion of experience, does not arise from experience as a fact, but is given by nature as a law, which, like other natural gifts, grows with our growth, and develops itself in a certain way, whatever may be the experience to which it is subjected. Its nature, like that of the tree, cannot be changed by the soil in which it is planted, though its growth may be advanced or stunted by this or other accidental circumstances.[1] But the immediate consciousness of law carries with it a consciousness of necessity and immutability in relation to the agent who is subject to it. For to suppose the law reversed in relation to myself, to suppose that it can ever become *my duty* to do what it is now my duty to forbear, is to suppose my whole mental constitution to be reversed, my personality still remaining unchanged;—a supposition which destroys itself; since my present mental constitution is included in the idea of my personality. Hence I cannot conceive myself as subjected to a different law of moral obligation from that of which I am conscious; nor yet can I conceive other beings so subjected; for I can only conceive their obligations at all by regarding their mental constitution in this respect as identical with my own. But I have no difficulty in supposing the existence of creatures who have no conception of duty at all (though even in this case I cannot distinctly conceive the nature of their consciousness); just as I can suppose the existence of creatures who have no conception of mathematical relations; and such a supposition is indeed actually made with regard to the lower animals. This explanation is sufficient to account for the necessary character of morality, regarded as a subjective obligation of the personal conscience. Its objective character, as indicating a standard above conscience, belongs to another branch of metaphysical inquiry.

The principles of substance and causality likewise depend, for their necessity as thoughts, on a previous necessity of intuition; but, in relation to both, it is requisite to distinguish between the necessary thought itself and the accidental associations by which it is accompanied. As regards material substances, for example, what do we mean when we say that extension, figure, colour, hardness, &c., are the attributes of *something* extended, figured, coloured, hard, &c.? Are we compelled to think that, besides the sensible qualities, there exists a distinct imperceptible thing to which those qualities belong; or can the language which apparently conveys this meaning be explained in any other sense? We are not now inquiring into the real existence of this supposed substratum; which is a question of ontology, not of psychology: we are only asking, Do we, as a mental fact, really suppose it to exist; and, if so, how can that supposition be accounted for? Are we, as a matter of fact, compelled to think that, besides the properties which we perceive by the senses, there exists also an insensible substratum, in which they inhere, to use the simile of Coleridge,[2] like pins sticking in a pin-cushion and hiding it? Consciousness surely tells us nothing of the kind; but what it does tell us is sufficient to explain how its testimony has been thus perverted. In the first place, it tells us that no sensible quality can be perceived or conceived by itself; but that each is necessarily accompanied by an intellectual apprehension of its relations to space, as occupying it and contained in it. Colour cannot be perceived without extension; nor extension without solidity; and solidity is not a single attribute, but includes in its comprehension the three spacial dimensions of length, breadth, and thickness. In the second place, it tells us that all sensitive perception is a relation between self and not-self; that all sensible objects are apprehended as occupying space, and thus as distinct from the apprehending mind, whether distinct or not from the bodily organism. Every attribute is thus intuitively perceived, and consequently is also reflectively conceived, as accompanied by other attributes, and as constituting, in conjunction with those attributes, a *non-ego* or sensible thing: but of an insensible substratum consciousness tells us, and can tell us, nothing; nor do we feel any necessity of believing in its existence, when the question is distinctly put before us, disentangled from its usual associations.

But does not the use of language, it may be asked, imply a real, though perhaps a confused consciousness of something more than this? Does not the name of each attribute separately denote relation, not merely to other attributes, but to a substance? Does not extension imply a thing extended, and colour a thing coloured, not merely a coloured extension or an extended colour? What, in short, is the difference denoted by the use of abstract and concrete terms, except that qualities are universally apprehended as really inhering in a subject, though logically distinguishable from it? An explanation of this may, we think, be furnished, partly by a fact of the sensitive consciousness, and partly by an association derived from another source. The fact is to be found in the distinction which has been pointed out in the preceding pages between sensation and perception. Any material phenomenon may be regarded in two points of view: First, by itself, as a particular affection of the nervous organism, distinguishable as such from any other, and present to consciousness as a mode of the sentient subject. Secondly, in conjunction with the apprehension of space, as extended, consisting of parts out of each other, and constituting one element of the complex phenomenon which is conceived as an object. The former point of view is indicated by the abstract, the latter by the concrete term. In the former we contemplate the sensible affection alone, as a state of the *ego*, without attending to the necessary accompaniment of its relation to space. In the latter we contemplate it in the opposite relation, as forming one element of the material *non-ego*, or sensible object existing in space. The association which has contributed to a different interpretation of these terms is furnished by the opposite class of intuitions, those, namely, of internal perception or self-consciousness. Modes of mind differ from modes of body, in being immediately given in relation to a common subject. While colour, and figure, and hardness, and other sensible qualities, are united together only by their coexistence in space, sensations, emotions, volitions, and other affections of mind are manifested in consciousness as modes of existence of one and the same indivisible self,—the subject of all, and yet identical with none. The personal self is neither a mode of consciousness nor the aggregate of many modes, but a substance, distinct from all its affections, though discerned in consciousness in conjunction with them. This one presented substance, *myself*, is the basis of the other notions of substance which are thought representatively in relation to other phenomena.[1] When I look at another man, I do not immediately perceive his consciousness; but I can mediately and reflectively transfer to another that of which I am directly cognisant only in myself. Beyond the class of conscious beings, I have only a negative idea of substantiality, except in so far as it is synonymous with the occupation of space.[2] Some imperceptible bond of union between the phenomena of matter may exist, or it may not; but if it does exist, it exists in a manner of which I can form no conception; and if it does not exist, my faculties do not enable me to detect its absence. But the immediate knowledge, which consciousness gives me, of my own presented unity, is sufficient to explain the association which has led to its representation in other objects.

---

[1] Arist. *Eth. Nic.* vi., 11. Διὸ καὶ φυσικὰ δοκεῖ εἶναι ταῦτα, καὶ φύσει σοφὸς μὲν οὐδείς, γνώμην δ᾽ ἔχειν καὶ σύνεσιν καὶ νοῦν. Σημεῖον δ᾽ ὅτι καὶ ταῖς ἡλικίαις οἰόμεθα ἀκολουθεῖν, καὶ ἥδε ἡ ἡλικιά νοῦν ἔχει καὶ γνώμην, ὡς τῆς φύσεως αἰτίας οὔσης.

[2] *Aids to Reflection*, Conclusion.

The principle of causality, as well as that of substance, has been disguised by associations which do not properly belong to it. In the first place, we must separate the special judgment from the general;—the assertion that this particular event is dependent on this particular cause, from the assertion that every event is dependent on some cause. The belief in the uniformity of nature is not a necessary truth, however constantly guaranteed by our actual experience. We are not compelled to believe that, because A is ascertained to be the cause of B at a particular time, whatever may be meant by that relation, A must therefore inevitably be the cause of B on all future occasions. This conviction may amount to a moral certainty; we may act upon it without hesitation in the affairs of life; but it has no such necessity that we are unable to conceive the contradictory.[3] But to conceive it possible that B may at one time be caused by A and at another by C, and that A may at one time produce the effect B and at another D, the other circumstances being in all the cases exactly alike, is very different from conceiving it possible that B may exist without being produced by any cause, and that A may exist without producing any effect. In the second place, therefore, we must ask what is the exact meaning of the assertion, that every event must be produced by *some cause*. In one sense, this judgment is unquestionably necessary. If *cause* be interpreted to mean no more than *temporal antecedent*, the assertion that every event must have a cause implies only that no event can be conceived as the beginning of all existence, but that in every case we are compelled to think that it has been preceded by some other. This is the necessary consequence of the subjection of our intuitions to the law of time. I can be conscious of an event only as taking place in time, and I can be conscious of time only in conjunction with a succession of events taking place in it. It is therefore impossible to conceive an absolutely first occurrence. The principle of causality is thus derived from the intuition of time, as that of substance is from space. To this necessary notion of *some antecedent* is afterwards united by association the empirical notion of the uniformity of nature; and the conception of cause thus assumes the form in which Hume and Brown, from different points of view, both regard it; namely, that of the invariable antecedent of a particular change. The law of time compels us to believe that there *must be* some antecedent phenomenon or aggregate of phenomena; experience, and the anticipations to which experience gives rise, tell us that this antecedent *is* invariable; and the complex judgment is apparently invested with the absolute necessity which of right belongs to one of its ingredients only.

But the causal judgment, as usually understood, appears to contain something more than the idea of antecedence. The cause is supposed, not merely to precede the effect, but to have *power* to produce it. Whether the notion of *invariable recurrence* is included or not, it seems at least to be regarded as certain that, *upon any one occasion*, the effect is so far completely dependent upon the cause, that, the latter being given, the former *cannot but* take place. The explanation of this impression may, we think, be found in another association, derived from the personal causality manifested in volition. In the exercise of an act of will, I am intuitively conscious of two things:—First, that I am acted upon, though not necessitated by, motives: secondly, that I act upon my own determinations as their producing cause. In the first relation I am conscious of a choice between two alternatives; that is to say, that from certain given antecedent motives, a particular consequent may or may not follow, as I choose to determine. In the second relation I am conscious of an exercise of power;[4] the final determination being called into existence by an act of my own will. To this intuition may be traced the origin of the idea of power and of causation, in a sense distinct from that of mere temporal antecedence. The power of which I am presentatively conscious in myself, I transfer representatively to other agents whom I suppose to be similarly constituted to myself; and thus I regard other men as being, like myself, the efficient causes of their own determinations, and, through their determinations, of their actions. But beyond the range of conscious beings, this representation of cause, like the corresponding one of substance, is inadmissible. The connection between the antecedent motive and the consequent determination is regarded as contingent, so long as a voluntary exercise of power is interposed between the two. But where consciousness, and consequently volition, is excluded, I can no longer regard the relation between the antecedent and consequent phenomenon as contingent. Contingence in a single succession[1] is only conceivable under the form of *choice*, by the interposition of the *ego*, the only given substance, between two successive phenomena. When this is excluded, the phenomena become co-adjacent; there is no choice, and consequently no conceivable contingence in the succession. The apparent necessity of the causal relation in every single instance is thus explicable as a negative idea. It is not so much a positive conception of necessity, as an inability to conceive the opposite. But this inability does not depend on a law of thought. It is not an essential, but an accidental inconceivability, dependent, according to the classification made in a previous page,[2] on a defect in the matter of intuition. The contingency is in this case inconceivable, because contingency can only be conceived at all in the form in which alone it is presented to intuition, namely, as a conscious choice between two alternatives.[3] If this explanation of the apparent necessity of the causal judgment be admissible, it will lead to some important consequences as regards the question of free will and determinism. But this controversy belongs rather to ontology than to psychology.

---

[1] "Ex iis vero quæ in ideis rerum corporalium clara et distincta sunt, quædam ab idea mei ipsius videor mutuari potuisse; nempe *substantiam*, durationem, numerum, et si quæ alia sint ejusmodi." (Descartes, *Meditatio Tertia.*) From this was probably borrowed the similar remark of M. Royer-Collard (see Jouffroy's translation of Reid, vol. iv., p. 350):—"Le moi est las eule unité qui nous soit donnée immédiatement par la nature; nous ne la rencontrons dans aucune des choses que nos facultés observent. Mais l'entendement, qui la trouve en lui, la met hors de lui par induction, et d'un certain nombre de choses coexistantes il crée des unités artificielles."

[2] Una est cujusque substantiæ præcipua proprietas, quæ ipsius naturam essentiamque constituit, et ad quam aliæ omnes referuntur. Nempe extensio in longum, latum et profundum substantiæ corporeæ naturam constituit; et cogitatio constituit naturam substantiæ cogitantis. Nam omne aliud quod corpori tribui potest, extensionem præsupponit, estque tantum modus quidam rei extensæ; ut et omnia, quæ in mente reperimus, sunt tantum diversi modi cogitandi." (Descartes, *Principia*, i. 53.)

[3] Into the controversies concerning the origin of this belief it is unnecessary to enter. Whether it be derived from association, or from an intuitive law of the mind, or from any other source,—whether it be conceived as absolutely certain, so long as the present constitution of the world lasts or not,—is immaterial. At any rate, it is not conceived as a law which in no imaginable world, and by no possible exertion of power, could be otherwise than it is: and this is sufficient to exclude it from the class of necessary truths which we are now considering.

[4] Those philosophers who derive the idea of causation exclusively from the succession of phenomena, are bound in consistency to re-

The above inquiry into the nature and origin of necessary truths will enable us to throw some light on the controverted question concerning the existence of innate ideas, —a question which should be discussed, not where Locke placed it, at the beginning of mental philosophy, but at the end; for its answer depends on an examination of the actual features of the phenomena of consciousness, and thus presupposes the facts of psychology, instead of being presupposed by them. Setting aside, as irrelevant, those arguments which are little better than quibbles on the word *innate*, such as Locke's appeal to the consciousness of newborn children, the real point to be determined is this:—Are there any modes of human consciousness which are derived, not from the accidental experience of the individual man, but from the essential constitution of the human mind in general, and which thus naturally and necessarily grow up in all men, whatever may be the varieties of their several experiences?[4] The previous analysis of consciousness will furnish an answer to this question. Every phenomenon of consciousness consists of two elements,—a matter, derived from experience; and a form, dependent on the original constitution of the mind. But the matter and the form are given in conjunction, and require an effort of analysis, aided by language, to separate them. This analysis may or may not be performed by this or that man, according to the circumstances in which he is placed. The forms of consciousness in general, and of its several modes,—personality, space, time, unity, plurality, totality,—may or may not be represented by the mind in their abstract character, as ideas or notions embodied in language; and the necessary truths based upon them may or may not be consciously discerned in the same character. A savage may never have contemplated the notions, *one*, *two*, *three*, *four*, &c., in the abstract: he may not know as an universal truth that two and two make four. But he knows the difference between a man and a tree, and he knows the difference between one man and many; and this knowledge contains the same ideas in the concrete. He embraces various sensible phenomena under the single notion of a man, though he has never asked himself the abstract question, How can the one be many, and the many one? Locke is, therefore, in one sense, right in denying the existence of innate ideas; for no idea can be formed independently of experience, and no idea need consciously be separated from the empirical accompaniments with which it is first manifested in con-

---

gard the idea of power, as distinct from that of succession, as a pure delusion. And this is directly asserted by Hume, *Inquiry concerning Human Understanding*, sect. 7; *Human Nature*, part iii., sect. 14; by Brown, *Inquiry into Cause and Effect*, p. 18; and by James Mill, *Analysis of the Human Mind*, vol. ii., p. 256. Unfortunately, this theory does not inform as how, consistently with the laws of the imagination, such a delusion could have originated.

[1] It is necessary to specify *in a single succession;* as, in another sense, those phenomena may be called contingent, which do not uniformly, in various successions, follow from a given antecedent. But in this case the antecedent is not regarded as the cause of the consequent at all. But, in the case of any single occurrence, we are compelled to conceive that there is some antecedent or other on which it is dependent, and which being given, the occurrence could not but take place, *unless it is the result of an act of free will.* This conviction, with the exception, is the phenomenon to be explained.

[2] See *ante*, p.

[3] In this reduction of the apparent necessity of the causal judgment to an impotence caused by the absence of the data for thought, I must acknowledge my obligations to the corresponding portion of the theory of Sir W. Hamilton, *Discussions*, p. 609. This acknowledgment is the more necessary, inasmuch as, except in so far as regards the condition of relativity in time, I am compelled to dissent from the views of that eminent philosopher. His statement of the causal judgment, as an inability to think that the complement of existence has been either increased or diminished, is open to various objections. In the first place, I am not conscious of any such inability. I have no difficulty in conceiving that the amount of existence in the universe may at one time be represented by A, and at another by A+B. It is true that I cannot conceive nothing becoming something; for I cannot conceive nothing *per se;* but neither, on the other hand, can I conceive A, or any part of A, becoming B, while A remains at the same time undiminished. But the *result* is perfectly conceivable, though the *process* is not so, and cannot on any hypothesis become so. In the second place, whether we represent the new appearance as a *change* or as a *creation*, we are equally compelled to suppose a cause of its taking place. To say that B previously existed under the form of A, is not to explain the causal judgment; for we have still to ask why A became B. In the third place, the theory fails to account for the origin of the idea of *power*, which, whether rightly or wrongly, all men instinctively attribute to the supposed cause. To represent it as a delusion is not sufficient; unless it can be shown how, consistently with the limits of thought, such a delusion could have originated. I regret, however, that Mr Calderwood, with some of whose criticisms I concur, should have charged the above theory with pantheism. If ever there was a philosopher whose writings from first to last are utterly antagonistic to every form of pantheism, it is Sir William Hamilton. Pantheistic his theory certainly is not; for it represents the pantheistic hypothesis as the result of a mere impotence of thought, exalting its own inability to think into the measure of all possible existence.

[4] "Innate," says Lord Shaftesbury, "is a word he (Locke) poorly plays upon: the right word, though less used, is *connatural.* For what has birth, or progress of the fœtus out of the womb, to do in this case. The question is not about the *time* the ideas entered, but whether the constitution of man be such, that, being adult or grown up, at such or such a time, sooner or later (no matter when), the ideas of order, administration, and a God, will not infallibly, inevitably, necessarily grow up in him." The latter part of the criticism is not decisive; for Locke cites the adult savage to show that these ideas do not necessarily grow up. The true answer is, that experience itself is partly innate.

sciousness. But, precisely in the same sense, we may deny the existence of ideas of sensation; for sense alone could distinguish no two ideas from each other, without the co-operation of the understanding, which invests the materials furnished by sensation with certain universal and necessary forms. Instead of attempting to classify the actual phenomena of consciousness under one or the other head,—instead of saying that certain ideas are wholly empirical, and certain others wholly innate,—we should rather say that every phenomenon of consciousness contains an adventitious and a native element; and that, without the union of these two, no consciousness is possible. The criterion of universality and necessity marks the native or *à priori* element; but this criterion cannot be applied to the complex phenomena of any complete act of consciousness, but only to the element, when separated by an act of analysis, and embodied in that symbolical form which is not consciousness itself, but a substitute for it.

Cognate to this is another question of far greater importance:—What are the limits of thought? Is the mind capable of transcending the boundaries of all possible experience: and is such a power manifested by its possession of necessary truths? for necessity is not the result of experience. Experience tells us *what is*, but not *what must be*. Here, again, we must distinguish between the complete facts of consciousness and the several elements which are logically distinguishable from each other. If by *experience* is meant all that is presented in any mode of intuition, matter and form included; and if the question is understood to mean, Can we contemplate in thought any object which has never been presented as an element in any mode of intuition? the answer must undoubtedly be given in the negative. But experience in this sense contains a necessary as well as a contingent—a formal as well as a material element. Either of these may be contemplated in thought, apart from the other; and either may be contemplated in relations in which experience has never presented it. We have never seen a straight line, except as part of a surface; nor a surface, except as composed of some material, such as wood, or slate, or paper. But when thought, assisted by language, has enabled us to distinguish these concomitant phenomena from each other, we may reproduce in imagination the straight line as a modification of pure space, and contemplate its necessary relations in that character. Thought is so far dependent on experience, that where experience is impossible, thought is impossible likewise: it is so far independent of experience, that it can contemplate apart from each other the native form and the adventitious matter, which experience always presents in conjunction.

"The dominion of man," says Locke, "in this little world of his own understanding, is much-what the same as it is in the great world of visible things; wherein his power, however managed by art and skill, reaches no farther than to compound and divide the materials that are made to his hand; but can do nothing towards the making the least particle of new matter, or destroying one atom of what is already in being. The same inability will every one find in himself, who shall go about to fashion in his understanding any simple idea, not received in by his senses from external objects, or by reflection from the operations of his own mind about them."[1] The preceding remarks will show with what modifications this statement should be received. It is true, in so far as it asserts that nothing can be represented in thought which has not, separately or in conjunction with other phenomena, been presented in intuition; but it is incorrect, in so far as it overlooks the fact that intuition has a necessary element, derived from the constitution of the mind, as well as a contingent element, derived from the phenomena of sensation and reflection.

But whether we regard the objects of consciousness as presented in intuition, or as represented in thought; whether we look to the necessary or to the contingent elements of which they are composed; there is one limitation which the very conception of consciousness, as a relation between a subject and an object, necessarily implies, and to which in all its modes it must inevitably submit. Nothing can be presented in intuition, or represented in thought, except as *finite*. So long as the relation between subject and object exists in consciousness, so long each must limit the other. The subject is distinct from the object, and the object from the subject, and neither can be the universe. Nay, the object itself can only exist, as such, under the conditions of limitation and difference: it can be discerned only as one out of many; as implying the existence of other things besides itself; and hence, again, as a finite portion of the universe. The infinite cannot be an object of human consciousness at all; and it appears to be so only by mistaking the negation of consciousness for consciousness itself.[2] The infinite, like the inconceivable, is a term which expresses only the negation of human thought:—nay, the two terms are in fact synonymous, for conception is limitation. But the limits of possible thought are not the limits of possible existence. The infinite may, nay, must exist, though we cannot conceive it as existing; for the denial of its existence involves a contradiction, as well as the assertion of its conceivability. Hence we learn the important lesson, that the provinces of reason and faith are not coextensive; that it is a duty, enjoined by reason itself, to believe in that which we cannot comprehend.

From the above examination of necessary truths, it may be shown that no matter of fact can be a matter of demonstration in the highest sense of the term. For it is essential to demonstration that its object should be such as we can construct from within, out of the forms inherent in our own mental constitution; and it is essential to the existence of a fact, as such, that it should be presented to us from without. A fact, as such, must exist independently of my thinking about it: an object of demonstration, as such, exists only in and by the act of conceiving it. This consideration is sufficient to explain the failure of all attempts to demonstrate, *à priori*, the being and attributes of God,—a failure which should rather be a matter of rejoicing than of regret to the believer. If we can demonstrate the attributes of those objects only which we have constructed for ourselves, it follows that a demonstrated God is a creature of the human imagination. Such a demonstration is not, indeed, incompatible with the real existence of the Deity; as the domonstrations of geometry are not incompatible with the existence in nature of perfect geometrical bodies; but it adds not one tittle to the evidence of his existence; and it encumbers theology with arguments too pretentious not to provoke criticism, and too feeble to endure it. "Mischief," says Waterland, "is often done by pretending to strict and rigorous *demonstrations*, where we have no occasion for them, and where the subject is too sublime to go far in, with clear and distinct ideas. Such attempts serve only to make that become a matter of *question*, which before was *unquestionable*, while standing only on *reasonable* presumption or *moral* proof."[3] The triumph over a weak defence of a truth is too often regarded as a triumph over the truth itself; and we may therefore rejoice that theology, in the hands of its best exponents, has wisely abstained from resting its claims to belief on the evidence of rigid demonstration.

Lastly, we may observe that the distinction which various schools of philosophy, under various names, have attempted to establish, between the understanding and the reason, a separate faculties of thought, is, on the above principles, unnecessary, and therefore untenable. Whether, with the ancients, we distinguish between νοῦς and διάνοια, the intuitive and the discursive thought, the faculty of principles and the faculty of deduction from principles; or, with the moderns, especially in Germany, between understanding, as the faculty of generalization from the intuitions of consciousness, and reason, as the faculty which endeavours, intuitively or discursively, to apprehend the supreme conditions on which consciousness itself depends; we alike divide that which is one and indivisible, and attribute to the faculty of thought an operation which it never performs. The function of thought is in all cases the same, namely, to represent reflectively what is presented intuitively; and the existence of necessary as well as contingent principles in thought, is to be explained, not by a double operation of the thinking faculty, but by the existence of a corresponding distinction between necessary and contingent facts in intuition. The hypothesis of a faculty of reason distinct from understanding may indeed be necessary, as an assumption, to support the systems of those philosophers who aim at constructing a philosophy of the absolute and the infinite; for intuition, and therefore thought, as described in the preceding pages, takes cognisance only of the relative and the finite. But this assumption, consistently carried out, involves the annihilation of consciousness itself. But the mention of the absolute and the infinite reminds us that we are entering on the domain of the second portion of Metaphysics,—Ontology, or the Philosophy of Being.

II. ONTOLOGY; OR, THE PHILOSOPHY OF THE REALITIES OF CONSCIOUSNESS.

The term Ontology, or the Philosophy of Being, has become, in the estimation of no inconsiderable class of critics, a mere synonym for barren and useless logomachy. And it must be confessed, that the manner in which this field of inquiry has been frequently cultivated has gone far to explain, if not to justify, the contempt into which it has fallen. The philosophy which attempts to deduce a science of realities from the most abstract and general conception of existence must, from the necessity of the case, deal with words, and not with things. It has been already observed, in the preceding pages, that the human mind possesses no positive notion answering to the term *existence* or *being* in general; and it follows that there can be no law of the human reason which can indicate any necessary results involved in such a notion, and no fact of human experience which can give rise to a corresponding intuition. Every existence which we can perceive, is definite and particular, limited and related; and every existence of which we can think, is definite and particular, limited and related likewise. It must therefore needs be that a science which starts from the assumption of being in the abstract (which is not a conception, but an equivocal term, capable of relation to many distinct conceptions), and attempts, by pure deduction and division, to reason down to the concrete existences which alone are objects of positive thought, must end by delivering, not differences of things, but distinctions of words. And this must be admitted to be the case with the speculations of ontology in much of their ancient and mediæval, and in some stages also of their modern, development. The science was divorced from psychology; and was therefore destitute of facts, and compelled to supply their place by the signs of facts. Reversing the law of all reasoning, that of proceeding from the known to the unknown, it endeavoured to arrive at the truths which are immediately known in consciousness, by commencing with the unknown and unknowable beyond it. But, profitless as such attempts ever have been, and ever must be, there were not wanting circumstances in the history of philosophy, calculated to invest them with an apparent importance, and to engage acute and subtle intellects in the hopeless investigation. The science of mathematics was almost completed, in the essential features of its pure and abstract character, as the science of the relations of number and magnitude, at a time when its most important applications to the explanation of the phenomena of the material world were but dimly conceived, and not at all executed. With the triumphs of this science—the earliest, the clearest, the most rigorous in its reasonings, the most unassailable in its conclusions—before their eyes, the patriarchs of philosophy might be justified in believing that, in the law of intellectual progress, the abstract and rational must precede the concrete and empirical,—that the necessary relations of things in general must be determined prior to the investigation of the actual attributes of things in particular. But though the relation of mathematical to physical science presents, in some respects, an analogy to that between the rational and empirical philosophy of mind, the analogy unfortunately fails in the very feature that is most essential to scientific progress.

OF DOGMATIC OR DEMONSTRATIVE METAPHYSICS.

The demonstrations of geometry are due to the possession by that science of concrete as well as abstract axioms; of *à priori* intuitions of objects, as well as analyses of notions. Had the geometer been confined to such general and abstract principles as, that the whole is greater than its part, or that the sums of equal things are equal,—principles which indicate merely the logical analysis of thoughts, not the geometrical intuition of magnitudes;—had he been debarred, as some theorists have wished to debar him, from the use of the axiom of parallel lines, and the assumption that two straight lines cannot inclose a space, and other similar principles, many of which are implied, though not expressed, in all geometrical reasonings,[1]—his science would have remained to the end of time a science of words only. Yet it is upon the model of the merely logical principles that the majority of deductive metaphysicians have framed their fundamental assumptions.[2] Definitions of being in various senses of the term, and of the attributes coextensive with being; divisions and subdivisions, with explanations of each, and analyses of the contents of the several notions; have constituted, for the most part, the entire apparatus of ontological reasoning,—a reasoning which, being based entirely upon the logical conditions of thought, can attain to no other truth than that which is implied in the formal harmony of one thought with another, and the consequent consistent use of the language in which thoughts are expressed. And, accordingly, ontology, thus treated, obtained the name, more suited to its performances than to its pretensions, of a *lexicon of philosophical terms.*[1] It is manifest, however, that such a method involves, however little its professors may be aware of the fact, a virtual abandonment of the problem which ontology undertakes to solve. That problem, as has been before observed, is to determine the relation which exists between the necessities of thought and the constitution of things. But a science which starts with a definition of being in general, commences with one member only of this relation, the notion of *being as conceived by us.* To verify this conception, by showing that being as it is corresponds to being as we conceive and define it, it is necessary that the conception should be compared with something distinct from itself; and the data for this comparison cannot be supplied by a merely logical development of one notion from another.

---

[1] It is with reference to these axioms that Kant proposes, as preliminary to all metaphysics, the question,—"How are synthetical judgments *à priori* possible?" For the general axioms are merely analytical judgments, in which the predicate contains nothing more than is already implied in the conception of the subject. The special axioms are the only ones in which an additional attribute is asserted of the subject; and, consequently, the only ones that can be considered as in any sense a statement of real relations.

[2] "Etenim Euclides demonstrationes suas in principia ontologica resolvit, quæ instar axiomatum absque probatione sumit; veluti quod totum sit majus qualibet sua parte, quod æqualia eidem tertio sint æqualia inter se." (Wolf, *Ontologia*, sect. 9.) In the same passage, these axioms are called "principia quæ mathesis pura ex ontologia mutuatur."

In point of fact, the speculations of demonstrative ontology accomplished far less than this. The analysis of a thought may be complete as a logical process, whether answering to reality or not, provided that its fundamental assumption represents at starting a positive and intelligible conception. But the fundamental assumption of ontology, that of *ens*, or *being in general*, represents nothing of the kind. What is being in general, apart from the special modes of being which are manifested in consciousness? When, in the crucible of abstraction, self and not-self, the factors of consciousness, and every special modification of either, have evaporated, what remains as the residuum? Absolute zero; a mere word with no thought answering to it; a being which is neither my being nor that of anything else, and which is therefore removed from all the conditions under which being is, or can be, made known to us. I have no conception of being in general which is not some being in particular; and to assume that the various modes of being which consciousness reveals to us are but subordinate species of one and the same genus, is to assume a fact which consciousness does not testify, and which, if it can be proved at all, must be the conclusion, and not the premise, of the science that deals with it. Deductive ontology, by assuming being as its starting-point, necessarily abandons thought to juggle with words.[2]

OF THE SUBDIVISIONS OF DOGMATIC METAPHYSICS.

A metaphysic of being in general, even if successful in its aim, can only be regarded as a preparation for a more special philosophy. Even if it could solve its own problem, it would answer none of the important questions which connect metaphysical inquiries with the interests and destinies of man; it would satisfy none of the yearnings which compel men to undertake the study of them. The ideas of God, of freedom, and of immortality, are too special to be elicited by the processes of general ontology, except in the form of pantheism, which disposes of them by annihilating them altogether. The idea of God becomes merged in that of the sum total of existence; that of freedom is destroyed by representing this quasi-deity as the sole real agent; that of immortality is exchanged for an absorption of the phenomenal self into the real universe. To preserve the heirlooms of human reason intact, it was necessary for philosophy to descend from the region of pure abstraction into one in which the conception of being could assume a more definite form. And here, at least, the investigations of the metaphysician had the advantage of starting from the testimony of consciousness. Every act of consciousness is given to us as a relation between *self* and *not-self.* These two elements, as mutually related, are necessarily viewed as modifying and limiting each other. But the consciousness of the relative and the limited suggests, by inevitable association, the notion of the absolute and the unlimited as its contrast. Hence arise the three fundamental ideas which underlie the whole fabric of ontological speculation,—conditioned existence, manifested in the two relative and finite forms of the *ego* and the *non-ego*; and unconditioned existence, implied in the suggestion of the absolute and the infinite. The investigation of these ideas has given rise to three branches of metaphysical philosophy,—rational psychology, rational cosmology, and rational theology:—the *ego* being identified with the human soul, regarded as a substance distinct from its phenomenal modifications;[3] the *non-ego* with the reality which manifests itself in the sensible world; and the absolute or unconditioned with the Deity.[4] But, in the prosecution of these inquiries, metaphysicians committed the same error which has been already noticed as vitiating the theories of being in general. They deserted the facts of consciousness, to take refuge in abstractions, of which we are not, and cannot be, conscious. Let it be granted that every phenomenon implies a corresponding reality; that the phenomena of the *ego* indicate the existence of the human soul; and the phenomena of the *non-ego*, that of a substantial universe; and the relation between the two, that of a being who is beyond relation;—still, in no fact of consciousness is the reality given apart from the phenomena which are related to it. The notions of an abstract self, modified in no particular manner; of an abstract world, isolated from the special phenomena of sense; and of an abstract Deity, apart from those finite attributes by which he is manifested in relation to the finite consciousness of mankind, can be given in no phase of consciousness; for if they were, the relation and succession which constitute consciousness would be annihilated. Whether these three metaphysical ideas all stand on the same footing within the domain of consciousness itself, is a question which we shall have to ask hereafter; but, assuming for the moment that they do, and assuming that in each there is a legitimate passage from the phenomena presented in consciousness to the ultimate realities beyond, it is clearly begging the whole question, and anticipating the inquiry which philosophy has not yet commenced, to start with the abstract notions of such realities, as if the problem had been already solved, and the passage found. Hence, like ontology in general, the three branches of ontology, if deductively treated, will deal with words and not with things. Unable to verify their fundamental assumptions by an appeal to the facts of consciousness,—unable even to determine whether those assumptions represent thought or the negation of thought,—they can but torture words under the name of analysing notions, and arrive at conclusions which indicate no more than a consistent use of language. Thought itself, in its bare and unmixed form, cannot be handled in any mental process. It must be contemplated either in the words which represent it, or in the things which it represents, or in the union of the two; and the whole difference between reasoning and logomachy depends upon a single criterion:—Can the relations of language, which our process exhibits as representing thought, be verified by an appeal to the facts of consciousness, of which thought itself is the representative? Such an appeal is manifestly impossible to those who commence their inquiries by assuming an abstraction of which consciousness does not and cannot take cognisance.

---

[1] Wolf, *Ontologia*, sect. 25.

[2] The following summaries, extracted from the works of two eminent metaphysicians of the seventeenth and eighteenth centuries, may enable the reader to form some notion of the treatment of ontology, in systems prior to the criticism of Kant. The contents of Burgersdyk's *Institutiones Metaphysicæ* are enumerated as follows:—"De natura metaphysicæ—De communi entis notione—De eo quod est medium inter ens et nihil in genere—De privatione et denominatione externa—De ente rationis—De relatione—De modis entium—De principiis incomplexis sive essentia et existentia—De principiis metaphysicæ complexis—De entis affectionibus in genere—De unitate et multitudine in genere—De unitate numerica et formali, de que principio individuationis—De unitate universali—De speciebus et gradibus unitatis—De diversitate sive distinctione et convenientia—De oppositione—De ordine—De veritate et falsitate—De adjunctis veritatis—De bono et malo—De localitate, temporalitate et duratione—De toto et parte—De causa et causato in genere—De causa materiali—De causa formali—De causa efficiente—De fine—De subjecto et adjuncto—De eo quod est necessarium, impossible, contingens et possibile—De potentia et actu—De perfecto et imperfecto, sive perfectibili et perfectione." The contents of Wolf's *Ontologia* are of a similar character:—DE NOTIONE ENTIS IN GENERE ET PROPRIETATIBUS QUÆ INDE CONSEQUUNTUR—*De principiis philosophiæ primæ*—De principio contradictionis—De principio rationis sufficientis—*De essentia et existentia entis, agnatisque nonnullis notionibus*—De possibili et impossibili—De determinato et indeterminato—De notione entis—*De generalibus entis affectionibus*—De identitate et similitudine—De ente singulari et universali—De necessario et contingente—De qualitate et agnatis notionibus—De ordine, veritate, et perfectione—DE SPECIEBUS ENTIUM ET EORUM AD SE INVICEM RESPECTU—*De ente composito*—De essentia entis compositi—De extensione, continuitate, spatio et tempore—De qualitatibus et magnitudine entis compositi—De motu—*De ente simplici*—De differentia entis simplicis et compositi—De modificatione rerum præsertim simplicium—De finito et infinito—*De respectu entium ad se invicem*—De dependentia rerum earumque relatione—De causis—De signo.

[3] The character of rational psychology, as distinguished from empirical, is thus stated by Wolf,—"Definio *psychologiam empiricam* quod sit scientia stabiliendi principia per experientiam, unde ratio redditur eorum quæ in anima humana fiunt . . . . In psychologia rationali ex unico animæ humanæ conceptu derivamus à priori omnia quæ eidem competere a posteriori observantur et ex quibusdam observatis deducuntur." (*Philosophia Rationalis, Disc. Prælim.*, sect. 111, 112.) Compare Herbart, *Allgemeine Metaphysik*, sect. 29.

[4] These three objects of metaphysical inquiry,—God, the world, the soul,—answer to Kant's three ideas of pure reason; but he arrives at them in a different way; namely, by regarding them as all alike intimations of the unconditioned, suggested by the three kinds of logical syllogism;—a derivation fanciful and extravagant, and which nothing but the profound genius of its author could have rescued from utter absurdity.

Thus, to illustrate our remarks by special instances, the aim of rational psychology is to frame definitions exhibiting the essential nature of the soul and its properties, as realities conceived by the intellect, underlying and implied by the phenomena presented in consciousness; and to prove by a demonstrative process that the notions thus defined necessarily flow one from another. Psychology is thus raised from a science of observation to one of demonstration; and its objects are transformed from phenomena presented in experience to realities contemplated by the intellect. The soul, by virtue of its essential nature as a simple substance, is shown to possess, of necessity, certain attributes as rationally conceived and defined—such as sense, imagination, intelligence, will, spirituality, indestructibility, and so forth; and the same conclusions are even demonstrated of other spiritual natures which partake of the generic attributes of the human soul.[1] The weakness of the whole process is, that it tacitly postulates as its starting-point a principle which is neither evident in itself, nor such as can be made evident by any process of thought. It assumes, that is to say, a transcendental definition of the real nature of the soul, beyond and above those facts and relations which are manifested in consciousness. But how is the truth of such a definition to be guaranteed? Of the soul as a simple substance, apart from its particular modifications, consciousness tells us nothing. Its permanent existence is known only in conjunction with and by means of its successive modifications. How, then, is this abstract conception of the nature of the soul to be verified? It cannot be self-evident; for self-evidence is nothing more than the instantaneous assent of consciousness; and the assumption in question cannot be submitted to the judgment of consciousness at all. It cannot be demonstrable; for it could only be demonstrated by the assumption of a higher notion of the same kind, concerning which the same question would then have to be raised. It cannot be generalized from experience; for experience deals with the facts of consciousness only, and tells us not of what *must be*, but only of what *is* or *seems to be.* Unable to verify his fundamental definition by any reference to the reality which it is supposed to represent, the metaphysician is compelled to confine himself to the relations of the language by which it is represented.

The case is still stronger as regards the other two branches of deductive metaphysics. Cosmology, as exhibited by Wolf, professes to deduce, from ontological principles, a demonstration of the nature of the world and the manner in which it is produced from simple substances.[2] The world, according to this method, is represented as an absolute whole, or entire system of causes and effects, which cannot be conceived as itself a part of any greater whole;[3] and the office of cosmology is to deduce, from the abstract principles of being in general, the necessary relations which the world, as a compound being, must exhibit. It is thus based, not on an examination of the mundane phenomena as they actually exist in the present system of nature, but on the general conception of the world, as a possible system, under which the actual system is included, as an individual under a species.[4] Cosmology, as thus exhibited, can contain nothing more than an analysis of general notions, and can lead to no conclusions but such as the philosopher has himself virtually assumed in his premises. The abstract notion of the world contains implicitly whatever attributes we choose to assume as its constituents; and the metaphysical or logical analysis of that notion can contain no more. For the world, as a possible system of realities, and not as an actual system of phenomena, is not an object of intuition, pure or empirical; and, without intuition, it is impossible to connect the concepts of the understanding with a single attribute, beyond those which they contain in their original comprehension.[5]

---

[1] The following table of the contents of Wolf's *Psychologia Rationalis* will exhibit a brief summary of this method,—"*De anima in genere et facultate cognoscendi in specie*—De natura et essentia animæ—De facultate sentiendi, sive sensu—De imaginatione et memoria—De attentione et intellectu—*De facultate appetendi*—De appetitu sensitivo et aversatione sensitiva atque affectibus—De appetitu et aversatione rationali, seu de voluntate et noluntate—*De commercio inter mentem et corpus*—De systematis explicandi commercium inter mentem et corpus in genere—De systemate influxus physici—De systemate causarum occasionalium—De harmonia præstabilita—*De variis animœ attributis, spiritu in genere, et animabus brutorum*—De spiritu in genere et spiritualitate animæ in specie—De animæ ortu, unione cum corpore, et immortalitate—De animabus brutorum." Compare Kant, *Kr. der r. v. Transc Dial*, B. ii., H. 1. Hegel, *Encykl.* sect. 34.

[2] Wolf, *Cosmologia Generalis*, sects. 2, 7. The following are the questions discussed by Wolf in this work, as constituting a metaphysical theory of the material world—*De notione mundi seu universi*—De rerum nexu et quomodo inde universum resultet—De essentia mundi et ejus attributis—*De notione corporum ex quibus mundus componitur*—De essentia et natura corporum—De elementis corporum—De ortu corporum ex elementis—De legibus motus—*De natura universa et perfectione mundi*—De natura universa in genere, itemque naturali et supernaturali—De perfectione mundi—De ordine mundi atque naturæ.

[3] Kant, *Leçons de Metaphysique traduites par Tissot*, p. 144.

[4] Wolf, *Cosmologia*, sect. 49.

[5] "Cosmology," says Hegel (*Encyklopædie*, sect. 35), "treated of questions concerning the contingency or necessity of the world, its eternity or limitation in space and time, and the formal law of its changes; together with those concerning human freedom, and the origin of evil. It contemplated its object, however, not as a concrete whole, but only according to abstract definitions. Thus, for example, it discussed such questions as, whether the world is subject to chance or necessity; whether it is eternal or created." A portion of the questions here mentioned were sometimes transferred to other branches of metaphysics; but the method in all cases was the same, and the results equally barren.

This criticism is still more applicable to the system of rational theology. In this science, we are supposed to start from a nominal definition of the Deity, as the most perfect being, containing in his nature the sum of all possible realities in an absolutely perfect degree.[1] But here again the question arises,—How do we know that our conception at all corresponds to the nature of the being whom it professes to represent? The object, which the conception represents, is either given in some fact of consciousness, or it is not. If it is not given, I cannot compare the conception with its object; for comparison is itself an act of consciousness, and cannot be applied to anything of which I am not conscious. If it is given, it must be given, like all other facts of consciousness, in the form of an object related to myself. By what right, again, do I venture to transcend that relation, and assume that what is given in relation to me is identical with that which exists out of all relation. We are not, be it remembered, discussing the sufficiency of the religious consciousness for the spiritual wants of man: we are only examining the claim of the metaphysician to found thereon a system of absolute and necessary truths. Such a system claims, in its very conception, a right to transcend consciousness. The form of consciousness is *myself*, and the facts of consciousness postulate my existence as their condition. By what warrant am I justified in reasoning from the relative to the absolute,—in identifying that which depends on me with that on which I depend. A conception of the Deity, in his absolute existence, appears to involve a self-contradiction; for conception itself is a limitation, and a conception of the absolute Deity is a limitation of the illimitable.

OF THE CRITICAL PHILOSOPHY OF KANT.

The above method of dogmatic metaphysics, of which the most complete specimen is furnished by the writings of the celebrated Leibnitzian philosopher, Wolf, received its death-blow from the criticism of Kant. The fundamental position of the Wolfian dogmatism consisted in the assumption that the realities of the intelligible world constitute a system of immutable truths, which furnish the reason and the explanation of the phenomena of the world of sense. The counter-theory of Kant consisted in showing that the conceptions of the understanding and the ideas of the reason are equally phenomenal and relative with the intuitions of sense. The whole field of consciousness, reflective as well as sensitive, he argued, is the product of an objective and a subjective element, and can in no case be regarded as the exact representation of an extra-mental reality. We can perceive only as the laws of our intuitive consciousness, exhibited in the forms of space and time, permit: we can think only as the laws of our reflective consciousness, manifested in the categories of the understanding, permit. The product, in both cases alike, is not a *thing in itself*, but a *phenomenon*, or thing such as the laws of our mental constitution determine it to appear to us. The object, in one mode of consciousness as much as in another, is coloured by the medium through which it passes to reach the mind; and, in bringing the phenomena of sense before the tribunal of intellectual conceptions, we are not comparing the phenomenal with the real, the representation with the thing represented; we are only comparing one class of phenomena with another, and judging the representations of the human senses by the representations of the human understanding. Even the ideas of the reason, which correspond to the three great objects of metaphysical inquiry,—God, the world, and the human soul,—are not representations of objects actually discerned in their own nature, but regulative principles of thought, fallaciously invested with an objective existence. A necessity of thought manifestly indicates a law under which we must think; but it does not therefore guarantee the existence of a corresponding reality out of thought. The true *thing in itself*, the *being*, as distinguished from the *phenomenon*, is not the object such as we are compelled to conceive it, but the object out of all relation to our faculties; and, as such, it is manifestly unknown and unknowable. To perceive a thing in itself would be to perceive it neither in space nor in time; for these are forms furnished by the constitution of our perceptive faculties, and form an element of the phenomenal object of intuition only. To think of a thing in itself would be to think of it neither as one, nor as many, nor under any other category;[2] for these, again, depend upon the constitution of our understanding, and form an element of the phenomenal object of thought. The phenomenal is the product of the inherent laws of our own mental constitution, and, as such, is the sum and the limit of all the knowledge to which we can attain.

The logical result of Kant's speculative philosophy (of his practical philosophy we can say nothing at present), was to prove that real being cannot be an object of human thought; and, consequently, that a system of ontology, in the highest sense of that term, is unattainable by human reasoning. But, partly in consequence of the inconsistencies of Kant himself, and partly because of the sweeping scepticism to which his method at least appeared to lead, it was almost inevitable that his successors should attempt to reconstruct on a surer basis the dogmatic metaphysics which his criticism had overthrown. The Kantian philosophy had confined itself too much to negative results: it had demonstrated the inconclusiveness of the earlier systems of metaphysics: it had exhibited in the clearest light those apparent self-contradictions of the human reason which make metaphysics, in some form or other, an intellectual necessity to man; but it had not attempted to solve the contradictions it exhibited: it had neither pointed out the way to a surer metaphysical system, nor placed the reason in a position to dispense with metaphysics altogether. Kant had only succeeded in showing that the household of human consciousness was divided against itself: he had neither been able to merge the contradiction in a higher principle of unity, nor to show that contradiction itself is an evidence of truth and reality. The want which a philosophy of the real attempts to satisfy still remained; and to meet that want it was necessary to reconstruct metaphysics by another method. Kant had proved that the real, in its highest sense, could not be an object of consciousness: his successors accepted the conclusion, and consistently attempted to construct a philosophy of the real which should be above consciousness. Kant had proved it to be impossible to bring the object in itself within the grasp of the subject: there remained the yet wilder attempt to expand the subject to the immensity of the object,—an attempt which necessarily ended in the identification and consequent annihilation of both.

OF THE SYSTEMS OF FICHTE, SCHELLING, AND HEGEL.

The philosophy of Fichte furnished the transition from a destructive criticism to a new form of constructive dogmatism. The primitive fact of consciousness is that of a relation between the *ego* and the *non-ego*, between *myself*, the conscious subject, and an object of which I am conscious. But, thus manifested, self and not-self are correlative terms, existing for each other only under the conditions of human consciousness; that is to say, as *phenomena*, in Kant's sense of the term. To attain to a philosophy of the real, it was necessary to merge this primitive relation between the subject and object of consciousness in a higher relation between the entire world of phenomena revealed by consciousness, and the ultimate reality beyond it. And this was partly accomplished by the theory of Fichte. Consciousness, in this system, is manifested solely as a modification of the *ego;* and the *ego* itself must be supposed to exist prior to, and independently of, any special modification of its existence. Hence the first postulate of philosophy is that of the existence of an absolute *ego* or unconscious subject, susceptible potentially of all modes of consciousness, but actually modified by none. The first formula of Fichte's system, "$A = A$," or the *ego* posits itself,[1] may thus be interpreted to mean, "the fact of a necessary thought implies the existence, not only of an actual thinker, but of a real subject, capable of becoming a thinker." But this real subject, though existing independently of consciousness, becomes aware of its own existence only in and by consciousness. And consciousness, as a particular phenomenon, depends upon something by which the impulse is given to the subject, whereby it determines itself to become conscious. Hence the *ego*, in becoming conscious of its own existence, supposes at the same time, though it is not conscious of, the existence of a *non-ego.* And this is expressed by the second formula "$-A \neq A$; or, the *ego* implies a *non-ego.*" But this implied *non-ego* is merely supposed by an act of thought, in order to account for the fact of the *ego* becoming conscious of itself. Hence arises the third formula of Fichte's system, "The *ego* and the *non-ego* are both posited by the *ego* itself,"—in other words, the relative and conscious *ego*, and its counterpart, the *non-ego* implied by consciousness, both owe their existence to the fact that the absolute *ego* becomes conscious of itself. Hence these are posited in and by the absolute *ego.*

---

[1] The following are the matters treated of in the second or *à priori* portion of Wolf's *Theologia Naturalis*:—"De notione entis perfectisimi et ejus existentia—De intellectu Dei—De voluntate Dei—De creatione, providentia, et potentia Dei—De atheismo—De fatalismo, deismo, et naturalismo—De anthropomorphismo, materialismo, et idealismo—De paganismo, manichæismo, spinozismo, et epicuræismo."

[2] For a list of the Kantian categories, see *ante*, p. 586.

The absolute *ego* is thus the one primitive existence, and, as such, must be absolutely free. Hence, in becoming conscious, the *ego*, by a free act, creates the whole contents of its consciousness—the modified *ego* and the *non-ego* together. The *non-ego* of Fichte thus assumes the position which in the Kantian philosophy was occupied by the *thing in itself*, being not the object of consciousness, but the supposed reality beyond; and this supposed reality is itself shown to possess only a secondary and derivative existence, being postulated to account for the fact of consciousness; which fact itself is the result of the self-determination of the absolute *ego.*

The error of this system (an error shared by most of the subsequent developments of German metaphysics) is, that it attempts to explain and account for the primitive dualism of consciousness, instead of accepting this fact as the principle from which the explanations of philosophy must take their start. Hence we have the contradictory ideas of an *ego* absolutely free, and yet compelled to posit the existence of a *non-ego.* The *ego*, we are told, strives to realize its own freedom. How came that freedom ever to be impaired or to need realization? Does anything ever freely operate to its own deterioration? Or rather, we may ask, does not freedom itself imply consciousness? Is it not a self-contradiction to suppose a free agent unconscious of its own freedom? The philosophy which starts from the single being of God is presumptuous enough, and deals sufficiently with the incomprehensible. But Fichte's system, in making *the ego* the first principle of all things, leaves no room for the distinct existence of a Deity; and hence Fichte is compelled to confess that he knows no other God than the moral order of things.[2] In this unsatisfactory position, the absolute *ego* is compelled to give way to a higher idea; and thus Fichte's later philosophy, while retaining its original terminology, virtually passes over to a new position, in which he had been already anticipated by Schelling.

The rival theories of Schelling and Hegel present the most perfect specimens, from two opposite points of view, of a system of metaphysics constructed, not merely independently of, but in direct opposition to, the laws of consciousness. The *ego* and *non-ego* of Fichte, in their original form, were entities beyond consciousness, but not necessarily antagonistic to it:—on the contrary, they were rather represented as harmonizing with and explaining consciousness itself. But as thus implied by, and yet not given in, consciousness, they necessarily remained unknown and unknowable. Consciousness might, perhaps, justify the inference *that* they are; but it could not possibly inform us *what* they are. The entities of Fichte were thus, though arrived at by a different process, virtually the same as those of the older metaphysicians,—the unknown subjects or causes of sensible or intellectual phenomena. To make the real an object of science, it was necessary that it should be directly given or revealed to intelligence:—there must be an absolute knowing to answer to the absolute being. Philosophy must postulate, not merely an object of knowledge beyond consciousness, but a manner of knowledge above it; and this was attempted in two ways,—by Schelling, from the side of the presentative faculties; and by Hegel, from that of the representative. The former based his philosophy on the fiction of an intellectual intuition emancipated from the conditions of space and time; the latter, on that of a logical reason emancipated from the laws of thought.

In the philosophy of Schelling, the *ego* is stripped of even the small remnant of personality which it retained in the original scheme of Fichte. That which in Fichte's system appears as an abstract *self*, modified in no particular manner, but susceptible of modification in any, becomes, from Schelling's point of view, abstract intelligence in general, having no personality, but capable of becoming personal. In Fichte's system, the absolute *ego* creates the several modes and objects of its own consciousness. In Schelling's, the absolute intelligence, by a free act, creates its own personality with its modes on the one side, and the material world, or system of nature on the other.[3] Thus the object, which in Fichte's system is posited by the subject, becomes in Schelling's identified with it; subject and object being merged in the absolute, which in its own nature is the indifference of the two, and which creates the distinction by becoming conscious of itself.[4] The system is thus at the same time realism and idealism: the world of things and the world of thought are but two opposite aspects of one and the same being, manifesting itself without or with consciousness.[5] The human reason is identical with the divine; and philosophy is the reproduction of creation, or rather is creation itself; for the philosophy of the absolute is above the condition of time: it is not an imitation or repetition of the divine thought, but the divine thought itself developed into consciousness.

It is obvious to ask how such a system, admitting it to be possible or even true, can be known to be possible or true. Can the individual man, supposing him to be a phenomenon and not a reality, become conscious of his own nonentity? The first testimony of consciousness is to the existence of the conscious subject: the idea of reality and existence arises in and by that testimony. Can I then, existing in consciousness, be at the same time conscious that I do not exist? Can I be conscious and not conscious, substance and accident, reality and phenomenon, personally existing and merged in the absolute, at one and the same instant, in one and the same act? This Schelling's theory virtually declares to be possible, and the means by which it is accomplished is intellectual intuition. This intuition is the instrument and the method of philosophy: it is the process by which the absolute becomes conscious of itself, by which the philosopher becomes conscious of his identity with the absolute.[1] It is an act out of time, and by which time is constituted; an act which is distinct from and above ordinary consciousness, which cannot be described in language or apprehended in conception, whose results cannot be communicated to ordinary consciousness, and, of course, cannot be verified by it.[2]

[5] *Ideen*, p. 64. *System des tr. Idealismus*, p. 17.

Let us grant for an instant such an abnormal state to be possible. Let us grant even that the state being above conception it is no argument against it that its conception is self-contradictory and annihilates itself. What even then would be proved, save that one portion of our knowledge is at variance with another, and that there is no arbiter to decide between them? *Cogito, ergo sum;* the act of knowledge is an act of personal existence:—this is the testimony of the normal consciousness. *Cogito, ergo non sum;* the act of knowledge is an act in which personal existence disappears in the absolute:—this is the testimony of the abnormal intuition. Neither of these can judge the other; for neither testimony can be translated into the language or represented in the thought of the other. It is mere idle boasting for the would-be philosopher to assert the superiority of his instrument over that employed by the rest of mankind; for superiority implies comparison, and comparison is an act of relation, and relation annihilates the absolute as such.[3] The controversy must remain undecided until a third faculty shall be discovered, which, being, in one and the same act, normal and abnormal, conscious and not conscious, existent and non-existent, may embody in one process the results of intellectual intuition and ordinary consciousness, and examine them on common principles before a common tribunal.

Something like this union of all contradictories is proclaimed in the logical idea of Hegel, the supreme principle of all truth and of all reality.[4] The method of Hegel commenced by attempting to justify the assumption of Schelling, and ended by superseding it. While admitting, as substantially true, the fundamental principle of Schelling's philosophy, the unity of subject and object in the absolute, Hegel protests decidedly against the method by which, according to Schelling's theory, this principle is apprehended. The intellectual intuition, which is demanded as the condition of all philosophy, is a faculty which any individual may or may not possess. The philosophy of Schelling thus appears to demand, as its condition, a special artistic talent or genius, an accidental gift of good luck. But philosophy must, from its nature, be capable of becoming common to all men; for it is based upon thought, and thought is the characteristic of man as man.[5] But the logical process which Hegel announces as common to all men is at least as far removed from the conditions of normal intelligence as the extraordinary endowment demanded by Schelling. The postulate upon which the entire system rests—the identity of thought and being—is constantly asserted, but never proved; and this assumed identity necessitates a conception of thought not only distinct from, but at variance with, the evidence of consciousness. Thought in consciousness is manifested in the form of successive modifications of the personal self, relative, determinate, special states of my individual existence. Thought in the system of Hegel is represented as an impersonal, absolute, indeterminate, universal, unconscious substance, determining itself in opposed and yet identical modifications, becoming all things, constituting the essence of all things, and attaining to consciousness only in man. Consciousness is thus the accident, not the essence, of thought; and the unconscious process of the idea in nature is regarded as fundamentally one with the conscious development of human intelligence. Hegel's famous theory of the identity of contradictions derives its whole plausibility from a twofold confusion,—of thought with being, and of identity with coexistence. In consciousness, two identical thoughts are undistinguishable from each other; and as consciousness is only possible as a cognition of differences, it follows that a system of identical determinations of consciousness is tantamount to the annihilation of all consciousness. The possibility of consciousness, therefore, implies the coexistence of opposites; but, for the very reason that there is coexistence, there is not identity. Any special modification of consciousness is discerned to be that which it is by being distinguished from that which it is not; and in this manner consciousness is only possible on the condition of a relation, not merely between subject and object, but between a plurality of objects opposed to each other. But, in order that these opposite objects should be regarded as identical, or rather as constituent elements of one and the same reality, it is necessary that the *notion* or *thing in itself* should be represented, not as a single object of consciousness, but as an unperceived substratum which underlies the relation between the two opposed objects, and out of which they mutually spring as distinct sides of one and the same reality. Being is thus no longer identical with thought;—or rather the term *thought* is used in an equivocal sense, to denote consciousness and unconsciousness at the same time. But it is nowhere explained how this abstract thought can exist independently of a thinking mind; nor how, supposing it to exist, and supposing the philosopher to become conscious of its existence, his consciousness is thereby identified with the object of which he is conscious.

The method of Hegel is sometimes described as an attempt to *re-think the great thought of creation;*[6] the philosopher being supposed to place himself at the point at which the Divine mind developed itself into finite existences, and to repeat that development in the process of his own system. This supposition is sufficiently presumptuous; but, as usually understood, it by no means expresses the full pretensions of Hegel's theory. Creation, in the Hegelian point of view, does not imply a creator, nor thought a thinker. Instead of commencing with God, as the beginning of all existence, this philosophy commences with zero. The *notion*, whose development constitutes the process alike of existence and of thought, is pure being, which is identical with pure nothing.[1] The union of being and nothing constitutes becoming;[2] and from becoming proceeds all determinate existence. The Hegelian process may thus be described as a creation of the Deity no less than of the world; for it recognises the existence of no Deity distinct from the world. But the philosopher, though aspiring to construct the universe, is virtually compelled to assume a prior universe as his foundation. Though he will not postulate a mover, he is compelled to postulate motion. The pure being, which is also pure nothing, has a power of self-development.[3] How this process takes place; or how pure nonentity can contain a principle of self-development; or how, if being and nothing are absolutely one and the same, they can at the same time be two elements united together; or how the union of the identical with the identical can form a compound distinct from its factor or factors,—these points Hegel has omitted to explain.

---

[1] *System des tr. Idealismus*, p. 50, sqq.

[2] *Ibid.*, pp. 59, 471.

[3] The acute and decisive criticism of Schelling's theory by Sir W. Hamilton, is too valuable to be omitted in this place. "We cannot at the same moment be in the intellectual intuition and in common consciousness; we must therefore be able to connect them by an act of memory—of recollection. But how can there be a *remembrance* of the absolute and its intuition? As out of time, and space, and relation, and difference, it is admitted that the absolute cannot be construed to the understanding. But as remembrance is only possible under the conditions of the understanding, it is consequently impossible to remember anything anterior to the moment when we awaken into consciousness; and the *clairvoyance* of the absolute, even granting its reality, is thus, after the crisis, as if it had never been." (*Discussions*, p. 23.)

[4] In the words of Hegel himself, "Die Idee kann als Subjekt-Objekt, als die Einheit des Ideellen und Reellen, des Endlichen und Unendlichen, der Seele und des Leibs, als die Möglichkeit, die ihre Wirklichkeit an ihr selbst hat, as das, dessen Natur nur als existirend begriffen werden kann u.s.f. gefasst werden, weil in ihr alle Verhältnisse des Verstandes, aber in ihrer unendlickken Rückkehr und Identität in sich enthalten sind." (*Encyklopädie*, sect. 214.) In the words of his disciple and expositor, Michelet:—"Die Idee ist als Werden, die Einheit von Sein und Nichts, als Unendliches, die Einheit des Etwas und seines Andern; Wesen und Erscheinung, Form und Materie, Inneres und Aeusseres, Möglichkeit und Wirklichkeit, Allgemeines und Besonderes, u.s.f. sind ebenso darin zur Identität gekommen" (*Geschichte der letzten Systeme der Philosophie*, vol. ii., p. 745.

[5] *Geschichte der Philosophie. Werke*, vol. xv., p. 592.

[6] "Den grossen Gedanken der Schöpfung noch einmal zu denken." Such, according to Hegel's editor, Michelet, is the true business of

There is a germ of truth in Hegel's opening paradox, "pure being is pure nothing," if it be understood as applied, where alone we have any data for applying it, to the necessary limitations of human thought. The conceptions of man are limited to the finite and determinate: we can conceive existence only under the conditions of relation and difference, as this particular kind of existence, distinguished from others. The conception of being in general which is no being in particular, is thus, to human intelligence, no conception at all; it indicates only the absence of any definite object of thought, and consequently of any power of thinking. But to convert this negation of the relative into an affirmation of the absolute, is to go beyond the ancient sophist, to make man's ignorance, instead of his knowledge, the measure of all things, and thus to dogmatize on no other grounds than the absence of all materials for dogmatism. And even this apotheosis of human impotence does not guarantee the fundamental assumption of the system; for if being is the same as non-being, and if being and thought are one, thought is also identical with the negation of thought; and the absolute thinking, which is absolute existence, is, by the same argument, no thinking at all.

OF THE SYSTEM OF HERBART.

The idealist systems of Fichte, Schelling, and Hegel, while differing considerably in their details, were characterized by one common principle. They all sought to escape from the phenomenal and relative character of the products of consciousness, by placing real being in an unity above consciousness. In antagonism to these, another offshoot of the Kantian criticism, the realism of Herbart, sought to attain the same end by means of a plurality below consciousness. The one attempted to generalize beyond the limits of thought; the other, to individualize beyond the limits of sense. According to Herbart, all the original notions which we form of the objects presented to us by experience, whether as regards external or internal phenomena, are, upon examination, found to involve contradictions, and thus to condemn themselves as inconceivable. The office of metaphysics is so to modify these notions as to remove the contradictions, and thus to reconcile the testimony of experience with the requirements of thought.[4] To attain this end, Herbart has recourse to a modified form of Leibnitz's theory of monads.[5] The phenomena of experience are regarded as dependent on the mutual relations of a number of real or absolute beings, simple, unextended in space, and subject to no succession in time, and thus without parts and without change. We are thus, he thinks, enabled to avoid the fundamental contradiction of experience, with which all philosophy has to struggle,—the antagonism between the one and the many; we escape from the paradox of maintaining that the same *thing* can consist simultaneously of various elements, or exist successively in various states. Every real being is simple in itself, though different one from another: the world of sensible experience is but an aggregate of phenomena, resulting from the mutual attraction and repulsion of insensible units; and the principle which pervades the whole is the effort of each unit for self-conservation.

Among many merits of detail, it is impossible to overlook the weakness of Herbart's fundamental assumption. His system, by deriving the known world of relations from an unknown world of absolute beings, postulates ignorance as its starting-point, and makes philosophy dependent on an assumption whose only guarantee is, that we have no means of verifying it. The existence of the supposed world of realities is unknown; for it confessedly lies beyond the limits of experience; and mere thought does not prove the reality of its object. Its relation to the world of phenomena is unknown; for the knowledge of a relation implies the knowledge of both correlatives. Its existence is assumed in order to solve certain supposed contradictions; and the assumption itself introduces other contradictions; for the conceptions of extension composed of unextended elements, and of attraction and repulsion out of time and space, are in appearance no less contradictory than those which they pretend to explain, and labour under the additional difficulty that they are not even apparently warranted by experience. The real world of Herbart is thus reduced to the condition of an occult cause,—an *ens rationis*,—which might perhaps be shown to exist had we the faculties requisite for discerning it; but which, upon the same supposition, might equally be shown not to exist; and which, to our present faculties, is encumbered with apparent contradictions which render the latter conclusion the more probable of the two.

---

philosophy. "In der That," he continues, "was können wir Anderes wollen, wenn wir über die Natur philosophiren, als das intelligibile Wesen der Natur, die zeugenden Ideen derselben, aus dem Innern unseres Geistes denkend zu reproduciren? (Hegel's *Werke*, vol. vii., Editor's Preface.)

[1] Das Seyn, das unbestimmte Unmittelbare ist in der That Nichts, und nicht mehr noch weniger als Nichts. . . . . Nichts ist dieselbe Bestimmung, oder vielmehr Bestimmungslosigkeit, und damit überhaupt dasselbe, was das reine Seyn ist." (Hegel, *Logik*, b. i., chap. i. Cf. *Encyklopädie*, sect. 87).

[2] Das Nichts ist als dieses unmittelbare, sich selbstgleiche, ebenso umgekehrt dasselbe, was das Seyn ist. Die wahrheit des Seyns, so wie des Nichts, ist daher die Einheit beider; diese Einheit ist das *Werden*." *Encykl.*, sect. 88. Cf. *Logik*, b. i., c. i.

[3] See the criticism of Trendelenburg, *Logische Untersuchungen*, vol. i., c. ii.

[4] "Die Metaphysik hat keine andre Bestimmung, als die nämlichen Begriffe, welche die Erfahrung ihr aufdringt, denkbar zu machen." *Lehrbuch zur Einleitung in die Philosophie*, sec. 149.

[5] "Herbart," says Trendelenburg, "has recourse, on the one side, to the Eleatics, and, on the other, to Leibnitz. From the former he acknowledges the pure conception of existence, but denies that existence is one. From the latter he accepts the plurality of existences, but refuses to endow the monads with a plurality of attributes." (*Ueber Herbart's Metaphysik*, p. 5.)

The theory solves none of the difficulties which give rise to it, but only conjectures that, under certain possible conditions of superhuman knowledge, they might be soluble;—a very legitimate position, if it were proposed as resting, not on reason, but on faith—not as explaining difficulties, but as bidding us rest content without explanation—not as the basis of a theory, but as a reason why theories are inadmissible. Let us grant, for the moment, Herbart's assertion that our intuition of objects in space and time is at variance with the laws of thought. It is no solution of the contradiction to reply that there may possibly be a superhuman intuition of objects out of space and time, and that, if we had such an intuition, there might perhaps be no variance. For we do not know that such an intuition is possible; and we do not know that, if it were possible, it might not present still greater variance. And so long as there is variance, what right has one of the adverse faculties of our nature to demand the submission of the other? Why should experience give way to thought, rather than thought to experience? "Which is the wiser here—justice or iniquity?" Which element of our nature testifies to the real, and which to the phenomenal?

OF THE PHILOSOPHY OF THE ABSOLUTE IN GENERAL.

This brief survey of the principal ontological systems of modern Germany, the only country in which the study of ontology proper has been zealously pursued in recent times, may, it is hoped, be of some use in clearing the field of discussion, and in bringing the great problem of philosophy under certain definite conditions, under which alone its solution can be attempted with a reasonable hope of success. In abstruse speculations of this character, we learn almost as much from the chart which tells us of rocks and shoals to be avoided, as from the compass which points out the direction in which we ought to steer; and the study of the philosophy of the absolute is at least serviceable in eliminating elements foreign to the investigation of the truth, and in teaching us, as Hegel himself said of the Newtonian optics, the manner in which metaphysical inquiries ought not to be pursued. Various and conflicting as are the theories of modern German philosophy, one common error may be detected as pervading all of them,—that of identifying reality with the absolute or unconditioned. Instead of examining the conception of the real as it is formed under the necessary conditions of human thought, and inquiring what is the object which corresponds to the conception so conditioned, they assume at the outset that real existence means existence dependent upon nothing but itself, and that the conception of real existence is a conception determined by no antecedent. Ontology is thus the absolute knowledge of absolute being; and, from this point of view, being and knowledge are necessarily one and the same thing; for if the object known is distinct from the act of knowing, the latter, to be valid, must conform itself to the nature of the former, and thus becomes relative and subject to conditions. Absolute knowledge is thus possible only on the condition that the mind, in the act of thought, creates the objects about which it thinks;—or rather, that the act of thought itself creates its own object and subject; for we clearly renounce *in limine* all pretension to absolute knowledge, if we admit that the act of knowing is in any degree dependent on the prior constitution either of a mind which thinks or of a thing about which it thinks. The philosophy of the absolute thus admits of a twofold refutation;—in the consequences to which it leads, and in the premises from which it starts. In its consequences it admits of no alternatives but atheism or pantheism;—atheism, if the absolute reality or creative thought is identified with myself;—pantheism, if it is identified with anything beyond myself. Subjective absolutism, or *egoism*, postulates self as the primitive reality on which all things depend, and acknowledges no God distinct from self and its modifications. Objective absolutism regards personality itself as a phenomenal manifestation of some higher reality, which alone is truly existent, and to which it gives the name, but not the nature, of God. Religion is equally annihilated under both suppositions; for if there is no God, whom are we to worship; and if all things are God, who is to worship him? Morality is equally annihilated under both suppositions; for if I am the absolute, I create my own moral duties, and cannot be required to conform to any standard independent of myself; and if I am a mode of the Divine Being, my actions flow from the self-determinations of the Deity, and are all equally necessary and equally divine. The premises from which these consequences issue are equally untenable with the consequences themselves. The primary testimony of consciousness affirms the distinct existence of an *ego* and a *non-ego*, related to and limiting each other. I know myself as existing in the midst of certain phenomena, which I did not create, and can only partially control. Pantheism contradicts the first element of consciousness, by denying the real existence of myself. Egoism contradicts the second element, by denying the real existence of anything distinct from myself. But if the testimony of consciousness on this point is false, how can I assume that it is true in any secondary and derived modification? How do I know that the very language of the philosopher of the absolute means what it appears to mean, or that my conviction of the truth of his system is not itself an evidence of its falsehood? Nay, how do I know that there is any philosophy of the absolute at all, or that the book in which, seeming to be myself, I seem to read it, has any contents, or communicates any knowledge, or is addressed to any reader?

OF THE CONDITIONS NECESSARY TO THE EXISTENCE OF ONTOLOGY.

Philosophy commences with doubt; and doubt is a state of consciousness. It is necessary, therefore, that the object of ontology, as a branch of philosophy, should be one to whose existence, at least in idea, consciousness bears positive testimony. This is not the case with the unconditioned, to the existence of which consciousness only negatively testifies, in so far as contradictory notions naturally suggest each other. The conceivable suggests the inconceivable; the real, the unreal; the possible, the impossible; and the conditioned, the unconditioned. To assume, from this suggestion alone, that we have a distinct conception of the unconditioned, or that there is a distinct reality answering to, or identical with, that conception, is as unwarrantable as to assume, on the same grounds, the reality of the unreal or the conceivability of the inconceivable. Thought is positive in so far as it represents an actual intuition; and two opposite objects, which can be both presented intuitively, may be both conceived reflectively, whether the terms by which the conceptions are denoted are positive or negative, contrary or contradictory. But, without a corresponding intuition, positive thought is impossible; and the intellectual intuition of Schelling is thus a necessary condition of the existence of any philosophy of the absolute. Unfortunately for the absolute, the intellectual intuition is a state of mind to whose existence consciousness does not and cannot testify;—nay, which it distinctly and positively declares to be impossible.

It is thus indispensable for the metaphysician, before commencing an inquiry into the nature of the real, to ask what is the actual conception of the real which consciousness furnishes; and what is the evidence on which we assert the existence of a corresponding object. It may be that the facts of consciousness present nothing but phenomena and that the real is merely suggested by language as the negation of the phenomenal; or it may be that some of the facts of consciousness exhibit certain characteristics, which indicate a higher amount of reality than can be assigned to others. Is the notion of the real positive or negative? and if it is positive, in what acts of consciousness do we find the corresponding intuition? When we have answered these questions, we shall have succeeded at least in confining the problem of ontology within definite limits: we shall have indicated the field of search, if we do not go so far as to discern the object. But the testimony of consciousness is clearer on the negative side than on the positive. It will assist our inquiry considerably if we can first ascertain, from the decisive evidence of consciousness, what the real of which we are in pursuit *is not.*

OF THEORIES OF THE REAL NOT FOUNDED ON CONSCIOUSNESS.

In the first place, the real of consciousness is not the Kantian *ding an sich*, or thing as it exists in its own nature, out of all relation to the human mode of perceiving it. Consciousness is given to us as the product of two factors, on both of which it is equally dependent,—the constitution of the person apprehending, and that of the thing apprehended. If either of these were changed, the result might be something totally different from its present appearance. In mathematical language, the result of consciousness is a *function* of the subject and the object together, and must be regarded as variable with the variation of either. To attain to a knowledge of a thing in itself out of relation to our faculties, it would be necessary to apprehend the thing with a new set of faculties, retaining at the same time a perfect recollection of our former mental constitution and its results, in order to separate what is relative and dependent on the existing constitution of the human mind from what is absolute and common to other orders of intelligent beings. It is manifest, therefore, that the real, in this sense of the term, represents nothing which can by any possibility be presented in consciousness.

In the second place, the real of consciousness is not the absolute which has reigned supreme in German philosophy since the time of Kant;—that is to say, an unconditioned first being, which exists in and by itself, and does not imply the prior or simultaneous existence of anything else. This has been already shown in our previous remarks on this theory, which exhibit its antagonism to the primitive dualism of consciousness, in which *self* and not-*self* mutually imply each other, and, consequently, in which neither of them is the absolute. It is also sufficiently shown by the admission of the absolutist philosophers themselves, who, by basing their systems on a supposed form of knowledge beyond, and even contradictory to, consciousness, virtually confess that the absolute has no existence in consciousness. The contempt with which the majority of German critics almost invariably mention the name of dualism, is a proof, among many others, of the necessity which they feel of lifting the standard of philosophy in opposition to the authority of consciousness.

In the third place, the real of consciousness is not the *substance* or *matter* of an earlier school of metaphysicians; that is to say, the insensible substratum of sensible qualities, viewed by itself, apart from those attributes by which it is made known to experience. We may not commence our inquiries with the assumption that the shape, the colour, the smell, and other sensible qualities of a rose are one thing, and that the rose itself, the thing possessing the qualities, is another. "The idea," says Locke, "to which we give the general name *substance*, being nothing but the supposed, but unknown support of those qualities we find existing, which we imagine cannot subsist *sine re substante*, without something to support them we call that support *substantia;* which, according to the true import of the word, is, in plain English, *standing under* or *upholding*."[1] "I perceive," says Reid, "in a billiard ball, figure, colour, and motion; but the ball is not figure, nor is it colour, nor motion, nor all these taken together; it is something that has figure, and colour, and motion. This is a dictate of nature, and the belief of all mankind."[2] Without attempting at present to anticipate the necessary inquiry into the validity of that law of belief which apparently compels us to refer a plurality of attributes to a single subject, we may safely assert that the notion of such a subject, as a being distinct from its attributes, is utterly empty and meaningless; and that no such being can be the object of metaphysical research. Consciousness does not testify that such a being exists or is conceivable;—nay, such a testimony would be impossible without the annihilation of consciousness itself. For consciousness is possible only under the condition of difference. I can be conscious of an object, as such, only by being conscious of it as distinguished from other objects; and this distinction is only possible by means of the special attributes which the object possesses. Deprive the billiard ball of its figure and colour, and all other sensible qualities, and do the same to the table on which it stands; and how is the ball to be distinguished from the table? The residuum, if there is any, is neither the ball as a ball, nor the table as a table, nor any one thing as distinguishable from any other thing, nor an object of consciousness as distinguished from the subject. It is the vague and empty notion of being in general which is no being in particular,—pure existence, which is identical, so far as human thought is concerned, with pure nothing. Things can be distinguished from each other only by their attributes; and to be conscious of a thing apart from its attributes, is to be conscious of a difference with no difference to be conscious of. "The knowledge of pure substance distinct from its qualities," says M. Cousin, "is impossible, for the simple reason that no such substance exists. Every real being is of such or such a kind; it is either this or that. If it is real, it is determinate; and to be determinate is to possess certain manners of being, transitory and accidental, or constant and essential. The knowledge of being in itself is therefore not only forbidden to the human mind, but is contrary to the nature of things.[3] Whether the existence of a thing distinct from any and all of its attributes be, as Reid says, a dictate of nature or not; at any rate, in the instance which he adduces, it is not *presented* as a fact of consciousness, but *inferred* from the presence of the attributes; and, in maintaining the veracity of the facts of consciousness themselves, we do not therefore maintain the validity of all the inferences to which those facts appear to lead. What is the exact fact upon which this inference is grounded, the principle on which it is made, and the amount of credit due to it, we shall endeavour to show hereafter by an examination of consciousness itself. For the present, it is sufficient to say, that the fact, whatever it may be, is not a direct cognition of the existence of a substratum of material attributes.

It thus appears that the celebrated hypothesis of Bishop Berkeley, so far as it merely denies the existence of matter, is not in any way contrary to common sense (if by common sense is meant the direct evidence of consciousness); inasmuch as it only denies that concerning which consciousness offers no evidence at all. For *matter*, in Berkeley's sense, does not mean anything which can be perceived by the senses; but only, as Locke defines it, "the supposed, but unknown support of those qualities we find existing." "I do not argue," says the bishop, "against the existence of any one thing that we can apprehend either by sense or reflection. That the things I see with mine eyes and touch with my hands do exist, really exist, I make not the least question. . . . If the word *substance* be taken, in the vulgar sense, for a combination of sensible qualities, such as extension, solidity, weight, and the like, this we cannot be accused of taking away. But if it be taken in a philosophic sense, for the *support of* accidents or *qualities without the mind*, then, indeed, I acknowledge that we take it away, if one can be said to take away that which never had any existence, not even in the imagination."[1] And had Berkeley confined himself to the sceptical side of the question,—had he contented himself with maintaining that we have no evidence for asserting that matter, in this sense of the term, has any existence,—he would have said no more than the testimony of consciousness fully warrants. But when he went a step beyond this, and not only doubted the existence of matter, but asserted its non-existence, he transcended the evidence of consciousness on the negative side, as much as his opponents did on the positive. If consciousness says nothing about the existence of matter at all, we are equally incompetent to affirm or to deny. The sceptic, so long as he remains a mere sceptic, is unassailable: the dogmatist, whether in affirmation or in negation, equally dogmatizes on the ground of his own ignorance. But, in admitting one portion of Berkeley's theory as perfectly tenable, we do not therefore accept his entire system of idealism. It is quite possible to take an intermediate course;—to admit, with Berkeley, that we have no right to assert the existence of any other kind of matter than that which is presented in consciousness; but to deny his other main position, that we are conscious only of our own ideas. If, in any mode of consciousness whatever, an external object is *directly presented* as existing in relation to me, that object, though composed of sensible qualities only, is given as a material substance, existing as a distinct reality, and not merely as a mode of my own mind. And, to this extent, the arguments of Reid and his followers, however inaccurate their analysis of consciousness may be in some of its details, are valid against idealism.

[3] *Histoire de la Philosophie Morale au dix-huitième siècle*, Leçon xii.

The antagonism of the Scottish philosophers to the theory of Berkeley, arose more on account of its supposed remote consequences, than of its immediate conclusions. It was supposed to furnish a legitimate foundation for the scepticism of Hume, who argued against the existence of mind on the same grounds on which Berkeley had denied the existence of matter. Within myself, he urged, I am conscious only of impressions and ideas, as in external sensation I am conscious only of extension, figure, and so forth. The substance called *mind* may therefore be a mere fiction, imagined for the support of the internal states of which I am conscious, just as the substance called *matter* is imagined for the support of sensible qualities.[2] But, in order that this conclusion may legitimately follow from Berkeley's principles, we must concede an additional premise, which Berkeley by no means admits,[3] namely, that the evidence of consciousness in relation to matter and to mind is of precisely the same character. If, as Locke maintained, and as the antagonists of Hume allowed, we have no immediate consciousness of *self*, but only of its several modes, the sceptical conclusion necessarily follows; and Hume, as a professed sceptic, had nothing to do with correcting the received dogmas of philosophy, but only with exhibiting their ultimate consequences. Those consequences can only be refuted if, by a more exact analysis of the facts of consciousness, it can be shown that the personal self, as the one permanent subject of various successive modes, is directly presented in intuition along with its several affections. But this analysis neither Reid nor Stewart attempted; and the consequence was, that in their hands the sceptical argument remained, in its main positions, unrefuted.

In the fourth place, it may be shown, by the same considerations, that the real of consciousness is not the *first matter* of the peripatetic philosophy; that is to say, an universal substratum, common to all objects of sense, and subject to the changes of form which constitute this or that definite object.[4] This first matter is, indeed, nothing more than the *matter* of the last hypothesis, stripped of some of its more glaring incongruities, but not thereby made more accessible to consciousness. The theory of a first matter avoids, indeed, the absurdity of saying that any one particular thing, such as a billiard-ball, is something distinct from its own sensible qualities; but the supposition which it assumes instead,—that of a subject which is all things in capacity, and nothing actually,—is only a more logical negation of all difference, and therefore of all consciousness; for consciousness is possible only through difference. The psychological value of the axiom on which this theory apparently rests,—namely, that all things are changed, and nothing created or destroyed; so that the quantity of real matter in the world can never be conceived as increased or diminished,—has been examined in a previous passage; but even if a greater amount of truth be assigned to this principle than our previous remarks have accorded to it,—whether it be regarded as a law, or merely as an impotence of mind,—it is at any rate a phenomenon of mind and not of matter: it can be explained on psychological grounds only; and it presents no fact in the constitution of things, but only a mode of our conceiving them. Unless the truth of that conception can be guaranteed by a positive intuition of its object, which in this case is impossible, we are not warranted in elevating a mere consciousness of the limit of our own powers of thought into a measure of the conditions of all possible existence.

In the fifth place, the real of consciousness, so far as the material world is concerned, is not to be found in the chemical elements into which bodies may be ultimately resolved. It does not express any metaphysical distinction to say that what appears to be air is in reality oxygen and nitrogen; or that water, ice, and steam are but different appearances of the same elementary particles. This is perfectly true as a physical fact; but it contributes nothing towards the solution of any problem of metaphysics. The chemical element, as well as the compound, is an object of sense, and its presence must be tested by sensible criteria. If, then, there is any apparent antagonism between sense and thought;—if there is any room for doubt whether what sense regards as a reality independent of myself, thought may not resolve into a transitory affection of my own mind,—such a doubt is equally possible, whether the object of sense be more or less minute, whether its presence be manifested by the immediate evidence of sight, or by the indirect test of experiment. In one respect, indeed, the chemical element has less of the character of a real object than the compound into which it enters; inasmuch as its presence must frequently be inferred rather than perceived,—detected in its effects on something else, not in its own proper nature. There will still remain the question, What is the *thing itself*, as distinguished from the test by which we discover its presence on particular occasions?

[3] In the third dialogue between Hylas and Philonous, Berkeley expressly says:—"I know or am conscious of my own being; and that I myself am not my ideas, but somewhat else,—a thinking, active principle, that perceives, knows, wills, and operates about ideas." Here he distinctly denies the position of Locke, and refutes by anticipation Hume's deduction from his own principles.

[4] Aristotle, *Phys. Ausc.* i. 7. Compare Harris, *Philosophical Arrangements*, chap. iv.

In like manner it may be shown, lastly, that the metaphysical question is in no way simplified by any theory, such as that of Boscovich, which regards the senses as immediately cognisant, not of matter in itself, but only of the attractive and repulsive forces which one particle exercises on another. For the ultimate atoms of matter being, upon this hypothesis, never presented in consciousness, could never have given rise to the distinction, which apparently exists in our minds, between the real and the phenomenal. That distinction must be suggested by something of which we are conscious; and if we are conscious only of forces, it must depend upon some difference in the forces themselves. The forces thus inherit all the metaphysical difficulties of the matter which they represent; and we must still have recourse to the analysis of consciousness itself, to determine in what manner the metaphysical doubt could have originated, and what are the data available for its solution. To inquire into the truth and value of Boscovich's theory itself, is a question of physics, not of metaphysics.

OF THE REAL AS GIVEN IN CONSCIOUSNESS.

Having thus simplified the problem by the elimination of foreign elements, we have next to inquire what is the positive testimony of consciousness itself, as regards the existence of a distinction between the phenomenal and the real, and how far the distinction thus indicated will enable us to ascertain the nature of the respective objects to which it refers? for that the distinction has a foundation in consciousness, however much its meaning may have been misinterpreted, is manifest, if it were only from the existence of such misinterpretation. Rightly or wrongly, men have thought that such a distinction exists:—why they have thought so, the examination of consciousness itself can alone explain.

It is necessary, in the first place, to determine clearly what it is of which we are in search. We must know what is meant by *reality*, and what by *appearance*, before we can classify the facts of consciousness as indicating one or the other. For here there is an ambiguity which, if not cleared up at the outset, may confuse the whole subsequent inquiry. It is one thing to distinguish between the real and the phenomenal, as exhibited in the facts of consciousness themselves: it is another to determine what are really facts of consciousness and what are not. There are judgments which are sometimes supposed to rest on the immediate testimony of consciousness, but which, rightly interpreted, are inferences only remotely suggested by it. I think I see a friend at a distance: on a nearer approach he turns out to be a stranger. Here the apparent testimony of sight is in reality an inference pursued through many successive stages. In the first place, I am not really conscious by sight of the presence of a distant object at all, but infer its presence from the consciousness of certain affections of the organ of vision. In the second place, when I have projected by association the impression of a certain coloured surface into a space exterior to my organism, I do not thereby know that this surface is a man: this is a second inference, implying memory, and comparison, and recognition of certain specific attributes. In the third place, when I have so far obliterated these connecting links as to fancy that I see a man, I do not thereby know a friend from a stranger: this is another act of inference, implying memory of certain individual features, and comparison of them with my present impression. Yet all this is performed with such rapidity as to appear an immediate act of perception; and John or Thomas is, in ordinary apprehension, as much an object of sight as redness or blueness.

This distinction is irrelevant to our present inquiry. When we ask how reality and appearance may be distinguished from each other by the testimony of consciousness itself, it is to be supposed that we have already ascertained what are facts of consciousness, and what are not. But this being granted, a second ground of distinction presents itself. Every fact of consciousness, as such, guarantees the existence of its object, so long as it is actually present. But there are some facts of consciousness which are instinctively acknowledged to indicate only the relative and transitory existence of their objects, and others which are supposed to imply something more than this. An affection of the nervous organism exists only as it is felt, and ceases to exist when it is felt no longer; it has no independent existence of its own, but is a mode of my being, created by the act of consciousness, and ending along with it. But, on the other hand, all men instinctively believe, and will believe in spite of the arguments of the idealist, that we are immediately conscious of an external world, and that that world exists when we are not conscious of it. The impression which the sight of a mountain makes on my optic nerve is destroyed when I shut my eyes; but no man believes that the mountain is destroyed along with it. Consciousness testifies that we have this belief; and on this testimony metaphysical systems have been built, which, however widely some of them may have wandered from the true solution of the question, all alike prove that the question itself is suggested by consciousness.

This latter distinction properly belongs to ontology; the former to psychology; though, in actual discussion, the two have been frequently mixed together. Among the facts, or supposed facts, of consciousness, the impressions of the senses, from the one or the other of the above points of view, have been, almost from the commencement of philosophy, especially noted as indicating appearance and not reality. The following may be cited among the arguments adduced in proof of this position:—In the first place, sensation is but the result of a transitory relation between the organ and its object:—colour, for example, exists neither in the eye by itself nor in the visible object by itself, but is produced by their temporary juxtaposition.[1] In the second place, the same object presents different impressions to the same sense, according to the condition of the sensitive organ itself.[2] A man with the jaundice sees all objects as yellow: one afflicted with colour-blindness sees as blue that which, in a healthy state of the eyesight, appears as red: to a diseased palate the taste appears bitter, which a sound palate receives as sweet. But if the abnormal state of the organs of sense produces an impression which is acknowledged to be apparent only, why should the normal state be regarded as giving a knowledge of reality? If the unusual appearance is wholly dependent on an extraordinary condition of the organism, is not the usual appearance equally dependent on the ordinary condition? And how can either of them represent a real object, which in itself is unaffected by any change in the condition of the person perceiving it? In the third place, the same object presents a different quality to different senses. An apple, for instance, is perceived by the sight as yellow, by the taste as sweet, by the smell as fragrant.[3] If the several objects of sense are distinct realities, the apple is not one but many; if, on the contrary, the apple is, as we are compelled to conceive it, one, it follows that the impressions of the senses are not real things, but unreal appearances of that which in itself is not diverse but uniform. In the fourth place, the same object presents different impressions to the same sense, according to the different circumstances in which it is placed. A tower, which at one distance appears to the eye as square, at another seems to be round; at one distance it appears larger, at another smaller.[1] But the tower itself undergoes no change of figure or size. It is manifest, therefore, that one at least of these impressions exhibits not that which is, but that which seems to be; and unless some reason can be assigned for preferring one to the other, we may reasonably conclude that both do so. In the fifth place, the sensible impression may take place without the presence of any external object by which it can be caused. Such is the case in dreams and spectral illusions, in which we appear to see, with all the vividness of actual sight, things which have no existence except in our own imagination.[2] But if this actually takes place in some instances, why may it not take place in all? By what criterion are we to distinguish the true from the false; or how can we be sure that the senses present to us real objects, when their testimony can be so well counterfeited by mere phantoms?

These difficulties are considerably increased, if we adopt, with the vast majority of philosophers in ancient and modern times, the representative theory of perception, and maintain that like can only take cognisance of like, and therefore that the mind, which is the seat of all consciousness, perceives through the senses, not material objects, but only its own ideas, by which material objects are represented. For how are we to guarantee that the idea has any resemblance to the object which it represents? To know that two things resemble each other, I must compare them together. But the material world, according to this hypothesis, is never perceived at all, and therefore cannot be compared with its supposed representative.[3] And the ideas, whether regarded as immaterial objects distinct from the percipient mind, or as modifications of the mind itself, are called into existence in and by the act of perception, and have no existence except when they are perceived[4]. On this hypothesis we are not warranted in affirming the existence of that of which we are never conscious; and the conclusion to which it naturally leads is that which denies the existence of matter, and makes the whole external world a series of phenomena dependent on the action of the mind.

Such are a few of the grounds on which philosophers, in all ages, have maintained that the senses are the sources of deception, not of truth, and are conversant with appearance only, not with reality. And a more accurate acquaintance with the physiology of the sensitive organs confirms the latter part of this verdict, though it furnishes a defence against the former. The senses do not deceive us with regard to an external world, because, rightly interpreted, they tell us nothing at all about it. We are deceived, not in the facts to which the senses bear witness, but in the inferences which we draw from them. The colour and the savour appear different in different states of health, because, in truth, as affections of the nerves of sight and taste, they are different in different conditions of the organism. The sensible qualities of a body are in fact, as they appear to be, distinct affections of the several organs; and it is not sense which tells us that these different qualities constitute a single thing. The tower, which appears to change its shape and size as we approach it, is not in reality the same visible object at any two steps of our progress. What we actually see at any moment is nothing but the rays of light in contact with the organ of vision; and every change of position places us in contact with a different complement of rays. The dream or the spectral apparition is as veritable an affection of the optic nerve as the commonest impression of sight; and we err only in inferring the presence of an external object, of which the sight itself in no case tells us anything. But, while we may thus defend the senses against the charge of deception, we are in another respect compelled to acknowledge that their objects are not things but phenomena. An affection of the nerves of sense is not a distinct reality existing independently of myself: it is but a transitory mode of my own consciousness, which exists only while I am conscious of it. A real object is not dependent for its being and properties on my being aware of them: it has an existence and attributes of its own, whether I am at this moment conscious of them or not. But the proper objects of the bodily senses,—colours, sounds, flavours, savours, and tactual sensations,—exist, as such, only in my consciousness, and cease to exist when my consciousness ceases. They may be caused by some permanent reality or realities independent of me; but of the existence and nature of this reality the senses tell us nothing.

It is not, therefore, to the senses, properly so called, that we must look for the distinction between reality and appearance in the material world. The only attribute of matter which these make known to us is the extension of our own organism; and, with regard to this, the distinction in question has no place. Were the senses the only channels of communication between mind and matter, we could never have thought of asking how much of that communication is real, and how much phenomenal. Whether my nervous organism exists, as an extended substance, out of the act of perception in which its extension is manifested, is a question which could never have arisen from the act of sensitive perception alone; for, in order to ask such a question, I must first be enabled to separate in thought the object of perception from the act of perceiving it, and thus to constitute it an extra-organic reality; and to do this, the extra-organic world must first be presented in some form of intuition. Apart from the associations which the senses derive from this intuition, all modes of perception would be regarded as equally real, or equally phenomenal; for the real and the phenomenal could never have been conceived as contrasted with each other.

The analysis of the facts of external intuition, which has been given in the preceding pages, will enable us to ascertain the meaning of the distinction, and to determine the limits within which the question which it raises can be intelligibly answered. Resistance to the locomotive energy is the only mode of consciousness which directly tells us of the existence of an external world; and the attributes which are made known to us in that relation are the only ones which are directly given as constituting a material reality. These attributes are *occupation of space*, implying size and figure; and *resistance*, more or less stubborn, implying the impossibility of two bodies occupying the same place. And these are, in fact, the tests of reality to which we instinctively appeal on all occasions, even where the circumstances of the case do not permit their actual application. A body is necessarily conceived as in space, and an external body as in a space exterior to our organism. This implies the occupation of a portion of space, which is size, and the limitation by surrounding space, which is figure. But I may not be able, in particular cases, to verify this conception by any empirical test. I may be placed blindfold against a wall, of which I am not able to feel the extremities. I cannot therefore pronounce empircally, either directly, from contact, or indirectly, from sight, that it is limited in its length and height, or that it is square, or circular, or of any other known figure. But I am compelled to believe that it has a definite size and figure, and that I should be able to feel them if I were in some other position. Again, a volume of smoke may offer no perceptible resistance to the motion of my arm. But here, again, I am compelled to believe that it offers some resistance, which, with more acute faculties, I should be able to perceive; for I cannot conceive myself as placing my hand in the midst of the smoke without displacing the particles with which it comes in contact. The atmosphere, whose ordinary pressure, like the music of the spheres, is unperceived because it is always present, exerts, as is well known, a resistance as great as 15lb. on the square inch; and wherever a body penetrates, it produces during its occupation an atmospheric vacuum. A body, then, is *presented* as real when it actually offers resistance to the locomotive effort: it is *represented* as real when we believe that it would resist if we were in a position to make the attempt. By this test the objects of the senses are instinctively, and often unconsciously, judged. The visible and tangible impressions, which are usually accompanied by the apprehension of resistance, are regarded, first, as signs of the presence of a real object, and afterwards as real objects themselves; and the sight of the sun in the sky gives us a conviction of its independent existence, as firm as if we could feel it supporting our tread. But that this conviction is indirect, not immediate,—the result of association, not of original intuition,—is evident from the fact that, when the association is broken, the belief in the reality of the object is instantaneously destroyed. Let an object be given as visible but unresisting, and it is at once acknowledged to exist in appearance only, and not in truth:—

[2] Plato, *Theætetus*, p. 157. Pyrrho *apud* Laert. ix. 82. Sext. Empir. *Pyrrh. Hyp.* i. 104. We have not noticed those arguments which are drawn from the comparison of one man with another, or of men with brutes. We are treating only of the distinctions indicated by consciousness; and we have no access to the consciousness of any other creature than ourselves.

[3] Sext. Empir. *Pyrrh. Hyp.* ii. 74. Berkeley, *Human Knowledge*, part i., sect. 8; Cousin, *Cours de* 1829, Leçon 21.

[4] Berkeley, *Human Knowledge*, part i., sect. 3; *Dialogues between Hylas and Philonous*, Dial. ii. Berkeley goes so far as to deduce from this position an argument for the being of God; on the ground that the world cannot have a continuous existence, except in some continuously percipient mind.

> "Ter conatus ibi collo dare brachia circum;
> Ter frustra comprensa manus effugit imago,
> Par levibus ventis volucrique simillima somno."[1]

These lines express the instinctive belief of all mankind in the true criterion of material reality,—a belief which is justified and explained by the testimony of consciousness read by the light of psychological research.

OF THE REAL IN COSMOLOGY.

The above observations may furnish materials for a criticism of that branch of metaphysics known as cosmology, or the ontology of the material world. They will serve to point out what are the facts of consciousness which give rise to the conception of such a science, and what are the limits within which that conception can be realized. The conception of reality in material objects is derived from the consciousness of extension and resistance in conjunction; and the philosophy of the real, in this department, has no legitimate field beyond the several conditions and relations of these attributes, as presented in various modes of experience. Its object, therefore, is not a supersensible world lying beyond the facts of consciousness, but the sensible world, in those properties which are primarily and directly made known to us as modes of resistance to the locomotive energy, such as gravity, cohesion, repulsion, motion, and their various subdivisions. Its method is not demonstrative, except in so far as the mathematical attributes of pure extension are applicable hypothetically to extension in conjunction with resistance. In the verification of this hypothesis in any particular case, and in those researches which belong to its own province, it deals with matters of fact; and matters of fact cannot, as such, be matters of demonstration. This limitation is confirmed, on further consideration, by those facts of consciousness which at first seem to point to a contrary conclusion,—the necessary principles and reasonings of geometry. For these have been shown to depend on certain forms or conditions of experience, derived from the constitution of the mind itself, and to imply the existence of nothing but a conscious mind, modified in a certain manner. Of the real existence of its object, geometrical reasoning tells us nothing; but only that, on the supposition of its existence, certain properties may be proved to belong to it;—the proof, however, being equally valid whether the supposed existence be in fact or merely in imagination. The test of the real existence of matter is resistance, without which extension alone is not conceived as an external reality: and to the modes of resistance, as such, the demonstrations of geometry are not applicable.

The above conception of cosmology is, it must be confessed, very different from that which metaphysicians in general have attempted to realize. Indeed it may be regarded by some as indicating rather a physical than a metaphysical system; and this charge must be admitted, if the science of physics is viewed in its most general extent, as embracing the universal properties of matter in general, as well as the special characteristics of this or that body.[2] But the fault, if it be one, lies, not in the conception, but in the facts of human nature on which it is founded. If our faculties are so limited as to present us only with physical attributes of matter, the metaphysics of matter can contain nothing more than the principles and results of physics in their most general extent. We may regret, if we please, the limitation, and sigh for a knowledge of a hyperphysical world; but our faculties do not convey such a knowledge, and all our sighing will not make them do so. The limitation is one which our Creator has thought fit to impose upon us, and, regret it as we may, we cannot escape from it.

But a philosophy which fails to solve, and even refuses to grapple with, certain problems, may vindicate itself by explaining why they are insoluble. Before quitting the subject of cosmology, it is necessary to point out in what respects the above sketch falls short of the highest conception of a metaphysical system, and why it does so. In the first place, it starts from the apprehension of matter as extended, and does not attempt to solve the higher difficulty involved in the notion of extension itself. Extension cannot be regarded as the unit of material reality; for it is dependent on a juxtaposition of parts whose reality cannot consist merely in their combination. Extension is a relation between parts, as exterior to each other; and a relation implies things related, which must be real in themselves, else no reality could result from their combination. This difficulty, with all the accompanying paradoxes involved in the infinite divisibility of matter, is abandoned as insoluble; and it is obvious why it is so. If space is a necessary form of intuition, involved in the laws of our mental constitution, it follows that, to explain the generation of space itself, we must go out of our constitution. To conceive the ultimate reality on which extension depends, I must conceive the non-extended becoming extended,—a conception which is impossible; first, because thought is only operative within the limits of possible intuition, and we can have no intuition of unextended matter; secondly, because, to conceive a relation between the unextended and the extended, I must be able to compare them together; and to do this I must be in and out of my mental constitution at the same moment. An ultimate unit of space is thus as inconceivable as a first instant of time; and for the same reason—because both space and time are necessary forms of intuition. In the second place, the riddle which has puzzled the metaphysicians of all ages still remains unanswered:—"How can the one be many, or the many one?" In other words, "How can a variety of attributes constitute a single object?" This problem also is insoluble; and for a like reason—because consciousness cannot account for its own laws. If consciousness is limited, the consciousness of that limit implies the existence of something of which we cannot think; and this is equally true of the limits of intuition and of those of thought. Now, it is a necessary condition of conception, as has been already shown, that its object must comprehend a plurality of attributes;—in other words, that thought is impossible except under the condition of diversity in unity.[1] To explain why this is so, would be to explain why our minds are constituted as they are; and this involves a criticism of the laws of thought themselves. But such a criticism manifestly destroys itself; for it can only be carried on by thought operating under the very laws whose validity is questioned. Whatever doubt, therefore, can be raised concerning the object of criticism must likewise affect the critical process itself. Wherever, therefore, we fix the limits of thought, something must remain inexplicable. From this we cannot escape, except by denying that thought has limits; and this denial again annihilates itself; for if thought has no limits, nothing is unthinkable; and if nothing is unthinkable, nothing is absurd; and if nothing is absurd, no system of philosophy is more reasonable than another, and the denial of limits is not more true than the assertion of them. In the third place, metaphysical philosophy is admitted to be concerned, not with matter as it is, but with matter as we conceive it; and this admission, too, is a necessary consequence of the laws of consciousness, in its manifestation, as a relation between a subject and an object. We cannot compare the object of consciousness with a thing of which we are not conscious; for comparison itself is an act of consciousness: we can only compare one object of consciousness with another,—the permanent with the transitory, the necessary with the contingent. There still remains the question, "Do things as they are resemble things as they are conceived by us?"—a question which we cannot answer, either in the affirmative or in the negative; for the denial, as much as the assertion, implies a comparison of the two.[2] If, then, *being* is interpreted to mean the absolute beyond consciousness, and *appearance* the relative within it (an interpretation, however, which is not warranted by the analysis of consciousness itself), it must be admitted that the philosophy of the material world, in its highest form, is not ontology, but phenomenology.

---

[1] Virgil, *Æn.*, ii. 792.

[2] According to Aristotle (*De Anima*, i. 1), physical philosophy is concerned with the special operations and attributes of this or that body as such, (*περὶ ἅπανθ' ὅσα τοῦ τοιουδὶ σώματος καὶ τῆς τοιαύτης ὕλης ἔργα καὶ πάθη*). If this definition be accepted, the attributes common to all bodies may be properly referred to a more general branch of philosophy.

OF THE REAL IN PSYCHOLOGY.

This admission, however, cannot be extended to the second branch of the metaphysics of being, which deals with the internal consciousness and the personal self; for here the interpretation on which it depends is utterly untenable. Psychology, like cosmology, cannot transcend the limits of consciousness; but in psychology it cannot in any sense be maintained that the real is that of which we are not conscious. My own consciousness is not merely the test of my real existence, but it actually constitutes it. I exist in so far as I am a person; and I am a person in so far as I am conscious. Were it possible, which it is not, to conceive the human soul as a substance of which consciousness is only an accidental mode,—which may exist at one time in a conscious, and at another in an unconscious state,—such a soul could in no sense of the term be called *myself;* the various modes of its existence could in no sense be called *mine.* The Cartesian *cogito, ergo sum,* is so far from being, as its opponents have maintained, an illogical reasoning from a premise to its conclusion, that its only fault consists in assuming the appearance of a reasoning at all. My consciousness does not *prove* my existence, because it *is* my existence. Descartes does not intend, as Reid imagined,[3] to reason from the existence of thought to the existence of a mind or subject of thought: he intends to state wherein personal existence consists; and he rightly places it in consciousness.[4] The opinion of Locke,[5] that the soul does not always think, is tenable only as a part of that false psychology which regards the soul as a substance projected, as it were, out of consciousness, the unknown substratum imagined as the support of known accidents.[6] If I am never conscious of myself, but only of my ideas, I can, of course, pronounce nothing concerning the conditions of my real existence; but then, upon the same supposition, I could never have known that *I* am conscious, or that the ideas are *mine.* If there is nothing given in consciousness but ideas, there is no such thing as personal existence; but only a multitude of isolated ideas, each conscious of itself. Put the question in another form: ask what is the evidence that *I exist* at all; and I can only adduce the direct witness of consciousness. The existence of *myself* is a fact of consciousness, not an inference from it; for an *I* must be presupposed to make the inference. The unconscious substratum of possible ideas may be *a soul,* in some arbitrary and unmeaning definition of that term; but assuredly it is not *myself.* If we could suppose a human body growing up to maturity without consciousness, and a conscious principle afterwards infused into it, the body in its previous

Cousin, "Sur le vrai sens du *cogito, ergo sum,*" printed in the earlier editions of the *Fragments Philosophiques*, and in vol. i., p. 27, of the collective edition of his works. The same position is well illustrated by Mr Veitch, in the introduction to his translation of the *Discours de la Méthode*, p. 22. See also *Principia*, p. i., sects. 8, 9, 53.

[5] *Essay*, b. ii. ch. i., sect. 10.

[6] Locke's assertion is but partially refuted by Leibnitz, (*Nouveaux Essais*, ii. 1.) who holds that, in sleep without dreams, the mind is in a state of obscure perception, not amounting to consciousness;—an opinion which is also maintained by Wolf, *Psychologia Rationalis*, sect. 59. But the opposite opinion, suggested by Aristotle, (*De Somno*, c. i., ἣ συμβαίνει μὲν ἀεὶ καθεύδουσιν ἐνυπνιάζειν, ἀλλ᾽ οὐ μνημονεύουσιν.)is adopted by some of the most eminent psychological and physiological writers of modern times, as confirmed both by *à priori* probability and by positive experience. (See Kant, *Anthropologie,* sects. 30, 36; Jouffroy, *Mélanges Philosophiques*, p. 290; Holland, *Chapters on Mental Physiology*, p. 80; Brodie, *Psychological Researches*, p. 147.) Some valuable remarks and illustrations of this position are contained in Sir W. Hamilton's unpublished Lectures on Metaphysics.

Ontology.

condition would be no more a part of myself than the limb which was amputated from me ten years ago, and which is now dissolved into its chemical elements. Yet the inquiry, how far personality is diminished by amputation or increased by corpulence, is not more irrelevant, than to ask when consciousness begins in the new-born infant, or in the fœtus in the womb. In so far as the rudiments of my body existed prior to the birth of consciousness, in so far they were not parts of myself: and I, as a person, had no existence. I hold that my personality is undiminished by the loss of a limb, simply because I am conscious that it is undiminished; and for the same reason I refuse to acknowledge that *I* existed in the rudimentary fœtus, or in the ovum, or in the spermatozoon, or in the organism of my remote ancestors.[1]

But when we place the personal existence in consciousness, it is necessary to distinguish between the accidents of consciousness and its essential constituents. A man who has lost his eyesight has in one sense less consciousness than he had before; he has lost that portion which consists in the sensations of vision. But his personality remains undiminished by the loss either of the bodily organ or of the affections of consciousness which that organ communicates. The same may be said of the other bodily senses; each of which may be conceived to be annihilated without any destruction of the personality of the conscious subject. This is the natural testimony of consciousness to the spirituality of man. We cannot help believing that the body and its organs, however necessary during the present life to certain modes of consciousness, however chronologically the occasion of the earliest development of consciousness in general, is yet no part of the conscious subject,—is not, in any sense of the term, *myself.* And this instinctive conviction of the untaught consciousness of mankind is further strengthened by all that science tells us of the constitution of the body and its organs. Of the animal body is emphatically true what Heraclitus and the general voice of philosophy after him declared of the objects of sense in general:[2]—it exists not, but is continually being produced; it no sooner comes into being than it ceases to be. At no two successive moments does it consist of exactly the same particles; and during the course of a long life, the entire system is many times destroyed and renewed again. Our whole physical existence is but a series of chemical changes; "the solid," to quote the words of a recent writer,[3] "melting into the liquid, the liquid congealing into the solid; whilst both stand so related to the air, which is the breath of life, that they are continually vaporising into gases." Yet amidst all these changes, the conscious subject, the personal self, continues one and unchanged. A similar distinction between the accidental and the essential must be made with regard to the internal consciousness: the matter of that consciousness is continually changing; while the form abides permanent and immutable: emotions, thoughts, volitions, succeed one another at every moment: the self,—feeling, thinking, willing,—is one and the same throughout. It is not necessary to my personal existence that I should feel joy or sorrow, anger or tranquillity; for the calm man of to-day is the same as the angry man of yesterday; and he who laughs to-day may weep to-morrow. Nay, more: not only is every special experience which constitutes the matter of consciousness alien to and separable from the personality of the subject; but even a portion of the form of consciousness must be regarded as having in this relation only a hypothetical and secondary necessity. The intuition of space, though necessarily accompanying every perception of matter, whether in our own organism or in the exterior world, is yet necessary only so long as we are in the body and conscious by the bodily senses. We cannot positively conceive a state of existence from which space is separated; yet, on the other hand, we are compelled to believe that existence in space is an attribute of body, and not of mind.

But when all these are set aside, there yet remain two conditions which I conceive as essential to my personal existence in every possible mode, and such as could not be removed without the destruction of myself as a conscious being. These two conditions are *time* and *free agency.* To consciousness, in its limited and human form of existence (of the divine consciousness we are not entitled to speak), it is essential that there should be a permanent subject with a succession of modifications. The consciousness of any object, as such, is only possible under the condition of change; and change is only possible under the condition of succession. Destroy this condition, and, though I am not warranted in saying that no kind of consciousness can exist, I am warranted in saying that such consciousness could not be *mine.* That a being now subject to the law of succession should be identical with one hereafter not so subject, implies a self-contradiction; for it implies a consciousness of the relation of present to past, and the absence of time, the basis of that relation. Succession in time is thus manifested as a constituent element of my personal existence, without which I could not be conscious of that existence; and, as consciousness is in this case reality, without which *I* could not exist. Again, consciousness in its human manifestation implies an active as well as a passive element;—a power of attending to the successive states of consciousness, as well as a succession in those states themselves. Attention appears to be necessary, not merely to the remembrance, but even to the existence of various states of consciousness as such;—indeed, attention is but consciousness in operation upon some definite object.[4] But in attention we remark, obscurely, indeed, but certainly, the presence, in a more or less obtrusive form, of the power of volition. It is impossible, indeed, to estimate by analysis the exact amount of will, in the strict sense of the term, that is implied in the ordinary cognition of objects; the frequency of the act having obliterated the distinctive marks of its several elements, before we are capable of reflecting upon them; but its presence as a constituent element is not the less surely implied, though it requires some research to disengage it. It is not going too far to say that, without the conscious exercise of volition, the distinction between the permanent subject and its transitory modes, between *myself* and *my affections,* could never have arisen in the human mind; and the consciousness of that distinction is even now observed to vary with the fact which gives rise to it, to become more or less vivid in proportion as the consciousness of voluntary action is more or less obvious. *I* am emphatically and prominently present to my own consciousness in the exercise of choice: those acts are peculiarly *mine,* which are consciously imputable to me as their cause, and for which I feel myself responsible.[5] Volition is not, indeed, the whole of personality, but it is one necessary element of it;—the consciousness of the one rising and falling with the consciousness of the other; both more or less vividly manifested, as is the case with all consciousness, according to the less or greater familiarity of particular instances; but never wholly obliterated in any;—capable at any moment of being detected by analysis, and incapable of being annihilated by any effort of thought. That a conscious being can, under no possible conditions, be a merely passive link in the chain of causation, is more than I can venture to assert; but this much I know, that such consciousness could not possibly be *my* consciousness;—that *I* could not become such a being, retaining my present personality unimpaired; but that I must be destroyed, and a distinct being substituted in my place. The freedom of the will is so far from being, as it is generally considered, a controvertible question of philosophy, that it is the fundamental postulate, without which all action and all speculation, philosophy in all its branches, and human consciousness itself, would be impossible.

---

[1] "For aught I know," says Coleridge, "the thinking spirit within me may be *substantially* one with the principle of life and of vital operation. For aught *I* know, it may be employed as a secondary agent in the marvellous organization and organic movements of my body. But, surely, it would be strange language to say, that *I* construct my *heart!* or that *I* propel the finer influences through my *nerves!* or that *I* compress my brain, and draw the curtains of sleep round my own eyes!" (*Biographia Literaria*, vol. ii., p. 158, ed. 1847.)

[4] See *ante*, p. 575

[5] See on this point, Kant, *Religion innerhalb der Grenzen der blossen Vernunft*, part i., sect. 1.

The task, then, of the metaphysician, in this branch of his science, is to unravel and solve the difficulties which accompany the conception of personality in its twofold character,—that of existence in time, and that of free agency. The fact itself is in both cases equally indubitable: it is as certain, from the testimony of consciousness, that we are free agents, as that our ideas occur in succession, one after another. We are not called upon to account for this;—which would be to account for our own existence; every attempt at which must manifestly assume the very fact which it professes to call in question;—but, assuming this as the basis of consciousness, and, in consciousness, of personal existence, we must endeavour to meet the objections to which it is apparently liable, and which will generally be found to arise from a misinterpretation of the testimony of consciousness itself. For instance, it has been asked, how can a real thing exist in time; and, if it does so, how can we be conscious of its existence? The earlier phases of its being have passed by, and exist no more; the future exist not yet; the present is perishing as we contemplate it: How can these several phenomena make one thing? and, if they could, how can we be conscious of it? To know that my past self is identical with my present, I must compare them together: this is impossible, as they cannot be made to exist together. Nay, even to compare the thought of one with the thought of the other, I must contemplate them successively; and thus each vanishes as the other presents itself.[1] The answer to this objection may be furnished by a more accurate analysis of the idea of time itself. The consciousness of time does not simply imply succession: it implies a permanent subject under successive modifications. The object of consciousness can only be presented as successive, on the condition that the subject is presented as continuous. It is only when I become an object of consciousness to myself, that I become a member of a successive series; but in this case the object is not the presented self, but my representative conception of that self. *My notion of myself* may alternate in consciousness with my notions of other things; but it can do so only on condition that the *presented self*, the subject, and not the object, of consciousness, remains one and indivisible. The subject, it is true, cannot be contemplated apart from its modifications; for this would be to transform it from a subject to an object; but the two elements are not the less clearly discerned in the relation of consciousness; though they are discerned only in conjunction with each other. For this reason, the language which implies succession becomes obviously improper when applied to the subject of consciousness. I may speak, accurately enough, of my earlier and later thoughts or feelings; but I cannot, with any philosophical accuracy, speak of an earlier and later *self*, even as a merely logical distinction, for the sake of afterwards identifying the two. To identify is to connect together in thought objects of consciousness given under different conditions of space or time; as when I pronounce the man whom I met in the street to-day to be the same who called at my house yesterday. But *myself*, the subject of consciousness, is never given under these different relations at all. It is that presentation from which our original notion of numerical identity is drawn, and which cannot be subjected to later and secondary applications of the same idea. These considerations may perhaps throw some light on the vexed question of *personal identity*,—a question which can only be asked concerning the represented self, or notion made an object; and which cannot be asked at all without presupposing the presented identity of the subject.

A like answer may be made to the objections against free will, drawn from the supposed necessity of a determining antecedent in time. Consciousness, rightly interpreted, repudiates both the extreme theories;—that of an irresistible determinant, or set of determinants, and that of an arbitrary will, altogether uninfluenced by motives. Two alternative motives are manifested in consciousness as both influencing, but neither compelling; and the freedom of the will consists, not in being absolutely uninfluenced, but in the power of determinining which of the two influences shall prevail. Of a temporal antecedent necessarily determining my volitions, consciousness tells me nothing;—nay, it tells me the very reverse, that the influence of such an antecedent is not necessary. It is only when the idea of volition is excluded, and, with volition, that of choice, and, with choice, that of contingence, that the temporal antecedent is transformed into a necessary determinant.[2] But this merely negative idea of necessity, which is, in fact, only an inability to conceive contingence, is derived solely from the absence of volition, and is inapplicable where volition is present. The only positive notion which I possess of *causative power* is that of *myself determining my own volitions*. This notion presupposes the freedom of the person, and has no existence whatever if that freedom be denied. To apply this notion in support of the hypothesis of necessity, is not only to go beyond, but actually to reverse the testimony of consciousness. It is, in fact, to say that the consciousness of myself having absolute power over my own volitions is identical with the consciousness of something else having absolute power over me.

But if we are conscious that we are free, we are free in reality; for, as regards the personal self, consciousness *is* reality. In this respect, the ontology of the personal self, which stands in the place of the rational psychology of the pre-Kantian metaphysics, occupies a very different position from the ontology of the material world, which inherits the unsolved problems of rational cosmology. The latter science, in its only attainable form, is but a phenomenology of a higher order. It can distinguish between the permanent and the transitory attributes of matter relatively to consciousness; but it is compelled to admit the possible existence of a further material world of things, of which we are not conscious, and which may or may not resemble the objects of which consciousness, and, through consciousness, philosophy, takes cognisance. But, as regards *myself*, this supposition is inadmissible. I exist as a person only as I am conscious of myself; and I am conscious of myself only as I exist. The consciousness of personality is thus an ontology in the highest sense of the term, and cannot be regarded as the representation of any ulterior reality. The neglect of this distinction forms the weak point in the otherwise masterly discussions of Kant on the antinomies of pure reason. Denying the existence of an immediate consciousness of self, and holding, as all who deny this must do, that the freedom of the will is incompatible with exist-

---

[2] See *ante*, p. 601.

ence in time, he endeavoured to save liberty itself, and, through liberty, morality, by a distinction between the phenomenal self of consciousness, and a real self of which we are not conscious. The self of consciousness, he said, is a phenomenon existing in time; and, as such, is necessarily determined by antecedent phenomena. If, then, phenomena were things in themselves, freedom would be impossible. But beyond the field of consciousness there must exist a transcendental self, the ground and support of the phenomena; and to this transcendental subject, as under no conditions of time, we may legitimately attribute a power of self-determination, or free causality. To this attempted solution obvious objections may be raised. In the first place, it may be urged that our real personal existence is the existence of consciousness; and no higher guarantee of reality can be admitted. The self of consciousness is the true self: that which is beyond consciousness, if such can be supposed, is in this case the phenomenon. In the second place, we are not compelled in thought to postulate the existence of any transcendental self at all; for consciousness itself presents the permanent subject of its own phenomena. In the third place, liberty is so far from being incompatible with consciousness, that it is directly given in consciousness itself; for I am immediately conscious that the temporal antecedents of my volition exercise no coercion upon it. Kant's solution is, in fact, the very reverse of the truth:—it is the self of consciousness which is really free: the hypothesis of necessity can only be maintained by the gratuitous supposition of a law of causality beyond consciousness, by which I am determined without knowing it. Such a perversion of the truth, on the part of so profound a thinker, can only be explained as a consequence of that suicidal position maintained as a canon of psychology by the philosophers of the last century; namely, that I have no immediate consciousness of myself, but only of my successive mental states,—a position which can only be described as one among many pernicious results of that reaction of physical upon mental science which, under the abused name of inductive philosophy, was permitted to poison with its crude analogies the very fountain and source of philosophy itself. The same consciousness which tells me that I am compelled to believe in the existence of a material world when I am not directly conscious of it, tells me also that I am directly conscious of myself, and that I exist in and by that consciousness. To overlook the distinction thus clearly laid before us is to confound with each other the two poles of speculative philosophy, the subject with the object, the necessary with the contingent, the permanent with the transitory, the *ego* with the *non-ego*.

Beyond the attributes manifested by consciousness as essential to personality, the ontology of the soul has no province. It cannot assume those attributes as the basis of any further demonstration; for the principles of demonstration are inapplicable to real objects. Neither the simplicity of the soul nor its immortality can be demonstrated as a necessary truth; for they are not implied in the conception of personality, and beyond that conception we have no intuition of necessary relations. The favourite representation of the soul as a simple substance, indivisible, and therefore indestructible, is one which, except so far as it is synonymous with continuous existence in time, is either untrue or unmeaning. If interpreted to mean that the conception of personality comprehends only a single attribute, it is untrue; if intended to state that the soul is not composed of parts coadjacent in space, it is unmeaning, except on the principles of materialism. A material atom is an intelligible expression, whether the object which it denotes is conceivable as really existing or not. A mental atom is as utterly unmeaning as the opposite expression of a mind composed of atoms.[1] Immortality, again, however surely guaranteed upon other grounds, cannot be represented as a necessary attribute of personal existence. That which did not exist once, may, without any absurdity, be supposed not to exist hereafter. The power which was sufficient to create is also sufficient to destroy; and if man is destined to exist for ever, it is from no inherent immortality of his own, but solely because such is the will of his Maker. That we are designed for a future life, may indeed be inferred from the direct testimony of consciousness, in so far as it reveals the existence within us of feelings and principles which do not find their full satisfaction in this life; but this inference, however legitimate, does not fall within the province of metaphysics.

OF THE REAL IN THEOLOGY.

In treating of the third branch of ontology, that of rational theology, it is necessary to take a different course from that adopted by the majority of those metaphysicians who have attempted theological reasoning at all. In the number of these, however, we cannot include those philosophers, whose systems, however veiled under the language of theism, or even of Christianity, exhibit a conception of the Deity which virtually amounts to pantheism. A personal God cannot be identified with all existence; and an impersonal Deity, however tricked out to usurp the attributes of the Godhead, is no God at all, but a mere blind and immoveable law or destiny,[2] with less than even the divinity of a fetish, since *that* can at least be imagined as a being who may be offended or propitiated by the worshipper. But, however much we may sympathize with the purpose of those philosophers who have endeavoured to demonstrate, *à priori*, the existence and attributes of a personal God, we cannot help feeling that such demonstrations, whatever may be their apparent logical validity, carry no real conviction with them to the believer or to the unbeliever.[3] And the reason of this is not far to seek. No demonstration from conceptions can prove the real existence of the object conceived; and, till this is done, the demonstration of the attributes of a hypothetical object proves no more than the connection between certain thoughts in our own minds.[4] The actual existence of an object can never be shown by thinking about it; for imaginary objects are as capable of being represented in thought as real ones. Reality must be tested, not by thought, but by intuition: we must be able to point to certain facts of consciousness in which the object of which we are in search is actually presented before us; or, at least, which can only be accounted for on the supposition that such an object exists. But this argument from the facts of intuition is not *à priori*, but *à posteriori:* it does not commence with a general conception, in order to exhibit by analysis the subordinate conceptions comprehended in it, or to construct in imagination a corresponding object; but it starts from certain facts of experience, manifested in the outer or inner consciousness, in order to determine the nature of the object which those facts present or point out to us.

---

[1] The only legitimate argument from the simplicity of the soul to its immortality is of a purely negative character. We are not authorized to say that we know the soul to be simple, and that therefore it is indestructible; but only that we do not know the soul to be compound (indeed, that the epithets *compound* and *simple*, as applied to the soul, have no meaning), and, therefore, that we cannot infer its mortality from the analogy of bodily dissolution. And this is, for the most part, the limit within which the argument is confined by one of the soberest as well as deepest of thinkers, the admirable Bishop Butler. The majority of philosophers, however, have not been so cautious in their reasoning.

[2] See Kant, *Beweisgrund zu einer Demonstration des Daseyns Gottes, Vierte Betrachtung*, sect. 3.

[3] For a criticism of some of the principal demonstrations of this kind, see Kant, *Kritik der reinen Vernunft.*, Abth. iii., B. ii., Hauptst. 3. The same grounds of objection are also applicable to other reasonings of this kind. Compare Waterland's *Dissertation on the Argument* à priori *for a First Cause.*

[4] See *ante*, p.602.

We must therefore begin our inquiry by asking, What are the facts of consciousness which appear directly to indicate the existence of a spiritual being superior to ourselves? Two of the intuitions of the internal consciousness appear especially to possess this character:—the *feeling of dependence*, and the *sense of moral obligation.* To these must be added, as an indirect and collateral witness, the *consciousness of limitation*, which, by suggesting, though not immediately presenting, the unlimited as its correlative, serves in some degree to interpret and connect the other two. The argument from causation, though holding an important place among the evidences of natural religion, can hardly be placed among those direct indications of consciousness which come within the legitimate province of metaphysics. We are immediately conscious, indeed, of the necessity of supposing a phenomenal antecedent to every event; but we are not immediately conscious of a necessity of conceiving that the series of phenomena is limited or unlimited. Nay, rather, we are conscious of two counter inabilities, which hinder us from conceiving either an absolutely first cause, or an absolutely unlimited series of causes and effects.[1] We have thus two contradictory hypotheses, one of which must be believed, though neither can be comprehended; and the evidence of reason being thus neutralized, we are bound to adopt that alternative which is most in harmony with the remaining testimony of consciousness. But, in so doing, we obey a moral, not an intellectual obligation; and our conviction, as far as the argument from causation alone is concerned, is not that of reason, but that of faith. The conclusion from the evidences of design in the works of creation, which is but a special form of that from causation, is likewise not an immediate suggestion of consciousness, but the gradual product of experience and comparison, arguing by analogy from what we have learned concerning the works of man to what we may infer concerning the works of God. Such arguments have great value in their own place, as illustrative of, and auxiliary to, the convictions forced upon us by our religious and moral instincts; but they are based upon reflection, not upon intuition; and, though they may serve to enlarge our conception of the Deity when once formed, they do not explain its origin and formation.

The province of the metaphysical theologian is confined to those evidences which belong to the direct testimony of the intuitive consciousness, as manifested in the feelings of dependence and moral obligation. The feeling of dependence is something very different from the mere recognition of the relation of subject to object in consciousness, and of the consequent limitation of the one by the other.[2] It is a feeling that our welfare and destination are in the hands of a superior Power; not of an inexorable fate or immutable law, but of a Being having at least so far the attributes of personality that He can show favour or severity towards those dependent upon him, and can be regarded by them with the feelings of hope and fear and reverence and gratitude, and be addressed in the words of prayer and praise. It is a feeling similar in kind, though higher in degree, to that which is awakened in the mind of the child by his relation to his parent, who is first manifested to his mind as the giver of such things as are needful, and to whom the first language he addresses is that of entreaty. With the first development of consciousness, there grows up, as a part of it, the innate feeling that our life, natural and spiritual, is not in our own power to prolong or to sustain; that there is One above us on whom we are dependent, whose existence we learn, and whose presence we realize, by the sure instinct of prayer. That this feeling is natural to us, is manifested by the universal practice of mankind;—every nation, however degraded may be its form of religion, having some notion of a superior being, and some method of propitiating his favour. We have thus, in the sense of dependence, the psychological foundation of one great element of religion—the fear of God.

But the mere consciousness of dependence does not in itself exhibit the character of the Being on whom we depend. It is as consistent with superstition as with true religion—with the belief in a malevolent as in a benevolent deity; it is as much, if not more, called into exercise by the painful and terrible aspects of nature as by the pleasing and encouraging. It indicates the power of God, but not necessarily his goodness. This deficiency, however, is supplied by the other psychological element of religion, the consciousness of moral obligation. It is impossible to maintain, as Kant has attempted to do,[3] the theory of an absolute autonomy of the will; that is to say, of an obligatory law resting on no basis but its own imperative character. The will, or practical reason, with its law of immutable obligation, is in itself a fact of the human constitution, and it is no more. Kant's fiction of an absolute law, binding upon all rational beings whatever, has only an apparent universality; because we can only conceive other rational beings by identifying their constitution with our own, and making human reason the measure and representative of reason in general. Why, then, has one part of my constitution, as such, an imperative authority over the remainder? What right has one part of the human consciousness to represent itself as duty, and another merely as inclination? There is but one answer possible. The moral reason, or will, or conscience—call it by what name we please—of man, can have no authority, save as implanted in him by some higher spiritual being, as a law emanating from a lawgiver. Man can be a law unto himself only on the supposition that he reflects in himself the law of God. If he is absolutely a law unto himself, his duty and his pleasure are undistinguishable from each other; for he is subject to no one, and accountable to no one. Duty itself becomes, in this case, only a higher kind of pleasure—a balance between the present and the future, between the smaller and the larger gratification. We are thus compelled, by the consciousness of moral obligation, to postulate a moral Deity, and to regard the absolute standard of right and wrong as constituted by the moral nature of that Deity.[1] The conception of this standard in the human mind may indeed be faint and fluctuating, and must be imperfect; it may vary with the intellectual and moral culture of the nation or the individual; and in its highest human representation it must fall far short of the reality. But it is present in all mankind, as a basis of moral obligation and an inducement to moral progress; it is present in the universal consciousness of sin—in the conviction that we are offenders against God. However degrading may be the practices into which men have fallen, under systems of false religion, it may be safely asserted that no man, and no nation of men, ever consciously deified vice as such. The voluptuous deities of the pagan mythology were deified as regards their enjoyments, not as regards their vices: their acts were contemplated as divine, not because they were breaches of morality, but because the worshipper falsely conceived them to be ingredients of happiness. The god of a nation of savage warriors may delight in revenge and bloodshed; but the supposed divinity of his acts does not consist in their cruelty: they are attributed to him because their infliction is an evidence of superiority; perhaps, also, because their endurance is a test of heroism. Even the worship of an evil principle is a worship of power, not of vice. He causes vice in man, but he is not himself vicious; for he transgresses no higher obligation of his own nature; and, even thus, he is not, in the proper sense of the term, God; for his worship implies no obligation to obey. The Deity, however falsely conceived, still represents a moral standard in the minds of his worshippers: the idea of the perfect goodness of God, as implied in the imperfect goodness of man, may be corrupted and degraded, but is never wholly extinguished. The consciousness of right and wrong, of duty and disobedience, even in its most perverted form, involves the consciousness of a being to whom duty and obedience are due; whose nature, however imperfectly represented, is necessarily conceived as moral; and whose commands, emanating from that nature, are manifested in the authority which they communicate to the moral principle in man.

---

[1] The counter arguments on either side are exhibited by Kant, in his first antinomy of pure reason. The same conclusion, however, is evident, without argument, from the direct testimony of consciousness. For to conceive an absolutely first member of the causal series is to conceive a beginning of all time, and thus to be conscious of a relation of time to an object out of time, and therefore out of consciousness; and to conceive an infinite series of causes and effects, we must carry our thought through an infinite succession of objects,—a process which would require an infinite time to accomplish it.

[2] In consequence of not distinguishing between these two, Schleiermacher (*Christliche Glaube*, sect. 4) has fallen into the error of representing our relation to the world as a feeling of partial dependence, and our relation to the Deity as one of absolute dependence. Thus represented, God can no longer be conceived as a person, but is nothing more than the world magnified to infinity; and the feeling of absolute dependence becomes the annihilation of our personality in the being of the universe. Of this feeling, the intellectual exponent is pantheism.

[3] See *Metaphysik der Sitten* (Abschn. ii., pp. 61, 71, ed. Rosenkranz). Thus refusing to acknowledge an intuition of God as a moral lawgiver, Kant is compelled to rest the evidence of the existence of the Deity on an assumed necessity of rewarding men according to their deserts, a necessity which implies an all-wise judge who can estimate merit in every degree. For an able criticism of Kant's theory, see Müller, *On the Christian Doctrine of Sin* (vol. i., p. 73, of the English translation).

But though we have thus the direct testimony of consciousness to the existence of a superior being, on whom our life and welfare depend, and from whom our moral obligations emanate, the being thus manifested does not yet realize the full idea of the Deity. For neither in dependence nor in moral obligation can we have an immediate intuition of the Infinite. The dependent is not absorbed in that on which it depends: the consciousness of our personal existence is not annihilated when we feel its relation to a higher power. Self and not-self still divide the universe of existence between them; and neither can be regarded as exhausting it.[2] But that which coexists with the finite cannot be itself conceived as infinite; otherwise the infinite and the finite together must be conceived as greater than the infinite. Nor yet can the finite be conceived as merged in the infinite; for this would be to conceive myself as existing and not existing at the same time. In like manner, it is impossible to conceive an infinite moral nature; for each moral attribute, as coexisting with others, limits and is limited by the rest; and the very conception of morality implies law, and law is itself a limitation. Yet, on the other hand, we cannot escape from the conviction that the infinite does in some manner exist, and exists, though we know not how, along with the finite; and though we can form no positive conception of its nature, we cannot regard the limits of our conception as the limits of all possible existence. We know that, unless we admit the existence of the infinite, the existence of the finite is inexplicable and self-contradictory; and yet we know that the conception of the infinite itself appears to involve contradictions not less inexplicable. In this impotence of reason we are compelled to take refuge in faith, and to believe that an infinite being exists, though we know not how, and that he is the same with that Being who is represented in consciousness as our sustainer and our lawgiver. For the contradictions involved in the denial of the infinite are positive, and definitely self-destructive; as we directly conceive the universe as limited, and yet as limited by nothing beyond itself; whereas the contradictions involved in the assumption that the infinite exists are merely negative, and might be soluble in a higher state of intelligence; as they arise merely from the impotence of thought, striving to reduce under the conditions of conceivability that which is beyond its grasp. Thus they are not contradictions manifested in the infinite itself, but only limitations in our power of comprehension. We are compelled, therefore, by reason, as well as by faith, to acknowledge that the infinite must exist; though how it exists, reason strives in vain to fathom, and faith rests content with the duty of believing what we cannot comprehend.

Hence we are compelled to admit that theology as well as cosmology, viewed as a branch of philosophy, is not a true ontology, but only a higher kind of phenomenology. We believe in the existence of an infinite God; and we know also that we cannot conceive Him *as* infinite. Our highest conception of the Deity is still bounded by the conditions which bound all human thinking, and therefore cannot represent the Deity as He is, but only as He appears to us. Such a representation, though sufficient for all the practical purposes of religion, is unable to satisfy in full the demands of a philosophical curiosity. But a sounder and more sober philosophy will tell us why those demands cannot be satisfied;—why the highest problems of speculative theology must and ought to be abandoned as insoluble. It tells us that our whole consciousness is relative, and therefore cannot comprehend the absolute; that our whole consciousness is limited, and therefore cannot comprehend the infinite. It tells us that a comprehended infinite could be no infinite at all; for comprehension itself is a limitation; and the unlimited must necessarily be the incomprehensible. To know God as He is, man must himself *be* God. The pantheist accepts this position, and identifies the Divine mind with the universal consciousness of mankind. The theist accepts it also, and is content to worship where he cannot understand.

---

[1] The theory which places the standard of morality in the *Divine nature* must not be confounded with that which places it in the arbitrary *will* of God. On the latter, see the remarks of Sir James Mackintosh, *Second Dissertation, ante*, vol. i., p. 312; and of Müller, *Christian Doctrine of Sin*, vol. i., p. 95. God did not create morality by his will: it is inherent in his nature, and coeternal with Himself; nor can He be conceived as capable of reversing it. But God did in one sense create human morality, when He created the moral constitution of man, and placed him in certain circumstances, such as those of mortality, of property, of sexual relation, &c., by which the eternal principles of morality are modified during this present life. On the foundation of morality in the nature of God, see Cudworth, *Treatise Concerning Eternal and Immutable Morality*, b. i., ch. iii.; b. iv., ch. iv. v. vi.

[2] Schleiermacher (*Christliche Glaube*, sect. 4, 5) maintains a different view. He resolves the religious consciousness into a feeling of *absolute dependence*, in which the consciousness of our own individuality and activity in relation to a distinct object of consciousness disappears in that of a passive relation to the infinite God. In this view he is followed by Mr Morell, who says that man, "in the presence of that which is self-existent, infinite, and eternal, may feel the sense of freedom utterly pass away, and become absorbed in the sense of absolute dependence." (*Philosophy of Religion*, p. 75.) Without dwelling on the difficulties and apparent contradictions involved in the notion of an absolute dependence which is, at the same time, a relative consciousness, this theory appears to be open to one fatal objection; namely, that it makes our moral and religious consciousness subversive of each other, and reduces us to the dilemma that either our faith or our practice must be founded on a delusion. The actual relation of man to God is the same, in whatever degree man may be conscious of it. If man's dependence upon God is really not destructive of his personal freedom, the religious consciousness, in denying that freedom, is a false consciousness. If, on the contrary, man is in reality passively dependent upon God, the consciousness of moral responsibility, which bears witness to his free agency, is a lying witness. When Schleiermacher assumes the existence of three degrees of consciosuness,—1. That of the infant, in which there is no conscious distinction of the subject from its object; 2. The middle state of distinct relation between self and not-self; and 3. The highest or religious consciousness, in which the relation again disappears,—he overlooks the fact that the second and third are not successive stages in the mental development, but must alternate with each other during a man's whole life; the one presiding over his moral duties, and the other over his religious feelings. On what ground is one of these states to be regarded as higher than the other, except in so far as it more truly reveals to us our actual state in the sight of God, as free or absolutely dependent? And as this state must be always the same, whether we are conscious of it or not, it follows, that in proportion as one of these states reveals to us the truth, the other must be regarded as testifying to a falsehood.

If this limitation of philosophical theology be admitted, the ground of many a controversy, and the root of many a heresy, is cut from under it at the very commencement of inquiry. In acknowledging the existence, and at the same time the incomprehensibility, of the infinite, we at once confess that we have sufficient grounds for belief, but not for theory. If we have no conception of the infinite attributes of God as such, we may not so interpret those attributes as to place them in antagonism, either to the direct testimony of consciousness, or to the plain language of Scripture; nor yet, on the other hand, can we distinctly show their compatibility with either, though we are bound to believe it. How, for example, can we reconcile man's free-will with God's foreknowledge? Rather, why should we attempt to do so, when in the attempt we must needs substitute our limited conception of the Divine nature for that nature as it is. We know not how an infinite intelligence contemplates succession in time: we know not whether his consciousness is subject to the law of succession at all. Eternity, in relation to the Divine mind, may be, as the schoolmen called it, a *nunc stans*, in which there is neither past, nor present, nor future. Foreknowledge may be merely a means of accommodating the representation of Divine omniscience to human faculties. To speculate in any direction,—to adopt a theory of *scientia media* on the one hand, or of absolute predestination on the other,—is to deify our own ignorance; to make the human conception the measure of the Divine reality. Why, again, cannot we conceive infinite power as undoing that which is already done. If the sun has risen this morning, why can we not conceive that even Omnipotence can now cause that it shall not have risen? Simply, because we cannot conceive infinite power at all:—the limitation is not of omnipotence in itself, but of all power as the object of human thought. How, again, can we reconcile the exercise of two Divine attributes with each other? How can infinite mercy pardon every sin, and yet infinite justice exact the utmost penalty? How can we tell, when we can conceive justice and mercy only in their finite forms, as they are capable of existing in human consciousness? It is obvious how the same principles may be applied to controversies concerning those deeper mysteries of the Christian faith which rest on the evidence of revelation only. But into this sacred ground it would be foreign to our present argument to enter.

OF THE REAL IN MORALITY.

The ontology of morals is subject to the same limitations with that of religion. If the standard of perfect and immutable morality is to be found only in the eternal nature of God, it follows that those conditions which prevent man from attaining to a knowledge of the infinite as such, must also prevent him from attaining to more than a relative and phenomenal conception of morality. And, in truth, man's moral, like his religious consciousness, will vary according to his state of mental and moral culture: he may have higher or lower ideas of duty, as he may have higher or lower ideas of God. But it does not, therefore, follow, as was maintained by the sophists of old, that each man is the measure of all things to himself, and that morality is nothing more than the law which any man or nation chooses to enact for a certain time within a certain sphere.[1] The very expressions, a *higher* and a *lower* standard, imply that there are degrees of right and wrong, even in relative and phenomenal morality;—that one human conception of duty may be more perfect than another, even if none can attain to absolute perfection. There is such a thing as an enlightened and an unenlightened conscience; though no man may presume to say that his own conscience has attained to the greatest amount of enlightenment of which even human nature is capable. It is a mark of the progressive character of natural morality and religion, that no new advance in knowledge contradicts the *principles* which have previously been acknowledged by the conscience; however much it may modify the particular acts by which those principles are to be carried out. To be zealous in God's service is a principle of religious duty common to Saul the persecutor and to Paul the apostle; though its result in action is at one time to destroy the faith, and at another to preach it. And it is a mark of the same character, that each fresh advance in moral and religious knowledge carries with it the immediate evidence of its own superiority, and takes its place in the mind, not as a question to be supported by argument, but as an axiom to be intuitively admitted. Each principle of this kind recommends itself to the minds of all who are capable of reflecting upon it, as true and irreversible as far as it goes; though it may represent but a limited portion of the truth, and be hereafter merged in some higher and more comprehensive formula. The principles, for example, that virtue, relatively to the human constitution, consists in observing a mean between two extremes, or in promoting the good of others, or in a reasonable self-love, all represent views containing a portion of truth; though none can be considered as exhausting the whole truth. While human nature is complex in itself, and susceptible of various relations and various duties arising out of those relations, it is not to be expected that all human virtue should be reducible to a single attribute, or capable of expression in a single formula. Yet its general character is not therefore doubtful, because it admits of being viewed in various special relations. Two men who differ in their definition of virtue will yet generally be agreed as to who is the virtuous man. "Let me die the death of the righteous, and let my last end be like his," expresses the conviction of one who, though far from righteous himself, was yet compelled to acknowledge the existence of a higher human standard than his own rule of conduct.[1] "As much as it has been disputed," says Bishop Butler, "wherein virtue consists, or whatever ground for doubt there may be about particulars; yet, in general, there is in reality an universally acknowledged standard of it. It is that which all ages and all countries have made profession of in public: it is that which every man you meet puts on the show of: it is that which the primary and fundamental laws of all civil constitutions over the face of the earth make it their business and endeavour to enforce the practice of upon mankind:—namely, justice, veracity, and regard to common good."[2]

---

[1] So far from it, that the above ground is constantly taken by the antagonists of the sophistical doctrine, for the express purpose of refuting it. Thus Plato, in the Dialogue especially devoted to the refutation of the dogma of Protagoras, that "man is the measure of all things," asserts that some portion of evil must needs exist in our mortal nature, and that we must endeavour to escape from it by an imitation, according to our power, of the Divine justice and holiness. (*Theætetus*, p. 176.) And Aristotle, after stating, as opposed to his own view, the sophistical position that all justice is conventional and variable, remarks,—*καίτοι παρά γε τοῖς θεοῖς ἴσως οὐδαμῶς.* (*Eth. Nic.* v. 7.) Even the comic poet, in his Dialogue between the Unjust and the Just Discourse, representing respectively the sophists and their antagonists, puts into the mouth of the latter the same argument:—

ΑΔ. *οὐδὲ γὰρ εἶναι πάνυ φημὶ δίκην,*
ΔΙ. *οὐκ εἶναι φῄς;* ΑΔ. *φέρε γάρ, ποῦ 'στιν;*
ΔΙ. *παρὰ τοῖσι θεοῖς.* (Aristoph. *Nubes*, 902.)

Nevertheless, there is an useful lesson to be drawn from the frequent fluctuations of men's moral theories, as well as from the general agreement of their practical confessions. It is not unusual for philosophers to reason as if they were possessed of an absolute, and not merely of a relative standard of morals;—as if they had attained to the conception of eternal morality, as it exists in the nature of God, instead of to that temporary modification of it which is adapted to a particular state of the constitution, and stage of the progress, of man. The works in which Kant and Fichte have attempted to construct an *à priori* criticism of revelation, upon moral grounds, are remarkable instances of this departure from the limits of all sound philosophy.[3] Both assume that the sole purpose of revelation must be to teach men morality; and both assume that the morality thus taught must be identical to the minutest particular with the system attained by human philosophy;—which last is supposed to be absolutely infallible. Hence Kant maintains that the revealed commands of God have no religious value, except in so far as they are approved by the moral reason of man; and Fichte lays down, among the criteria of a possibly true revelation, that it must contain no intimation of future reward or punishment, and must enjoin no moral rules which cannot be deduced from the principles of the practical reason. Whereas, in truth, the principles of the practical reason are susceptible of additional enlightenment with every stage of man's progress in this life (and it may be also with every stage of his progress in the life to come), and revelation, in two sentences, has conveyed to us a principle of human morals, which the philosophy of ages had toiled after in vain, and which the philosophy of a later day has been content to borrow without acknowledgment, and to pervert in attempting to improve:—"Thou shalt love the Lord thy God with all thy heart, and with all thy soul, and with all thy strength, and with all thy mind; and thy neighbour as thyself."[4]

OF THE REAL IN THE PHILOSOPHY OF TASTE.

With the ontology of morals is not unfrequently associated that of taste. The good and the beautiful were in the Greek language often expressed by the same word; and are by many regarded as alike expressing absolute and immutable principles, equally independent of human opinion, and equally objects of philosophical inquiry.[5] But, in truth, the object of the so-called philosophy of æsthetics appears, even in its highest form, to have far less of an absolute and immutable character than belongs to the objects of metaphysical inquiry, even within the limits to which they have been confined in the preceding pages. The beauty of an object appears to depend, not so much on the character of the object itself, as on the feeling of pleasure which it excites in the spectator; and this, again, on the accidents of his present constitution.[6] This appears to be the case even with the moral beauty of an action, when that quality is viewed apart from the other ingredients of its moral character. The consciousness that a certain action is morally pleasing to me is not necessarily connected with that of its moral rectitude; though the two have frequently been confounded together in the various theories concerning the moral sense.[7] But it is easy to conceive that moral obligation might remain undiminished, even if no gratification were derivable from the observance of it; while, on the contrary, it seems impossible to conceive the existence of an obligation to be pleased, apart from the apprehension of the moral character of the act. The beauty of sensible objects appears to exhibit still more fully the marks of a merely phenomenal and relative character. A slight change in the shape and refractive power of the eye would alter all our perceptions of the form and colour of objects, and, with them, the impressions of beauty and deformity derived from this source. And if the senses themselves are confined to the apprehension of phenomena, how can the beauty of the objects of sense lay claim to a higher character? Can we then assert that sensible beauty is a reflection and imitation of ideal beauty, even in the same manner and degree in which our perceptions of moral duty aim at and imply a divine standard of right and wrong? Even the fluctuation in the opinions of various individuals and nations, though far from being a decisive criterion in any case, appears to be acknowledged by the general sense of mankind to be a test more conclusive in questions of taste than in those of truth or rectitude. The very name *taste* seems to imply something subjective, and, to a considerable extent, arbitrary. The maxim, "*De gustibus non disputandum est*," may be the exaggerated expression of a popular conviction; but, at any rate, it carries no such shock to the natural feelings of mankind, as does the sophistical assertion that the distinctions between truth and falsehood, virtue and vice, are based on convention, and not on nature. Nor is it difficult to detect the foundation of truth which underlies the exaggeration. The maxim is true, in so far as it virtually asserts that beauty is subjective, not objective; an affection of the person who is conscious of it, existing only in and by that consciousness, not a permanent quality, existing in things, and capable of being expressed by a general notion.[8] But it is exaggerated, in so far as it apparently denies the existence of a common sense of beauty, among men of cultivated minds, by virtue of which similar affections will be produced in different minds by the same object.[9] But this admission, while it saves the standard of taste from the charge of arbitrariness and instability, at the same time removes the philosophy of taste from the province of ontology, and limits it to a psychological investigation of those relations between the imagination and the understanding which give rise to the consciousness of beauty in an object actually present.[1]

[2] *Dissertation on the Nature of Virtue.*

[3] See Kant's *Religion innerhalb der Grenzen der blossen Vernunft*, and Fichte's *Versuch einer Kritik aller Offenbarung*.

[4] See Kant's criticism and attempted explanation of these precepts, *Kritik der praktischen Vernunft*, B. i. Hauptst. iii. (p. 209, ed. Rosenkranz).

[5] See especially M. Cousin's Lectures, *Du Vrai, du Beau, et du Bien*, where absolute beauty is referred to the same Divine standard with absolute goodness and absolute truth: and so Hutcheson entitles his treatise *An Inquiry into the Original of our Ideas of Beauty and Virtue*.

[6] See Kant, *Kritik der Urtheilskraft*, sects. 1, 6, 15. (*Werke*, iv., pp. 46, 56, 76.) The sublime, as well as the beautiful, is admitted by Kant to be not a quality of things, but a feeling of our superiority over nature. (*Ibid.*, sect. 28, p. 122.)

[7] See *ante*, p. 580.

[8] See Kant, *Kritik der Urtheilskraft*, sect. 17. (*Werke* iv., p. 81.)

[9] See Kant, *Kritik der Urtheilskraft*, sects. 6, 22. Kant resolves the feeling of beauty into an indefinite consciousness of *fitness with reference to an end* (Zweckmässigkeit), but without the representation of any definite end. He admits, however, that this consciousness is merely subjective, and that there can be no objective rule, capable of determining beauty by conceptions.

CONCLUSION.

We have thus indicated, rather than discussed, some of the manifold aspects of the great fundamental problem, which, various in its external forms, but one in its real import, has stimulated the researches of thoughtful men in all ages, under the names, used for the most part synonymously, of First Philosophy, Ontology, or Metaphysics:—the problem, namely, to distinguish *that which is* from *that which seems to be.* Whether we look to its earliest definite statement, in the dogma of Parmenides, that being is one and unchangeable, and that variety exists only in the fancy of men; or to the boast of Zeno, that he would explain all things if there were only given to him the one;—whether we examine Plato's conception of the science of dialectic, as that which contemplates real existence by the aid of the pure intellect, illuminated by the brightness emanating from the essential form of good; or ask the question which the same philosopher describes as embracing at once the deepest mysteries of philosophy and the pettiest quibbles of sophistry, How can the one be many, or the many one;—whether we adopt Aristotle's definition of the first philosophy, as the science which contemplates being as being, and the attributes which belong to it as such; or, with Descartes, assume the fact of our own personal existence, manifested in consciousness, as the one primary and indubitable truth;—whether, with Leibnitz, we regard the sensible world as composed of an aggregate of unextended monads or metaphysical points; or, with Kant, divide objects into noumena and phenomena, things as they are in themselves and things as they are related to human faculties; or, with Fichte, postulate the existence of an absolute self, implied by, though not given in consciousness; or, with Schelling, attempt by intellectual intuition to reach the point of indifference in which the relations of subject and object are merged in the identity of both; or, with Hegel, found a philosophy on the hypothesis of an absolute thought, identical with absolute being, and susceptible of development into the various modes of personal and impersonal finite existence; or, with Herbart, find a common object of all metaphysical inquiries in the solution of the contradictions which present themselves in experience;—in all these, and other different statements, we recognise only verbal varieties of one and the same fundamental distinction;—a distinction which, however perverted in artificial systems, must have a natural origin in the human mind; which must be given in one mode of consciousness, or else it could not have been invented in any.

We have endeavoured to ascertain the primary and presentative fact of consciousness in which this distinction is given,—a fact upon which all the secondary and representative varieties of it must be based; and thus to fix the limits within which a science of real being is possible, and beyond which it cannot be carried. This fact seems to be discoverable in the relation between a permanent self and its successive modifications, which forms the condition of all human consciousness. If this be admitted, ontology, in the highest sense of the term, becomes identified with psychology; and the future task of the metaphysician will consist in exhibiting the conditions involved in the idea of personal existence, and solving the difficulties to which that idea appears to give rise. To attempt to accomplish this task in detail would require a far greater space, and a more minute examination, than is possible within the reasonable limits of an article like the present. We must content ourselves with having pointed out the fact that such problems exist, and stated the reasons for believing that they are not to be abandoned as insoluble.

Beyond the range of personal existence we have no positive conception of real being, save in the form of those more permanent phenomena which constitute our general conceptions of certain objects, as distinguished from the transitory phenomena with which those conceptions are at certain times associated. Here ontology is but a higher kind of phenomenology: its object is not a thing in itself, but a thing as we are compelled to conceive it; and to attempt to give to this branch of philosophy a more absolute character is to substitute negative ideas for positive,—to desert thoughts, and to take refuge in words which have no real meaning, save in relation to a different mode of consciousness. We do not, therefore, attempt to solve the higher problems of cosmology and theology, nor even to indicate the conditions under which they might be solved. But we have attempted to show why they are insoluble, and what is the origin of that delusion which has led men in various ages to fancy their solution possible, and to devise systems for accomplishing it. The failures of great minds are often not less instructive than their successes; and the time that is spent in wandering among the mazes of metaphysical speculation will not be wholly lost, if it teach us that knowledge which it is the end and aim of all sound philosophy to inculcate,—the knowledge of ourselves and of our faculties; of what we may and what we may not hope to accomplish; of the laws and limits of reason; and, by consequence, of the just claims of faith. (H. L. M.)

Metapontum
||
Metastasio.

METAPONTUM, or METAPONTIUM, a city of Magna Græcia, was situated on the Tarentine Gulf, 14 miles from Heraclea, and 24 from Tarentum. It was colonized by Achæans about the beginning of the seventh century B.C.; but some ascribe to it a much earlier origin. In the early period of its history Metapontum was in all probability in alliance with Sybaris and Crotona, cities likewise of Achæan origin; and it was imbued to a considerable extent with the opinions and doctrines of Pythagoras, who retired to this city and spent there the last days of his life. His tomb was still to be seen there in the time of Cicero. The Metapontines assisted the Athenians in their Sicilian expedition (415 B.C.), being at that time in a flourishing condition of wealth and prosperity. They embraced the side of Pyrrhus in his war with the Romans, and after its conclusion fell under the Roman yoke. When Hannibal invaded Italy the Metapontines, after the battle of Cannæ, were well disposed to him; but, on account of a garrison of Romans, were unable openly to desert to him till 212 B.C., when the city was occupied by a Carthaginian garrison. When Hannibal was compelled to leave Italy he removed, along with his own troops, the inhabitants of Metapontum; and from that time the city disappears from history. Some remains of it are still to be seen.

METASTASIO, PIETRO, whose original name was *Pietro Trapassi*, was born in Rome, 3d January 1698. His father, Felice Trapassi, a native of Assisi, had been forced by the poverty of his family to enter the Corsican regiment of the pope, had subsequently married, supported himself by copying legal documents, and saved money enough to open a shop in Rome, in partnership with a friend, for the sale of oil, meal, and other things of the kind. His mother was Francesca Galasti of Bologna. They had two sons, the elder of whom, Leopoldo, afterwards became an advocate, and distinguished himself as a religious polemic; and two daughters. Pietro from his earliest years showed an extraordinary talent for improvisation, and was accustomed to entertain his playmates in the street with impromptu rhymes. The celebrated jurist Gravina, having accidentally heard him so engaged while passing his father's shop one day, was so much interested by his precocious talent, and by the sweetness and modesty of his manners, that he proposed to his parents to adopt and educate the boy as his own son. The proposal was accepted. Gravina, who was a Grecian and a pedant, changed his name to Metastasio, from the Greek equivalent to *trapassamento*. Intending to educate him for the bar, where he thought his powers of improvisation and eloquence might be turned to most account, he sent him to his cousin Caroprese, in Calabria, to be taught Greek and philosophy. In a letter to Mattei, the poet dwells on these youthful studies with enthusiasm. Gravina did not, however, interdict what was his own favourite employment, the reading of the ancient poets, nor the practice of improvisation; and the handsome, modest, and vivacious boy was loved and admired in Naples and Crotona by the society to which the influence of his patron admitted him. He relates in one of his letters that he was accustomed at this time to engage in poetic contests with the most distinguished *improvisatori;* but the excitement being found prejudicial to his health, Gravina caused him to break it off, and apply himself more closely to the study of the Greek poets and of the early Italian writers, and to the cultivation of a correct style. For this course of conduct Metastasio afterwards expressed his gratitude, censuring the practice of improvisation as extremely injurious to taste and labour. At the age of twelve he translated the *Iliad* of Homer in *ottava rima;* and two years later he composed the tragedy of *Giustino*, on the model of his patron's dramas,—stiff and feeble imitations of the Greek,—borrowing the plot from the *Italia Liberata* of Trissini. An edition of this tragedy is extant, printed in 1713. In a letter to Calsabigi, who superintended the Paris edition of his work in 1755, he expresses his regret that this immature production had been included. Yet it is not without beauties prophetic of the *Olimpiade*. The story is simple and affecting, and the plot is developed with much clearness. In 1714 Caroprese died, leaving Gravina his heir, who in consequence went into Calabria and rejoined his adopted son. These mingled occupations of poetical and legal study Metastasio pursued till the death of his benefactor in 1718. The blow was severely felt by the poet, who composed on the occasion an elegy entitled *La strada alla gloria*, which he recited, amid the tears of the audience, to the literary society founded by his distinguished patron. Gravina bequeathed him his Roman property, amounting to 15,000 scudi (between L.3000 and L.4000); and finding himself at the end of two years nearly penniless, he resolved to resume his legal studies. With the view of opposing a powerful barrier to his inclination, and escaping the seductions of society, he went to Naples, and placed himself under the tuition of the eminent lawyer Castagnuola, whose aversion to poetry was such that Metastasio was compelled to observe the strictest secrecy in his favourite pursuits. His genius was, however, too well known, and too highly appreciated by the refined society in which he moved, to permit him long to resist the struggles of nature, seconded by admiration and flattery. He composed an epithalamium of 100 stanzas, in *ottava rima*, on the occasion of the marriage of the Marchese Pignatelli; and on the same occasion, perhaps, his first musical drama, *Endimione*, in 1721. But the event that fixed his destiny was the following:—The birthday of the Empress Elizabeth, consort of Charles VI., occurring during her pregnancy, the viceroy wished to celebrate it with unusual splendour, and requested Metastasio to write an opera. The latter complied, exacting a promise of strict silence with regard to the author's name, and produced *Gli Orti Esperidi*, which was received with the most unusual and unbounded applause. The viceroy was so highly gratified that he presented the poet with 200 ducats. At first every one was ignorant of the author, and supposed it to be the work of some Roman poet: not even the composer, Porpora, nor the actors knew. But Marianna Bulgarelli, known as "La Romanina," from her birthplace, who had performed the part of Venus with great success and profit, succeeded in discovering him. *Gli Orti Esperidi* was published, with the name of the author, the same year at Naples. The opera of *Angelica*, also composed by Porpora, was produced on the same occasion in 1722. It is not clear whether it was before or after the production of *Angelica* that Metastasio finally determined on abandoning the legal profession. He quitted the house of Castagnuola, and went to live with La Romanina and her husband. She introduced him to Porpora, from whom he received instructions in the theory of music, and doubtless much insight into the converse adaptation. From La Romanina herself he confesses to have learned much. Mattei asserts, as from good authority, that the finest situations in his next work, *Didone Abbandonata*, written for the carnival 1724, were suggested by this accomplished actress. This opera, composed by Sarro, and produced at Naples in that year, and afterwards composed by Vinci, and produced at Rome and Venice in the following years, rapidly spread the fame of Metastasio over the peninsula as the great dramatist of the age. In 1727 La Bulgarelli took leave of the stage, of which she had been now for eighteen years an ornament, and returned to her native city, taking with her her husband and her *cicisbeo*. *Catone in Utica* was written for the Roman stage in 1728, and was Metastasio's first (if we except *Giustino*) and last attempt in regular tragedy. The reception it met with convinced him that it was impossible to harmonize the requirements of the musical drama with those of tragedy: he changed the conclusion, adapting

Metastasio.

it to the powers of his actors and the taste of his audience, and never forgot the lesson. *Catone* was composed by Vinci for Rome, and next year by Leo for Venice. *Ezio*, *Alessandro nell' Indie*, and *Semiramide* rapidly followed, extending his fame, but not much improving his circumstances. Feeling himself partially dependent on La Bulgarelli, and with no very brilliant prospects, he became despondent, when in September 1729 he received a letter from Prince Pio of Savoy, director of the court theatre in Vienna, commissioning two dramas, and inviting him thither to occupy the post of imperial poet, with an annual salary of 3000 florins. This appointment he owed to his fame, to the influence of the Princess Althan, and the generosity of Zeno, who retired on a pension. Metastasio welcomed it with eagerness. He merely requested time to complete his Roman engagements, chiefly the *Artaserse;* and having done so, he took a tender farewell of his family, and of the faithful Marianna, whom he never saw again, and repaired to Vienna in April 1730. He was received with cordiality in the house of Niccolo de Martinez, *cerimonière* of the apostolic nuncio, where he continued to reside till his death.

The dramas which he produced in the year succeeding his arrival, *Adriano in Siria* and *Demetrio*, both composed by Caldara, and performed within a few days of each other, had great success. That of *Issipile*, written in the following year, moved the emperor from his customary reserve, and procured the poet his personal congratulations. His fame increased with the operas of *Giuseppe*, *Demafoonte*, and the *Divine Olimpiade*, which successively appeared in 1733. To the plaudits of the *Olimpiade* the emperor added the more solid recompense of a treasurership in Naples, of which, however, he was in a few years bereft by the war of the succession. His life at this period may best be read in his letters to La Bulgarelli, written with great expansion and confidence. His soul was in his work: the scenes which touched his audience had first moved himself. "I send you," he writes, "a sonnet composed while I was writing a pathetic scene (it was the ninth scene of the second act of the *Olimpiade*), with which I was so much affected, that I found myself in tears." He sends her directions for the representation of *Demetrio* in Rome, asks her for suggestions and for advice, and talks of the applause he was receiving. While engaged on the *Clemenza di Tito*, February 1734, the news of Marianna's death reached him. For some time he was quite overpowered. She bequeathed him her whole fortune, amounting to 25,000 Roman scudi, which he at once made over to the widower. There cannot be much doubt as to the nature of his connection with the actress. The pious expressions he makes use of on the occasion, in a letter to a friend (Burney, vol. i., p. 109), are not sufficient to refute an inference so entirely warranted by all the facts, and by the state of society then, and unfortunately still, existing in Italy. His immediate and generous renunciation of her legacy procured him great credit. That act was one quite in harmony with the tenor of his whole life. From this time onward Metastasio's life was laborious and peaceful, little disturbed in outward appearance by the political distractions that followed the death of Charles VI. in 1740, or that of Charles VII. in 1744. On the former occasion he received excellent and honourable proposals from various courts, but he adhered to the fortunes and service of Maria Theresa, whom he had taught Italian, and who was personally attached to her tutor. During this period he produced his best works, writing only at the command of the court, and writing rapidly. He told Burney that the opera of *Achille in Sciro*, produced in 1736 on occasion of the marriage of Maria, was written in eighteen days, and that of *Ipermestra*, in 1744, in nine. The operas of *Temistocle* and *Attilio Regolo*, with the exception of the *Olimpiade* perhaps his best works, belong to this period; *Temistocle* being produced in 1738, and *Regolo* being interrupted in 1740 by the death of the sovereign.

This continual labour, and the ungenial climate of Vienna, brought on in 1745 a serious illness, which obliged him to suspend his exertions. His malady was chiefly a nervous one, and he suffered from it more or less till his death. An occasional visit to his native country would perhaps have better reconciled his constitution to the severity of the Austrian climate, of which he so often bitterly complains; but excepting an annual visit to the seat of the Princess d'Althan in Moravia, he never stirred from Vienna. His days were spent in the society of the Martinez, and of a few congenial friends. Burney, who visited him in 1772, gives an interesting account of his mode of life and his conversation (*State of Music in Germany*, &c., vol. i., p. 298 ff.); but the principal, almost the only, source of information about him during this latter period are his own delightful letters. These give a fine picture of the nobleness, generosity, and kindness of his disposition. His most intimate friend was the celebrated singer Farinelli, to whom he writes as his "twin brother" (*gemello*), and who appears to have deserved and reciprocated his affection. These letters also show how thoroughly he had studied and comprehended the requirements of the composer, and with what care and judgment he adapted his dramas to the necessities of music. The ancient poets he read assiduously. Ovid was his particular favourite, as we might guess from the frequent occurrence of Ovidian sentiments in his works. In spite of the care of Gravina, he does not appear to have ever mastered the Greek language sufficiently to enable him to appreciate their tragic writers. The analysis he has left of them proves this; and he confesses to the difficulty he had of reading the *Poetics* of Aristotle, of which he has also left an imperfect abstract. Of the Italians, his great favourite and model was Tasso, to whom he revolted at an early age from the Ariostisti, and Marino, the so-called depraver of Italian poetry, whom he always read before sitting down to work. Metastasio died in Vienna on the 12th of April 1782. A fever, caught by exposing himself on the occasion of the pope's visit, carried him off in twelve days. He was buried in the church of St Michael. He left the younger Martinez heir to his real property and a fortune of 130,000 florins, with deduction of 2000 for each of the two sisters and 3000 for each of the three brothers of the legate. He had survived all his Italian relatives.

The dramatic works of Metastasio are of the very highest excellence in their kind. Judged simply as dramas, and in front of Shakspeare, Corneille, and Racine, they will be pronounced exceedingly defective in point of characterization, motive, and probability; but regarded as compositions to be set to music, they are unequalled. What are excellences and necessities in the spoken drama, become, when transferred to the sung drama, difficulties in the way of the composer and the audience. On the other hand, the improbabilities of incident and situation which would shock an audience in the spoken drama, tend to heighten the pleasure derived from music; the music itself, the greatest improbability, being already conceded. In estimating his powers, all those points in which Metastasio falls infinitely short of the real dramatists must be taken into account; but in estimating the value of his works, it matters little whether he was deficient in true dramatic genius, or voluntarily renounced its exercise. One thing only is to be regretted, that Metastasio did not exercise more judgment in the choice of his subjects: we may grant all his sentiments, incidents, and motive, but not that they should be introduced into history, or attached to great historical characters. Cæsar, Amilcar, and Regulus, are too distinctly marked and too incongruous with the subject to be made the heroes of a love story. With such a choice, besides, the defects of

Metellus.

historical and local colouring become quite too glaring. Metastasio, in his letter of thanks to Zeno, says that the latter was his master and model. Apostolo Zeno rescued the Italian opera from the debasement into which it had sunk, and which is so admirably described in Marcello's *Teatro alla Moda*. He is a poet of high ability, if not of first-rate genius. He as much surpasses his pupil in force of characterization, simplicity and strength of expression, and accuracy of historical colouring, as he falls short of him in sweetness, delicate clearness, and musical adaptability. It is in these that Metastasio's great merit consists. His songs are already music. "He exerted himself to fulfil every demand of music. He shortened the recitative; he enlivened the dialogue. And as his mother tongue, now in the highest degree refined, was quite at his command, he made of the Italian rhythm a syllable music, which is single in its kind." (Bouterwek, *Gesch.* ii., p. 493.) The Italian critics have almost deified Metastasio. In respect of style, perhaps, they are the only proper judges; but it is impossible to agree with all that Andres, Arteaga, and Baretti have uttered in his praise. The sweetness, harmony, and lyrical rounding and finish of many of Metastasio's arias and canzonettes are quite unequalled; and one is rather surprised to learn the mechanical coolness with which he was accustomed to set to work. Of the canzonette *La Partenza* and that to Nice, *Grazie agl' injanni tuoi*, are perhaps the finest, as they are the most celebrated.

Metastasio, late in life, counted forty editions of his works in his own library. The best are,—the Paris edition of 1755, in 9 vols. 8vo, published under the direction of Calsabigi; the Turin, 1757, 10 vols. 4to, founded on the former, and frequently reprinted till 1780, when the Herissant edition, in 12 vols. 4to, appeared at Paris, under the care of Pezzana, from a copy of the Turin edition corrected by the author. The Conte Pajala published the posthumous works at Vienna in 1795. The Genoa edition of 1802 and the Padua of 1811 are the most valuable. (W. H. C.)

METELLUS, the name of a noble family of the Cæcilian *gens*. Of this family the following are the most notable members:—

Quintus Cæcilius Metellus Macedonicus, who was appointed prætor in 148 B.C. Having received Macedonia as his province, he routed and captured Andriscus, the pretended king of that country. He then turned his arms against the Achæans, and encountering their prætor Critolaüs near Thermopylæ, gave him a severe defeat. After gaining a victory over the Arcadians near Chæroneia, he returned to Rome in 146 B.C., and was honoured with a triumph and with the surname of Macedonicus. Elected to the consulship in 143 B.C., Metellus was intrusted with the war against the Celtiberians in Nearer Spain. During the two years of this command he maintained with a steady hand the severest discipline among his soldiers, and the most skilful tactics against the enemy. His censorship in 131 B.C. was rendered notable by his proposing that every Roman should be forced by law to marry. The speech with which he introduced this motion was long afterwards read by Augustus in the senate, and has been partly preserved by A. Gellius in his *Noctes Atticæ*. Metellus lived to be universally respected, and to see his four sons enjoy the highest honours and the highest offices in the state. He died in 115 B.C., after exhibiting in his life a picture of human felicity which ancient writers have considered remarkable and almost unexampled.

Quintus Cæcilius Metellus Numidicus, who became consul in 109 B.C., and was sent into Numidia to carry on the war against Jugurtha. No sooner had he assumed the command than the Roman cause, which was formerly on the descendant, began forthwith to prosper. He routed the enemy near the River Mathal, ravaged the country without opposition, and by an artful system of intrigues kept the Numidian king in a restless terror for his life. In the following year, however, he was forced by the wary strategy of Jugurtha to protract the war. This delay was employed by his lieutenant, the ambitious Marius, to ruin his military reputation. The consequence was, that in a short time the low-born Marius superseded the aristocratic Metellus in the consulship and the command of the army. On his arrival at Rome in 107 B.C. Metellus was received with great applause, and was honoured with a triumph and with the title of Numidicus. During his censorship in 102 B.C. his zeal for the aristocracy led him to attempt to expel from the senate two inveterate plebeians Servilius Glaucia and Appuleius Saturninus. In 100 B.C. the latter obtaining the tribunate, returned the blow of Metellus, and by the aid of Marius, who was then consul, succeeded not only in depriving him of his seat in the senate, but in effecting his banishment. With cheerful resignation Metellus set out to Rhodes, carrying along with him his friend Ælius Præconinus, the rhetorician, and bent upon burying all gloomy thoughts in the deep problems of philosophy. He was roused, however, from his studies in the following year by the news that the popular party had suffered a severe check by the death of Saturninus, and that his own banishment was repealed. Not long after his return to Rome, Metellus is supposed to have been poisoned.

Metellus.

Quintus Cæcilius Metellus Pius, who received the surname of Pius from his affectionate endeavours to effect the recall of his father Numidicus from banishment. He was elected prætor in 89 B.C., and gained his first distinction as one of the leaders of the Marsic war. From carrying on hostilities against the Samnites he was summoned in 87 B.C. to defend Rome from Marius, who had returned from exile, and was marching towards the city to wreak vengeance on his enemies. Deeming it imprudent to dare so redoubtable a foe, Metellus repaired to Africa, and did not return to Italy till 84 B.C. He was among the first to greet Sulla on his landing at Brundusium in 83 B.C., and was one of the most effective lieutenants of that general in his protracted struggle with the Marian party. In 82 B.C. he gained three successive victories over the forces of Carbo; and in 79 B.C. he was sent as proconsul into Spain to check the victorious career of Sertorius. His ignorance, however, of that country, and the increasing infirmities of age, rendered him unfit to cope with the alert movements and guerilla strategy of his enemy. Only after a campaign of seven years was his military reputation redeemed by a victory over Sertorius. He returned to Rome in the following year to celebrate a triumph. Metellus Pius had been consul along with Sulla in 80 B.C., and he had also been appointed *pontifex maximus*. He died about 63 B.C.

Quintus Cæcilius Metellus Celer, who was elected to the prætorship in 63 B.C. In this capacity he was intrusted with the command of the three legions that guarded the Picentine and Senonian districts during the Catilinarian conspiracy. Anticipating the attempt of the rebel army to escape into Gaul, he threw himself into the passes of the Apennines, and thus compelled Catiline to turn back upon his pursuers, and to hazard that battle which issued in his defeat and death. In 60 B.C. Metellus was elected to the consulship, and exerted the entire power of his office in opposing the measures of Pompey, who was at that time considered the deadliest foe of the aristocracy. So determined, indeed, was his opposition, that he chose to be dragged to prison by order of the tribune rather than sanction an agrarian law for the provision of Pompey's soldiers. With the same unflinching resistance did he meet the agrarian law of Cæsar in 59 B.C. His death happened in the same year, not without raising suspicions that he had been poisoned by his wife Clodia, the profligate sister of Clodius.

Quintus Cæcilius Metellus Pius Scipio, who was the adopted son of Metellus Pius, and became tribune of the people in 59 B.C. In 52 B.C. Pompey took his daughter Cornelia in marriage, and chose himself as his colleague in the consulship. Metellus now became a puppet in the hands of his ambitious son-in-law. In 49 B.C. he proposed in the senate that Cæsar should be commanded to disband his troops, on pain of being treated as a public enemy. On the outbreak of the civil war which followed the execution of this proposal, the command in Syria was allotted to Metellus. No sooner had he taken possession of his province than his vicious character and his inability to govern burst forth into strong manifestation. The most exorbitant taxes were wrung from the people, the country was overrun by swarms of pillaging soldiers, and the blackest crimes passed unchallenged. From this scene of ruthless oppression he was summoned in 48 B.C. to play a part in the impending struggle between Pompey and Cæsar. He joined his son-in-law shortly after the skirmish at Dyrrhachium, and commencing forthwith to portion out the honours which the coming victory would leave at the disposal of his party, he became involved in a hot quarrel with some of his comrades touching his own claims to succeed Cæsar in the office of *pontifex maximus*. On the fatal day of Pharsalia he led the centre of the Pompeian army, and after he had seen his ambitious hopes scattered in the rout of his flying squadrons, he repaired to Africa to seek the aid of Juba, King of Numidia. The partizans of Pompey in that country placed him at their head. He was engaged in using his prerogative in his old practice of pillaging and oppressing when Cæsar arrived, towards the close of the year 47 B.C. In the following year Metellus was completely defeated at Thapsus. Escaping on board of a small fleet, he was intercepted by a squadron under P. Sittius, and was on the point of being captured when he stabbed himself, and then flung himself into the sea.

METEMPSYCHOSIS, a word of Greek origin signifying the passage or transmigration of souls, is applied to a peculiar system of doctrine, of high antiquity, respecting the destiny of the human soul. According to the more general forms of this system, the souls of men after death are supposed to enter successively into various bodies, and to animate various existences, which differ only in their external forms. It is equally difficult for man to believe in the ultimate annihilation of his spirit and to conceive of a future state of existence totally different from the present, independent alike of sense and of the laws of organized life. Accordingly, the mind seeks naturally for some mode of reconciling these two antagonistic conceptions—some system of faith, no matter how obscure, whereby "the longing after immortality" may be gratified, and the instinctive shrinking from annihilation find itself respected. And hence the origin of metempsychosis; the first form in which the doctrine of the immortality of the soul is presented to the human mind. Metempsychosis was maintained by the Egyptians, the Hindus, and the Greeks. Herodotus informs us (lib. ii., sec. 123), that the Egyptians were the first to adopt the doctrine of the soul's immortality; and it is generally to them that the invention of the metempsychosis is attributed. They held that the human soul immediately after death entered into some animal, called into existence at the same instant, and that after having successively assumed the forms of all the animals which inhabit the land, the water, and the air, it returned, after completing a cycle of 3000 years, into the body of a man, to recommence eternally the same endless pilgrimage. With the Hindus, again, the idea of metempsychosis is more metaphysical, more universal, than that of the Egyptians, and is closely allied to the idea of emanation maintained by that highly speculative race. As matter is the last degree of the emanations of Brahma, it follows that life, which is the union of the soul with matter, is essentially an evil. This being the case, all the developments of life, such as actions, sensations, pleasure, pain, &c., must of necessity share in the same degradation. Accordingly, the proper business of the soul is to die to everything earthly—to elevate itself by contemplation to that absolute repose in the bosom of the Deity from which it originally came forth. The soul must expiate in this world the sins of its previous life; and in order to purification, the impenitent are at death condemned to pass from one body into another of a more or less perfect form, according to the upward or downward tendency of their nature. Such is the doctrine taught in the philosophy of Vaisechika. According to the Vedanta system, again, the soul is not an emanation but a part of Brahma; a spark from an eternal fire. It knows neither birth nor death; it endues itself only for a time in a corporeal envelope, where it is afflicted by the darkness of ignorance, and subjected to the sufferings attendant upon evil. It visits various bodies in succession, and the circle of its metamorphoses embraces all organized nature, from a plant up to a man. Divine knowledge alone can extricate it from this circle of sorrow and humiliation; and this knowledge can only be attained by the soul stripping itself of all personality both of feeling and will; after which it precipitates itself into the bosom of the Deity, as a river discharges its waters into the sea.

It is a current belief that the idea of metempsychosis passed from Egypt into Greece; but this opinion is not well founded. For not only are traces of this doctrine to be found in the latter country, as the name of Orpheus will suggest, long previous to any authentic intercourse between those two nations, but Herodotus himself expressly distinguishes between the ancient and the modern partizans of metempsychosis in Greece; between the doctrine current in the country before the time of Pythagoras and the form of it introduced by that philosopher, who was the first Greek speculator initiated in the religious science of the Egyptian priests. But whether original or borrowed, the doctrine as found in Greece was in complete harmony with the genius of the Greek people. It was removed alike from the cloudy mysticism of India and from the miraculous naturalism of Egypt. It was Pythagoras who gave the doctrine its most precise form. He limited the metamorphoses of the soul to animal life, and, instead of a fortuitous entrance, he maintained that each individual soul passed into that particular form of organized animal existence which was most in harmony with its own faculties and condition.

Plato, in adopting this Pythagorean doctrine, attempts in the *Phædo* to establish it from two sources, and thus elevates it into the class of philosophical ideas. His first proof is drawn from the general order of nature, and the other from the human consciousness. Nature, says Plato, is governed by the law of contraries; death succeeds life, and life must succeed death. Again, we find evidence of the same state of pre-existence in the fact of reminiscence. That intellectual suggestiveness and inventive power so frequently noticeable in the subtler workings of the understanding, by which the mind makes such swift conquest of whole territories of the realm of knowledge, are only to be attributed to the fact that all this knowledge was once fully comprehended in a previous state of existence. But how far Plato insisted on this doctrine, or whether it was aught more than a piece of suggestive hypothesis, it is difficult to determine. We find the idea of metempsychosis assuming new developments during the later stages of Greek speculation. We encounter it subsequently in the school of Alexandria, in the bosom of Judaism, and in a father of the church. The hypothesis of a pre-existent state was, with Origen, a favourite mode of explaining certain biblical difficulties; and the same argument, particularly in its bearings on original sin, has been recently revived by an eminent American divine.

METEOROLITE. This term is derived from the Greek *μετεωρα*, *a meteor*, and *λιθος*, *a stone*, and denotes a stony substance, exhibiting peculiar characters, and the descent of which to the earth is usually accompanied by the appearance and explosion of a fire-ball.

Luminous meteors have in all ages been observed in the atmosphere. It is also well known that their disappearance has frequently been attended with a loud noise; but that they should moreover terminate in the fall of one or more solid bodies to the earth's surface, is a position so repugnant to our ordinary conceptions of the tenor of physical events, that we cannot admit it as a fact upon slight or scanty evidence.

One passage may be cited from the books of the Old Testament in corroboration of the descent of stones from the atmosphere. In the 11th verse of the 10th chapter of Joshua we find,—"And it came to pass, as they fled from before Israel, and were in the going down to Beth-horon, that the Lord cast down *great stones* from heaven upon them unto Azekah, and they died."

If from sacred we turn to the early period of profane history, we shall find the annals of public events very copiously interspersed with notices of such strange appearances. Through the midst of fable which envelopes the history of the *bætuli* we discern some characters which correspond with those of meteorolites. Thus in the *Λιθικα*, a poem falsely ascribed to Orpheus, the *σιδηριτης* is said to be "rough, heavy, and black." Damascius, in an extract of his Life of Isidorus, preserved by Photius, relates that the *bætuli* fell on Mount Libanus, in a "globe of fire." A fragment of Sanchoniathon, preserved by Eusebius in his *Præparatio Evangelii* (i. 10), moreover informs us, that these stones were fabricated by the god Uranus or Heaven, one of whose four sons was named Bætul. In the same chapter we are told that Astarte found a "star" which had "fallen from heaven," and honoured it with consecration in the city of Tyre. The stone denominated "the mother of the gods," if we can believe Appian, Herodian, and Marcellinus, "fell from heaven." Aristodemus, cited by the Greek scholiast on Pindar, asserts that it fell encircled by fire, upon a hill, at the feet of the Theban bard. It is said to have been of a black colour, and of an irregular shape. Herodian expressly declares, that the Phœnicians had no statue of the sun polished by the hand, but only a certain stone, circular below, and terminated acutely above, in the form of a cone, of a black colour, and that, according to report, it "fell from heaven," and was regarded by the people as the image of the sun.

Amongst various instances which might be selected from Livy is that of a shower of stones on the Alban Mount, in the reign of Tullus Hostilius, or about 652 B.C. The senate was assured that stones had really fallen, "haud aliter quam quum grandinem venti glomeratam in terras agunt."

But one of the most remarkable cases which occurs in the records of antiquity is that which is mentioned in the 58th chapter of the second book of Pliny's *Natural History*, of a large stone which fell near Ægospotamos in Thrace, in the second year of the 78th Olympiad, or, according to our chronology, about 467 years before the Christian era. Pliny assures us that this extraordinary mass was still shown in his day, and that it was as large as a cart, and of a burned colour. According to Plutarch, in the Life of Lysander, the inhabitants of the Chersonesus held the Thracian stone in great veneration, and exhibited it as a public show. This event is also recorded in that curious document, *The Parian Chronicle*, among the Arundelian marbles, in these terms—"From the time when *the stone fell* at Ægospotamos, and the poet Simonides died at the age of ninety, during the archonship of Theagenides at Athens, is 205 years." Pliny gives another instance of an aërolite which fell in Lucania about 56 B.C.; and Cæsar records the descent of another at Accilla 46 B.C.

From this period till near the close of the fifteenth century, any historical notices which we have been enabled to collect are so vague and scanty, that in this abridged view of the subject we may pass them over in silence.

Professor Bantenschoen, of the central school of Colmar, first directed the attention of naturalists to some of the old chronicles, which commemorate, with much naïveté, and in the true spirit of the times, the fall of the celebrated stone of Ensisheim. The following account accompanied this very singular mass when it was suspended in the church:—"In the year of the Lord 1492, on Wednesday, which was Martinmas eve, the 7th of November, there happened a singular miracle; for, between eleven o'clock and noon there was a loud peal of thunder, and a prolonged confused noise, which was heard to a great distance, and a stone fell from the air, in the jurisdiction of Ensisheim, which weighed 260 pounds, and the confused noise was, moreover, much louder than here. There a child saw it strike on a field situated in the upper jurisdiction, towards the Rhine and Inn, near to the district of Gisgard, which was sown with wheat; and did it no harm, except that it made a hole there; and then they conveyed it from that spot, and many pieces were broken from it, which the landvogt forbade. They therefore caused it to be placed in the church, with the intention of suspending it as a miracle, and many people came hither to see this stone."

Again, Trithemius, in his Hirsaugiensian Annals, employs language to this effect:—"In the same year, on the 7th day of November, in the village of Suntgaw, near the townlet of Ensisheim, not far from Basil, a city of Germany, a stone, called a thunder-stone, of a prodigious size, for we know from eye-witnesses that it weighed 255 pounds, fell from the heavens. Its fall was so violent that it broke into two pieces. The most considerable is still exhibited at the door of the church of Ensisheim, suspended by an iron chain, as a proof of the fact which we have mentioned, and to preserve it in the public recollection." We learn also from Paul Lang, "that there arose a furious storm on the 7th of November 1492, and that whilst the thunder roared, and the heavens appeared all on fire, a stone of enormous size fell near Ensisheim."

It is worthy of observation that these chroniclers lived at the period which they assign to the descent of the stone, and that although their names are hastening to oblivion, Trithemius yielded to few of his contemporaries in labour and learning; whilst Lang, a German Benedictine, had travelled in search of historical monuments, arraigned the license of the Catholic clergy, and applauded the independence of Luther and Melancthon.

In the Commentary of Surius, a Carthusian monk of Cologne, mention is made of a shower of large stones which fell in Lombardy in 1510. These stones were harder than flint, and smelled of sulphur. The heaviest weighed 120 pounds. The same event is more particularly related by Cardan, in his work entitled *De Rerum Varietate* (lib. xiv., c. 72). According to this author, near the River Adda, not far from Milan, and at five o'clock in the evening, about 1120 stones fell from the air, one of them weighing 120 pounds, and another 60 pounds. Many were presented to the French governor and his deputy. In the Memoirs of the Emperor Jehan-schah, written in Persian by himself, and translated by Colonel Kirkpatrick, is an account of the stone that fell in the province of Lahore in 1620; and Ferishta has recorded, in the true oriental style, the conversion of "this son of thunder," as he calls it, into two scimitars, a dagger, and a knife, by order of the emperor. The emperor says,—"Here I had this substance weighed in my presence. Its weight was 160 tolahs.[1] I committed it to a skilful artizan, with orders to make of it a sabre, a knife, and a dagger. The workman reported that the substance was not malleable, but shivered into pieces under the hammer. Upon this I ordered it to be mixed with other iron. Conformably to my orders, three parts of the *iron of lightning*[2] were mixed with one part of common iron, and from the mixture were made two sabres, one knife, and one dagger."

The celebrated Gassendi informs us, that on the 27th of November 1627, about ten o'clock in the morning, during a very clear sky, he saw a flaming stone, of the apparent diameter of 4 feet, fall on Mount Vaision, an eminence situated between the small towns of Perne and Guillaumes in Provence. This stone was surrounded by a luminous circle of different colours, nearly resembling the rainbow, and its fall was accompanied with a noise like the discharge of artillery. It weighed 59 pounds, and its specific gravity was to that of common marble as fourteen to eleven. It was of a dark metallic colour, and extremely hard. From a curious book printed at Paris in 1672, and now become very scarce, entitled "*Conversations tireés de l'Académie de M. l'Abbe Bourdelot contenant diverses Recherches et Observations Physiques, par le Sieur Legallois*, we make the ensuing extract:—"A member presents a fragment of two stones which fell near Verona, one of which weighed 300 and the other 200 pounds. These stones," says he, "fell during the night, when the weather was perfectly mild and serene. They seemed to be all on fire, and came from above, but in a slanting direction, and with a tremendous noise. This prodigy terribly alarmed 300 or 400 eye-witnesses, who were at a loss what to think of it."

No philosopher of the present day doubts the descent of stony bodies from the atmosphere; and the testimony of innumerable witnesses of their fall, with phenomena nearly similar, places *meteorolites* among the established facts of natural science. If several of the early notices of them are obscure, we have, in the end of the last and in the present century, many descriptions of their appearance, on their descent, by intelligent witnesses; so that scepticism on this subject can be no longer entertained. It is also very remarkable, that wherever they have fallen, in Europe, in India, or America, their composition is nearly identically the same, and agrees in composition with no known mineral. This has been established by the careful experiments of the Hon. Mr Howard, of Vauquelin, Laugier, Klaproth, and Berzelius, as well as by the investigations of Bournon and many other mineralogists. Their general composition may be stated as follows:—Silica, 40 per cent.; malleable iron, 25; nickel, from 6 to 8; with a small quantity of iron pyrites, and variable proportions of alumina, lime, magnesia, manganese; with traces of chrome, cobalt, and sulphur. In the present century many have fallen in France, Germany, India, and America; and in our own islands one fell in Yorkshire in 1795, another in Gloucestershire in 1835, a third near Glasgow in 1804, and two in Ireland from 1810 to 1813. We shall now proceed to more detailed instances.

We have now to direct our attention to a report of M. de Lalande, inserted in the *Historical Almanac* of Bresse for 1756. In the month of September 1753, about one o'clock afternoon, when the weather was very hot and very serene, without the least appearance of clouds, a very loud noise, like the discharge of two or three cannons, was heard within the circumference of six leagues, but was of very short duration. This noise was loudest in the neighbourhood of Pont-de-Vesle; and at Liponas, a village three leagues from the last-mentioned place, it was even accompanied with a hissing like that of a cracker. On the same evening there were found at Liponas and at Pin two blackish masses, of a form nearly circular, but very uneven, which had fallen on ploughed ground, and sunk by their own weight to the depth of half a foot below the surface. One of them weighed about twenty pounds; and a fragment of one of them, weighing eleven and a half pounds, was preserved in the cabinet of M. Varenne de Beost at Dijon. The basis of these masses resembled a grayish whinstone, and was very refractory; and some ferruginous particles were disseminated in grains, filaments, or minute masses, throughout the substance of the stone, especially in its fissures. On the 15th of September 1760, according to the Abbé Bachelay, about half-past four o'clock afternoon, there appeared near the Chateau de Chevabrie, in the neighbourhood of Luce, a small town of the province of Maine, a stormy cloud, from which proceeded a loud peal of thunder, like the discharge of cannon, and followed by a noise which was mistaken by several people for the lowing of oxen. This sound was heard over a space of about two leagues and a half, but unaccompanied by any perceptible flame. The reapers in the parish of Perigué, about three leagues from Luce, on hearing the same noise, looked up, and saw an opaque body, which described a curve, and fell on soft turf upon the high road from Mons, near which they were at work. They all quickly ran up to it, and found a sort of stone, nearly half of which was buried in the earth, and the whole so hot that it could not be touched. At first they ran away in a panic; but upon returning to the spot some time afterwards, they found the stone precisely in the same situation, and sufficiently cooled to admit of being handled and narrowly examined. It weighed seven ounces and a half, and was of a triangular form.

On the 20th of November 1768 a stone fell at Mauerkirchen, near the River Inn in Bavaria, which weighed 38 pounds, and was of a triangular form, being about eight inches in thickness. Its fall was accompanied by a hissing noise. The next remarkable case that has been recorded occurred on the 20th of August 1789 at Barbotan, near Roquefort, in the Landes of Bordeaux. A much more remarkable phenomenon, however, of the same description occurred near Agen on the 24th of July 1790. An inhabitant of St Sevère communicated the following particulars to M. Darcet the chemist, who was then resident at Paris:—"Our town's-people were yesterday very much alarmed. About a quarter-past nine o'clock in the evening there suddenly appeared in the atmosphere a fire-ball, dragging a long train, which diffused a very vivid light over the horizon. This meteor soon disappeared, and seemed to fall at one hundred paces from us. It was quickly followed by an explosion louder than that of a cannon or of thunder. Everybody dreaded being buried under the ruins of his house, which seemed to give way from the concussion. The same phenomenon was seen, and the report heard, in the neighbouring towns, as Mont de Marsan, Tartas, and Dax. The weather in other respects was very calm, without a breath of wind or a cloud, and the moon shone in all her brightness." Those which fell on the houses produced a noise, not like that of stones, but rather of a substance which had not yet acquired compactness.

M. Baudin mentions, that as M. Carris of Barbotan and he were walking in the court of the Castle of Mormes, about half-past nine o'clock in the evening of the 24th of July 1790, when the air was perfectly calm and the sky cloudless, they found themselves suddenly surrounded by a pale clear light, which obscured that of the moon, although the latter was nearly full. On looking up they observed, almost in their zenith, a fire-ball of a larger apparent diameter than that of the moon, dragging a tail which seemed to be five or six times longer than the diameter of its body, and which gradually tapered to a point; the latter approaching to blood-red, though the rest of the meteor was of a pale white. This luminous body proceeded with great velocity from south to north, and in two seconds split into portions of considerable size, like the fragments of a bursting bomb. These fragments became extinguished in the air, and some of them, as they fell, assumed that deep red colour which had been observed at the point of the tail. Two or three minutes afterwards M. Baudin and his friend heard a dreadful explosion, like the simultaneous firing of several pieces of ordnance; but they were not sensible of any tremulous motion under their feet, although the concussion of the atmosphere shook the windows in their frames, and threw down kitchen utensils from their shelves. When these gentlemen removed to the garden the noise still continued, and appeared to be directly over their heads. Some time after it had ceased, they heard a hollow sound rolling in echoes for about 50 miles along the chain of the Pyrenees, and at the end of about four minutes gradually dying away in distance. At the same time a strong sulphurous odour was diffused in the atmosphere. The interval which occurred between the disruption of the meteor and the loud report induced M. Baudin to conjecture that this fire-ball must have been at least 8 miles from the earth's surface, and that it fell about 4 miles from Mormes. "The latter part of my conjecture," says he, "was soon confirmed by an account which we received of a great many stones having fallen from the atmosphere at Juillac and in the neighbourhood of Barbotan." It appears, indeed, from the concurring testimony of intelligent persons worthy of credit, that the meteor really exploded at a little distance from Juillac, and that its fragments were found lying in an almost circular space of nearly 2 miles in diameter. Some of them weighed 18 or 20, and a few, it is alleged, even 50 pounds. M. de Carris procured one of 18 pounds, which he transmitted to the Academy of Sciences at Paris. That examined by M. Baudin was small, but heavy in proportion to its size, black on the outside, grayish within, and interspersed with many minute, shining, metallic particles.

---

[1] A tolah is about 180 grains troy weight.

[2] This expression is equivalent to our term *thunderbolt*.

Our chronological series of cases has now brought us to the fall of several meteorolites near Sieña, the particulars of which, as reported by the Earl of Bristol and Sir William Hamilton, are recorded in the first part of the *Philosophical Transactions* for the year 1795 (p. 103). The date of the Sieña meteor is the 16th of June 1794. On the 13th of December in the following year, about three o'clock in the afternoon, another of these singular stones, weighing about 56 pounds, fell near the country-house of Captain Topham in Yorkshire. The captain's report, which is inserted in the *Gentleman's Magazine* for 1796, is distinct and satisfactory; whilst the chemical examination of the mass, detailed in Mr Howard's paper in the *Philosophical Transactions* for 1802, affords a still more decisive proof of its atmospheric origin. M. de Drée also found it to correspond exactly in aspect and character with fragments of meteoric stones from Benares and Ville-Franche. The original mass is larger than a man's head. It weighed 56 pounds, and is now in the British Museum.

Mr Southey, in his letters from Spain and Portugal, transcribes the authenticated relation of another instance of the descent of a stone from the clouds on the 19th of February 1796. But we pass to some of the most important details relative to the stone which is affirmed to have fallen near Ville-Franche, in the department of the Rhone, on the 12th of March 1798. It was transmitted to Professor Sage, member of the National Institute. "It is of an ash-gray colour," says M. Sage, "granulated, and speckled with gray, shining, and pyritous metallic points. One of its surfaces is covered with a dingy black enamel about the third of a line in thickness. This stone acts very powerfully on the magnetic needle."

An account of the same meteor was published in the *Journal de Physique* by M. de Drée. From his minute and deliberate investigation, it appears that the fire-ball had scarcely fixed the attention of the inhabitants of Sales and the adjacent villages, when its rapid approach, accompanied by a terrible whizzing noise, like that of an irregular hollow body traversing the air with unusual velocity, inspired the whole commune with alarm, especially when they observed it passing over their heads at an inconsiderable elevation. It left behind a long train of light, and emitted, with an almost unceasing crackling, small vivid flames like little stars. Its fall was remarked at the distance of only fifty paces by three labourers. These three witnesses attest the astonishing rapidity of the meteor's motion and the hissing which proceeded from the spot where it fell.

On the 19th of December 1798, about eight o'clock in the evening, the inhabitants of Benares and its neighbourhood observed in the heavens a very luminous meteor, in the form of a large ball of fire, which exploded with a loud noise, and from which a number of stones were precipitated near Krakhut, a village about 14 miles from the city of Benares. Mr Davis, the judge and magistrate of the district, affirmed that in brilliancy it equalled the brightest moonlight. "Of these stones," says Mr Howard, "I have seen eight nearly perfect: externally they were covered with a hard black coat or incrustation, which in some parts had the appearance of varnish or bitumen; and on most of them were fractures, which, from their being covered with a matter similar to that of the coat, seemed to have been made in the fall by the stones striking against each other, and to have passed through some medium, probably an intense heat, previous to their reaching the earth. Internally they consisted of a number of small spherical bodies of a slate colour, imbedded in a whitish gritty substance, interspersed with bright shining spiculæ, of a metallic or pyritical nature. The spherical bodies were much harder than the rest of the stone; the white gritty part readily crumbled on being rubbed with a hard body; and on being broken a quantity attached itself to the magnet, but more particularly the outside coat or crust, which appeared almost wholly attractable by it."

An account of the extraordinary shower of stones which fell near L'Aigle in Normandy, on 26th April 1803, appeared in the following letter addressed by M. Marais, an inhabitant of the place, to his friend in Paris:—"An astonishing miracle has just occurred in our district. Here it is, without alteration, addition, or diminution. It is certain that it is the truth itself. On Friday (26th of April), between one and two o'clock in the afternoon, we were roused by a murmuring noise like thunder. On going out we were surprised to see the sky pretty clear, with the exception of some small clouds. We took it for the noise of a carriage or of fire in the neighbourhood. We were then in the meadow, to examine whence the noise proceeded, when we observed all the inhabitants of the Pont de Pierre at their windows and in gardens, inquiring concerning a cloud which passed in the direction of from S. to N., and from whence the noise issued, although that cloud presented nothing extraordinary in its appearance. But great was our astonishment when we learned that many and large stones had fallen from it, some of them weighing 10, 11, and even 17 pounds, in the space between the house of the Buat family (half a league to the N.N.E. of L'Aigle) and Glos, passing by St Nicolas, St Pierre, &c., which struck us at first as a fable, but which was afterwards found to be true. The following is the explanation given of this extraordinary event by all who witnessed it:—They heard a noise like that of a cannon, then a double report still louder than the preceding, followed by a rumbling noise, which lasted about ten minutes, the same which we also heard, accompanied with hissings, caused by these stones, which were counteracted in their fall by the different currents of air, which is very natural in the case of such a sudden expansion. Nothing more was heard; but it is remarkable that, previously to the explosion, the domestic fowls were alarmed, and the cows bellowed in an unusual manner. All the country people were much dismayed, especially the women, who believed that the end of the world was at hand. A labourer at La Sapée fell prostrate on the ground, exclaiming, 'Good God, is it possible that thou canst make me perish thus? Pardon, I beseech thee, all the faults I have committed.' The most trifling objects, in fact, might create alarm; for it is not improbable that history offers no example of such a shower of stones as this. The piece which I send was detached from a large one weighing about 11 pounds, which was found between the house of the Buats and Le Fertey. It is said that a collector of curiosities purchased one of 17 pounds weight that he might send it to Paris. Everybody in this part of the country is desirous of possessing a whole stone, or a fragment of one, as an object of curiosity."

At the sitting of the Institute on the 9th of May, Fourcroy read a letter from L'Aigle addressed to M. Vauquelin, and which sufficiently corroborates the preceding statements. But we pass to the substance of M. Biot's letter addressed to the minister of the interior, and published in the *Journal des Débats*. This very eminent philosopher was deputed by government to repair to the spot, and collect all the authentic facts. He left Paris on the 5th of June, and instead of proceeding directly to L'Aigle, went first to Alençon, which lies 15 leagues to the W.S.W. of that place. He was informed on his way that a globe of fire had been observed moving towards the north, and that its appearance was followed by a violent explosion. From Alençon he journeyed through various villages to L'Aigle, being directed in his progress by the accounts of the inhabitants, who had all heard the explosion on the day and at the hour specified. Almost all the inhabitants of twenty hamlets, scattered over an extent of upwards of 2 square leagues, affirmed that they were eye-witnesses of a dreadful shower of stones which were darted from the meteor. The following is his summary of the whole evidence:—"On Tuesday, 6th Floreal, year 11, about one o'clock P.M., the weather being serene, there was observed from Caen, Pont d'Audemer, and the environs of Alençon, Falaise, and Verneuil, a fiery globe of a very brilliant splendour, and which moved in the atmosphere with great rapidity. Some moments after there was heard at L'Aigle, and in the environs of that town, in the extent of more than 30 leagues in every direction, a violent explosion which lasted five or six minutes. At first there were three or four reports like those of cannon, followed by a kind of discharge which resembled the firing of musketry; after which there was heard a dreadful rumbling like the beating of a drum. The air was calm and the sky serene, except a few clouds, such as are frequently observed. . This noise proceeded from a small cloud which had a rectangular form, the largest side being in a direction from E. to W. It appeared motionless all the time that the phenomenon lasted; but the vapours of which it was composed were projected momentarily from different sides by the effect of the successive explosions. This cloud was about half a league to the N.N.W. of the town of L'Aigle. It was at a considerable elevation in the atmosphere, for the inhabitants of two hamlets, a league distant from each other, saw it at the same time above their heads. In the whole canton over which this cloud was suspended, there was heard a hissing noise like that of a stone discharged from a sling, and a great many mineral masses, exactly similar to those distinguished by the name of *meteoric stones,* were seen to fall. The district in which these masses were projected forms an elliptical extent of about 2½ leagues in length, and nearly 1 in breadth, the greatest dimension being in a direction from S.E. to N.W. forming a declination of about 22 degrees. This direction, which the meteor must have followed, is exactly that of the magnetic meridian, which is a remarkable result. The greatest of these stones fell at the south-eastern extremity of the large axis of the ellipse, the middle-sized in the centre, and the smaller at the other extremity. Hence it appears that the largest fell first, as might naturally be supposed. The largest of all those that fell weighs 17½ pounds. The smallest which I have seen weighs about 2 gros (a thousandth part of the last). The number of all those which fell is certainly above two or three thousand."

It deserves to be remarked, that the L'Aigle stones were very friable for some days after their descent, that they gradually acquired hardness, and that after they had lost the sulphurous odour on their surface, they still retained it in their substances, as was found by breaking them. That some of the relations to which we have referred are vague and unsatisfactory cannot be denied, but the circumstantial testimony conveyed by others is pointed and positive; and the whole mass of historical proof, especially when combined with the argument deduced from the identity of the physical and chemical constitution of the stones, appears to us to be altogether irresistible.

In the course of our inquiry into this novel and interesting subject we have ascertained a variety of circumstances which render it highly probable, if not indubitable, that those detached masses of native iron, the history of which has so often staggered and perplexed the geologist, are only modifications of meteoric depositions. The Tartars, for example, ascribe the descent of the Siberian mass described by Pallas, Chladni, and others, to a period that is lost in the remoteness of antiquity; and whilst tradition thus favours our hypothesis, the analogy which is obviously observable, in point of texture and chemical characters, with those of other solid bodies the fall of which is no longer questioned, strengthens tradition. According to the discoveries of Proust and Klaproth, native iron, reputed meteoric, differs from that which occurs in a fossil state by the presence of nickel. The former of these celebrated analysts obtained 50 grains of sulphate of nickel from 100 of the South American mass, and his results are corroborated by Mr Howard and the Count de Bournon.

Of the two pieces of Siberian iron now in the British Museum, one of which was transmitted by Dr Pallas, weighs several pounds; and another presents a cellular and ramified texture analogous to that of some very light and porous volcanic scoriæ. When attentively examined, there may be perceived in it not only empty cells, but also impressions or cavities of greater or less depth, and in some of which there remain specks of olivine. The iron itself is very malleable, and may be easily cut with a knife or flattened under the hammer. The specific gravity is 6487, which is obviously inferior to that of unforged iron that has undergone fusion, and may be partly owing to the oxidizement of the surface of the iron, and partly to the many minute cavities in its substance, which are often rendered visible by fracture, and which have their surface also oxidized. The fracture is shining and silvery, like that of white cast-iron; but its grain is much smoother and finer, and it is much more malleable when cold. The heavier specimen is more solid and compact, exhibiting no cavities or pores, though its surface is ramified and cellular. So blended and incorporated is its compact part with the olivine mentioned above, that if the whole of the latter could be subtracted, the remainder would consist of iron in the metallic state, and would display the same cellular appearance as the preceding specimen, or as the superficial portion of that now described. "I cannot help observing," says the Count de Bournon, "that there appears to exist a very interesting analogy between these transparent nodules and the globules I described as making part of the stones said to have fallen on the earth. This analogy, though not a very strong one, may lead us to suppose that the two substances are similar in their nature, but that the globules are less pure, and contain a greater quantity of iron."

Having now, as we apprehend, sufficiently established the existence and nature of meteorolites, we hope that our readers will excuse us from enlarging on the various causes which have been assigned for their origin, as these seem to lie beyond the reach of our present state of knowledge. After a candid and patient review of the principal theories, we conceive that most of them are open to many and formidable objections.

The terrestrial hypotheses, we believe, begin already to be generally abandoned as untenable. Until the phenomenon of exploding meteors had been distinctly observed and recorded, Lemery and others could maintain, with some degree of plausibility, that lightning might tear up the ground, and convert soil into a compact mass. But the appearances of a thunder-storm and of a fire-ball are now ascertained to differ in various important particulars. Spectators worthy of credit have seen the latter terminate in the fall of solid bodies, and the composition of these solid bodies has been found to differ from that of all the known fossil substances on the surface of the globe. It is in vain, then, to allege that they are formed on the ground by common lightning, which has often produced very extraordinary effects, but which never generated thousands of stones in fine calm weather. The supposition that such stones have been projected from some of our volcanoes is hardly less conceivable. The ashes which accompany a violent eruption of Ætna or Vesuvius have, from their levity, been carried to a very considerable distance; but we are totally unacquainted with any projectile force which could dart solid masses many hundred miles through such a dense medium as the atmosphere. The compact lavas of burning mountains are never found remote from the scene of their formation, and none of them present the characters and aspect of the stones which we have described. Of those who contend for the *atmospherical* formation of meteorolites, scarcely any two agree in regard to the manner in which such formation is effected. The celebrated Muschenbroeck in one part of his writings ascribes the descent of stones from the air to earthquakes and volcanic eruptions; an opinion which later observations have disproved. In other passages, however, he seems to incline to a modification of the atmospherical hypothesis, and endeavours to trace the origin of shooting stars to an accumulation of the volatile matters which are suspended in the air. M. Salverte has given extension to the theory of formation from vapours by having recourse to the agency of hydrogen gas. According to him, in consequence of the decomposition of water, which is constantly going on at the surface of the earth, immense quantities of hydrogen gas are continually rising into the atmosphere, and ascending to its higher regions. As this gas is capable of dissolving metals, it carries along with it a portion of iron and nickel. During thunder-storms this gas is kindled by electricity; the metals are deposited, reduced, melted, and vitrified; in other words, meteors are produced and stones formed. But this hypothesis is scarcely more satisfactory than the others. It does not account for the presence of magnesia and silica, nor does it explain why the stones are always composed of the same materials. In general we may observe, that if the origin of meteorolites be really atmospherical, the matters of which they are composed must have existed in one of two states, namely, in very attenuated particles or concretions of the matters themselves volatilized and held in solution in the air, or only in the *elements* of these matters. In the first case, when abandoned by their menstruum to their reciprocal tendencies, they would unite by aggregation only; in the second, by chemical combination. M. Izarn, who has published a treatise on *Atmospherical Lithology*, has entered into a somewhat obscure exposition of his own theory, founded on this principle. We shall give the summary, as nearly as we can, in his own words:—

"Gaseous substances, arranged in spherical masses in the upper regions of the air, being admitted, the various agitations of the atmosphere should naturally waft some of these masses from their insulating medium into one capable of combining with them. If the combination begins, the disengagement of light is explained. In proportion as the combination advances the specific gravities are changed, and consequently a change of place will commence. Motion being once impressed, the mass traverses other media, capable of supplying new principles, which, still increasing the weight, determine the curve; and when at length the principles which are at work have attained the requisite proportion for extinguishing the elements in the birth of the compound, the grand operation is announced by the explosion, and the product takes its place among the solids." That the stones in question are produced by chemical combination in the higher regions of the atmosphere, and that they are thus formed from their own elements, are suppositions fully as probable as any that have been advanced on the subject; but whether the union of their parts be effected in the manner detailed by M. Izarn we are unable to determine, because our range of data is as yet too circumscribed to warrant any specific or decisive conclusions.

A much bolder theory has been suggested, and its *possibility* demonstrated, by Laplace, who shows that meteorolites may be the products of lunar volcanoes. We shall present the reasoning upon which this extraordinary hypothesis is founded, in the popular and perspicuous language of Dr Hutton of Woolwich. The respect due to the name of Laplace will justify the length of the extract. "As the attraction of gravitation extends through the whole planetary system, a body placed at the surface of the moon is affected chiefly by two forces, one drawing it toward the centre of the earth, and another drawing it toward that of the moon. The latter of these forces, however, near the moon's surface, is incomparably the greater. But as we recede from the moon, and approach toward the earth, this force decreases, whilst the other augments; till at last a point of station is found between the two planets, where these forces are exactly equal, so that a body placed there must remain at rest; but if it be removed still nearer to the earth, then this planet would have the superior attraction, and the body must fall towards it. If a body, then, be projected from the moon towards the earth, with a force sufficient to carry it beyond the point of equal attraction, it must necessarily fall on the earth. Such, then, is the idea of the manner in which the bodies must be made to pass from the moon to the earth, if that can be done, the *possibility* of which is now necessary to be considered. Now, supposing a mass to be projected from the moon, in a direct line towards the earth, by a volcano or by the production of steam by subterranean heat; and supposing, for the present, these two planets to remain at rest; then it has been demonstrated, on the Newtonian estimation of the moon's mass, that a force projecting the body with a velocity of 12,000 feet in a second would be sufficient to carry it beyond the point of equal attraction. But this estimate of the moon's mass is now allowed to be much above the truth; and, on M. Laplace's calculation, it appears that a force of little more than half the above power would be sufficient to produce the effect; that is, a force capable of projecting a body with a velocity of less than a mile and a half per second. But we have known cannon-balls projected by the force of gunpowder with a velocity of 2500 feet per second or upwards; that is, about half a mile. It follows, therefore, that a projectile force, communicating a velocity about three times that of a cannon-ball, would be sufficient to throw the body from the moon beyond the point of equal attraction, and cause it to reach the earth. Now there can be little doubt that a force equal to that is exerted by volcanoes on the earth, as well as by the production of steam by subterranean heat, when we consider the huge masses of rock, so many times larger than cannon-balls, thrown on such occasions to heights also so much greater. We may easily imagine, too, such cause of motion to exist in the moon as well as in the earth, and that in a superior degree, if we may judge from the supposed symptoms of volcanoes recently observed in the moon by the powerful tubes of Dr Herschel; and still more, if we consider that all projections from the earth suffer an enormous resistance and diminution by the dense atmosphere of this planet, whilst it has been rendered probable, from optical considerations, that the moon has little or no atmosphere at all to give any such resistance to projectiles.

"Thus, then, we are fully authorized in concluding that the case of *possibility* is completely made out; that a known power exists in nature capable of producing the foregoing effect, of detaching a mass of matter from the moon, and transferring it to the earth in the form of a flaming meteor or burning stone: at the same time we are utterly ignorant of any other process in nature by which the same phenomenon can be produced. Having thus discovered a way in which it is possible to produce those appearances, we shall now endeavour to show, from all the concomitant circumstances, that these accord exceedingly well with the natural effects of the supposed cause, and thence give it a very high degree of *probability*.

"This important desideratum will perhaps be best attained by examining the consequences of a substance supposed to be projected by a volcano from the moon into the sphere of the earth's superior attraction, and then comparing those with the known and visible phenomena of the blazing meteors or burning stones that fall through the air on the earth. And if in this comparison a striking coincidence or resemblance shall always or mostly be found, it will be difficult for the human mind to resist the persuasion that the assumed cause involves a degree of probability but little short of certainty itself. Now the chief phenomena attending these blazing meteors or burning stones are these: 1. That they appear to blaze out suddenly; 2. That they move with a surprisingly rapid motion, nearly horizontal, but a little inclined downwards; 3. That they move in several different directions with respect to the points of the compass; 4. That in their flight they yield a loud whizzing sound; 5. That they commonly burst with a violent explosion and report; 6. That they fall on the earth, with great force, in a sloping direction; 7. That they are very hot at first, remain hot a considerable time, and exhibit visible tokens of fusion on their surface; 8. That the fallen stony masses have all the same external appearance and contexture, as well as internally the same nature and composition; and, 9. That they are totally different from all our terrestrial bodies, both natural and artificial.

"Now these phenomena we shall proceed to compare with the circumstances of a substance projected by a lunar volcano, and in the order in which they are here enumerated. And, first, with respect to the leading circumstance, that of a sudden blazing meteoric appearance, which is not that of a small bright spark, first seen at an immense distance, and then gradually increasing with the diminution of its distance. And this circumstance appears very naturally to result from the assumed cause. For, the body being projected from a lunar volcano, may well be supposed in an ignited state, like inflamed matter thrown up by our terrestrial volcanoes, which, passing through the comparatively vacuum in the space between the moon and the earth's sensible atmosphere, it will probably enter the superior parts of this atmosphere with but little diminution of its original heat; from which circumstance, united with that of its violent motion, this being ten or twelve times that of a cannon-ball, and through a part of the atmosphere probably consisting chiefly of the inflammable gas rising from the earth to the top of the atmosphere, the body may well be supposed to be suddenly inflamed, as the natural effect of these circumstances; indeed it would be surprising if it did not. From whence it appears, that the sudden inflammation of the body on entering the earth's atmosphere is exactly what might be expected to happen.

"2. To trace the body through the earth's atmosphere, we are to observe that it enters the top of it with the great velocity acquired by descending from the point of equal attraction, which is such as would carry the body to the earth's surface in a very few additional seconds of time if it met with no obstruction. But as it enters deeper in the atmosphere, it meets with still more and more resistance from the increasing density of the air, by which the great velocity of 6 miles per second must soon be greatly reduced to one that will be uniform, and only a small part of its former great velocity. This remaining part of its motion will be various in different bodies, being more or less as the body is larger or smaller, and as it is more or less specifically heavy; but for a particular instance, if the body were a globe of 12 inches diameter, and of the same gravity as the atmospheric stones, the motion would decrease so as to be little more than a quarter of a mile per second of perpendicular descent. Now, whilst the body is thus descending, the earth itself is affected by a twofold motion, both the diurnal and the annual one, with both of which the descent of the body is to be compounded. The earth's motion of rotation at the equator is about 17 miles in a minute, or two-sevenths of a mile in a second; but in the middle latitudes of Europe little more than the half of that, or little above half a quarter of a mile, in a second; and if we compound this motion with that of the descending body, as in mechanics, this may cause the body to appear to descend obliquely, though but a little, the motion being nearer the perpendicular than the horizontal direction. But the other motion of the earth, or that in its annual course, is about 20 miles in a second, which is eighty times greater than the perpendicular descent in the instance above mentioned; so that, if this motion be compounded with the descending one of the body, it must necessarily give it the appearance of a very rapid motion in a direction nearly parallel to the horizon, but a little declining downwards; a circumstance which exactly agrees with the appearances of these meteoric bodies, as stated in the second article of the enumerated phenomena.

"3. Again, with regard to the apparent direction of the body; this will evidently be various, being that compounded of the body's descent and the direction of the earth's annual motion at the time of the fall, which is itself various in the different seasons of the year, according to the direction of the several points of the ecliptic to the earth's meridian or axis. Usually, however, from the great excess of the earth's motion above that of the falling body, the direction of this must appear to be nearly opposite to that of the former. And, in fact, this exactly agrees with a remark made by Dr Halley, in his account of the meteors in his paper above given, where he says that the direction of the meteor's motion was exactly opposite to that of the earth in her orbit. And if this shall generally be found to be the case, it will prove a powerful confirmation of this theory of the lunar substances. Unfortunately, however, the observations on this point are very few, and mostly inaccurate; the angle or direction of the fallen stones has not been recorded, and that of the flying meteor commonly mistaken; all the various observers giving it a different course, some even directly the reverse of others. In future it will be very advisable that the observers of fallen stones observe and record the direction or bearing of the perforation made by the body in the earth, which will give us perhaps the course of the path nearer than any other observation.

"4. In the flight of these meteoric stones it is commonly observed that they yield a loud whizzing sound. Indeed it would be surprising if they did not. For if the like sound be given by the smooth and regularly-formed cannon-ball, and heard at a considerable distance, how exceedingly great must be that of a body so much larger, which is of an irregular form and surface, too, and striking the air with fifty or a hundred times the velocity.

"5. That they commonly burst and fly in pieces in their rapid flight is a circumstance exceedingly likely to happen, both from the violent state of fusion on their surface, and from the extreme rapidity of their motion through the air. If a grinding-stone, from its quick rotation, be sometimes burst, and fly in pieces, and if the same thing happen to cannon-balls when made of stone and discharged with considerable velocity, merely by the friction and resistance of the air, how much more is the same to be expected to happen to the atmospheric stones, moving with more than fifty times the velocity, and when their surface may well be supposed to be partly loosened or dissolved by the extremity of the heat there.

"6. That the stones strike the ground with a great force, and penetrate to a considerable depth, as is usually observed, is a circumstance only to be expected from the extreme rapidity of their motion and their great weight, when we consider that a cannon-ball or a mortar-shell will often bury itself many inches, or even some feet, in the earth.

"7. That these stones, when soon sought after and found, are hot, and exhibit the marks of recent fusion, are also the natural consequences of the extreme degree of inflammation in which their surface had been put during their flight through the air.

"8. That these stony masses have all the same external appearance and contexture, as well as internally the same nature and composition, are circumstances that strongly point out an identity of origin, whatever may be the cause to which they owe so generally uniform a conformation. And when it is considered,

"9. That in those respects they differ totally from all terrestrial compositions hitherto known or discovered, they lead the mind strongly to ascribe them to some other origin than the earth we inhabit; and none so likely as coming from our neighbouring planet.

"Upon the whole, then," continues Dr Hutton, "it appears highly probable that the flaming meteors and the burning stones that fall on the earth are one and the same thing. It also appears impossible, or in the extremest degree improbable, to ascribe these either to a formation in the superior parts of the atmosphere, or to the eruptions of terrestrial volcanoes, or to the generation by lightning striking the earth. But, on the other hand, that it is possible for such masses to be projected from the moon so as to reach the earth, and that all the phenomena of these meteors or falling stones, having a surprising conformity with the circumstances of masses that may be expelled from the moon by natural causes, unite in forming a body of strong evidence that this is in all probability actually the case."

M. Poisson, a very ingenious French mathematician, has shown, by an algebraical calculation, the possibility of a projectile reaching our planet from the moon. His calculation, however, which may be found in the work of Izarn quoted above, proceeds on the supposition that our satellite has no atmosphere, or next to none. There are, no doubt, appearances which seem to favour this supposition, but they do not amount to positive proof of the fact.

The hypothesis of Dr Chladni, which likewise boasts of its advocates, deserves to be stated. As earthy, metallic, and other particles form the principal component parts of our planet, amongst which iron is the prevailing part, other planetary bodies, he affirms, may consist of similar, or perhaps the same, component parts, though combined and modified in a very different manner. There may also be dense matters accumulated in smaller masses, without being in immediate connection with the larger planetary bodies, dispersed throughout infinite space, and which being impelled either by some projecting power or attraction, continue to move until they approach the earth or some other body, when, being overcome by attractive force, they immediately fall down. By their exceeding great velocity, which is increased by the attraction of the earth and the violent friction in the atmosphere, a strong electricity and heat must necessarily be excited, by which means they are reduced to a flaming and melted condition, and great quantities of vapour and different kinds of gases are thus disengaged, which distend the liquid mass to a monstrous size, until, by still further expansion of these elastic fluids, they must at length displode.

Such are the principal hypotheses which have been advanced on the origin of meteorolites. We shall conclude this article by a list of these bodies contained in the British Museum.

Aerolites in the British Museum, with Time and Place of their descent, when known.

Ensisheim, 1492; Reichstadt, Bohemia, 1723; Bechin, Bohemia, 1753; Agram, Croatia, 1754; Saharampore, Delhi, 1758; Maurkirchen, Austria, 1768; Bobric, Chazkow, 1787; Sieña, Italy, 1794; Thwing, Yorkshire, 1795; Sales, France, 1798; Benares, India, 1798; L'Aigle, France, 1803; Borgo, Parma, 1804; Possil, near Glasgow, 1804; Timochin, Russia, 1807; Weston, Connecticut, 1807; Casignano, Parma, 1808; Stannern, Moravia, 1808; Tipperary, Ireland, 1810; Berlanguillas, Spain, 1811; La Vendée, France, 1812; Adare, Limerick; 1813; Wiburg, Finland, 1814; Agen, France, 1814; Chassigny, France, 1815; North Carolina, America, 1816; Joussac, France, 1819; Juvènas, France, 1821; Nanjemoy, Maryland, 1825; Sandwich Islands, 1825: Nashville, Tennessee, 1827; Chesterfield, Virginia, 1828; Berar, India, 1828; Charvallas, India, 1834; Tennessee, 1835; Aldworth, Gloucestershire, 1835; Bokkeveld, Cape of Good Hope, 1838; Little Piney, Missouri, 1839; Triguerre, France, 1841; Carthage, Tennessee, 1847; Bishopville, South Carolina, 1847; Cabarras, North Carolina, 1849.

Fragments of Meteoric Iron, date of fall unknown.

1. Part of the Otumpa mass sent from South America by Sir Woodbine Parish,—it weighs 1400 lb.; 2. Part of the Siberian mass of Pallas; 3. Aix-la-Chapelle; 4. Tennessee; 5. Alabama; 6. Kamisdorf, Saxony; 7. Lockport, New York; 8. Red River, Texas; 9. Arva, Hungary; 10. Elbogen, Bohemia; 11. Cape of Good Hope; 12. Heidelberg; 13. Durango, Mexico; 14. Zacatecas, do.; 15. Xiquipilco, do.; 16. Atacama, Bolivia; 17. Gran-Chaco, Peru; 18. Lenarto, Hungary; 19. Green County, Tennessee; 20. Benidego, Brazil; 21. Senegal; 22. Kentucky; 23. Cocke County, Tennessee; 24. Læsegen Lake, Brandenburg; 25. Colima di Brianza, Milan; 26. Esquimeaux knives of meteoric iron, brought by Captain Ross from Lat. 76. 12. N., Long. 53. W.

METEOROLOGY.

(1.) METEOROLOGY, which, in its ancient and etymological sense, included all the appearances of the heavens, as well astronomical as atmospheric, is at present restricted in its meaning to the description and explanation of that class of phenomena which group themselves under the heads of the weather, of the seasons, and of climate—phenomena which, scientifically regarded, are referable almost entirely to the investigation of those laws which govern the ever-varying affections of the atmosphere of our globe in its relations to heat, moisture, and electricity, and the movements which the changes of those relations, brought about by astronomical or other causes, impress upon its parts.

(2.) Were it not for this last-mentioned class of relations, those, namely, which depend on the mobility of our atmosphere, and the consequent perpetual local interchange of its parts more or less heated, and more or less moist, *inter se*, the problems presented by meteorology would be of a very simple nature. Whatever be the temperature of the interior of our globe (and there is every reason to believe it very high), it has been amply demonstrated, that the escape of its internal heat into space through its surface, for many ages past and to come, may be regarded as uniform, and so excessively slow as to be quite inappreciable as a cause of any portion of the temperature prevalent on the surface, still more so of any variation in that element. Local conflagrations and volcanoes (whatever influence geologists may ascribe to the latter in earlier states of our planet) are absolutely insignificant at present for the supply of warmth, so that it is to the sun alone that we have to look as the ultimate source of heat, and therefore also, in all probability, of electrical excitement. Supposing, then, no lateral communication or transfer between the columns of air incumbent on adjacent parts of the earth's surface, the totality of atmospheric and climatic change in any given locality would be limited to periodical and perfectly regular fluctuations of temperature depending on the direct heating power of the sun at its various altitudes above the horizon during the day, and its withdrawal during the night, and to the ultimate generation and condensation of vapour equally periodic and regular, immediately consequent on such fluctuations, over those parts of the surface occupied by water. No rain would ever fall on, or cloud form over, any part of the land, which would be perfectly arid, and dependent for its temperature, at any spot, on the greater or less aptitude of its materials at that spot for absorbing and retaining the sun's rays. It is needless to add that, under such circumstances, the ocean only would possess the conditions indispensable to animal or vegetable life.

(3.) The mobility of the air, while it destroys this simplicity of sequence, and substitutes for it the variety and complexity of phenomena we actually observe, lands us, while seeking for their explanation, among mechanical difficulties of a very high order. If there be one part of dynamical science more abstruse and unapproachable than another, it is the doctrine of the propagation of motion in fluids, and especially in elastic fluids like the air, even when the amount and application of the original acting forces are known and calculable. But in this case, the acting forces consist in local dilatations of parts of the atmosphere by the sun's heat during the day, and contractions by cold during the night—in the permanent difference of temperature in the equatorial and polar regions—in the evaporation of moisture in some parts, and its precipitation in rain in others, which act directly as a motive force, displacing air, and indirectly by carrying heat in a latent form from one region to another. And as if the problems arising out of these considerations alone were not sufficiently complex and intractable, the occupation of one part of the surface of our globe by land and another by sea, differing as they do in their relations to heat, in their evaporation of moisture, and in their resistance to the motion of bodies of air passing over them; the irregular form of the continents, and the existence on them of mountain chains which confine, obstruct, and divert the free courses of aerial currents—all concur to fill the subject of meteorology with difficulties utterly insurmountable if attacked by those methods of calculation which have proved so signally successful in many other branches of science.

(4.) And yet it is these very difficulties, and this excessive complication, which, by forcing us to abandon the *deductive* mode of philosophizing from sheer inadequacy of methods, throws us on the opposite, or *inductive* course of inquiry in the very attitude most favourable to success. For it is not because the general principles of dynamics are *inapplicable* to the subject that we are deterred from resorting to them as our sole dependence, but because we neither possess data sufficiently wide and precise to afford ground for their application, nor command enough of them as instruments to grapple with such data in all their particularity if we had them. In our assurance of their *general applicability*, we possess an invaluable clue, which precludes all groping in the dark for causes, and which serves at every step to direct the course our induction ought to take, and the forms in which it is desirable that our acquirements should be invested so as to be most available for constructing a complete theory. We come to the subject, in short, as we have every reason to believe, with a clear apprehension of all the principal efficient causes, and a pretty distinct conception of their *direct* action. It is the number and simultaneous operation of their derivative causes, the immense influence and complication of their *indirect* actions, which constitute the difficulty of this branch of physics. But, on the other hand, our knowledge of these causes throws the whole burden of the inquiry on the discovery of subordinate or derivative laws, and never leaves us at a loss (as in so many other departments of physical research) for the interpretation of those laws when discovered, or for the best and most philosophical way of expressing them in terms conveying their true theoretical import.

(5.) And hence arises one of the most marked peculiarities of this our science, viz., that while in respect of the general explanation of its phenomena it may be said to be nearly complete, inasmuch as there are few of its more important facts and broad features which cannot be rationally and satisfactorily accounted for, and referred to the recognized operations of physical agents, yet when we would follow out the results of their actions in "number, weight, and measure," and as exhibited in specified time and place, theory affords us little or no assistance. Meteorology, in short, in all that concerns numerical valuation, is pre-eminently a science of detail, and one in which all the subordinate laws which are susceptible of numerical statement have to be made out by laborious and continued observation carried on in every region of the globe. The results of such observation, accumulated in masses, and discussed by the application of those powerful and refined processes of calculation which modern invention has devised, become cleared of accidental error, freed from the influence of transient and purely local causes of irregularity, and presented in the form of mean or average conclusions, each expressing some general fact or law of progressive change. Thus, while on the one hand *deductive* theory, based on our knowledge of the acting causes and the circumstances under which they act, pursues their operation clearly to a certain extent, and less and less distinctly as it becomes lost in their entanglement; it is yet enabled to point out the directions where light is to be looked for, the lines of inquiry which *inductive* observation ought to pursue, and the form of the results which it ought to aim at securing.

(6.) The course we shall follow in the present article will be in accordance with this general view of the subject. We shall first pass in review the agents concerned, and the laws which regulate their mutual reactions. We shall then apply our knowledge of these laws to the general explanation of the phenomena of meteorology in their order of importance and natural sequence, and finally afford as complete a view as the very confined limits of this article will allow of those subordinate laws of periodic fluctuations which meteorologists are agreed upon, a knowledge of which, as modified by geographical situation, constitutes the science of climatology; as well as of the combined system of observation and calculation by which this knowledge may be most availably obtained and extended.

Of the Sun as a source of Heat, and of the measure of its direct action. Actinometry.

(7.) The absolute uniformity of the sun's emission of heat is open to considerable doubt. From some recent inquiries by Professor Wolf, it would appear subject to a periodical increase and diminution connected with the abundance and paucity of spots on its disc, a connection surmised by the late Sir William Herschel. That the appearance of such spots is periodical, has been shown by Professor Schwabe. The period assigned is 11.11 years from minimum to minimum, or almost exactly nine periods to each century, commencing at the beginning of the century itself. The last year (1856) has been remarkable for an almost total absence of spots—a fact in perfect agreement with this law. As the planet Jupiter, the largest in our system, revolves about the sun in nearly this time (11.9 y.), it would almost seem as if these singular appearances stood in some connection with electric or magnetic reactions between the sun and planets, the comparatively small discordance of periods being due perhaps to the action of the other planets.[1]

(8.) Independent, however, of any such cause of inequality, the amount of solar heat momentarily received by the earth is subject to a regular annual fluctuation to the extent of one-fifteenth of its mean amount, due to the eccentricity of the earth's orbit—the heat received *in perihelio* (or on the 1st of January) being to that *in aphelio* (July 2d) as 16 to 15. As the sun is vertical over the southern tropic about the former epoch, and over the northern about the latter, it would seem at first sight that the southern hemisphere would receive per annum a larger supply of heat; but the unequal angular velocity of the earth in its orbit, which varies (see ASTRONOMY) in the same precise ratio, effects an exact compensation in this respect by giving a *shorter* duration to a *hotter* summer in the southern hemisphere, and a *longer* to a *cooler* one in the northern.

(9.) The *general* dependence of climate on geographical situation, the high temperature observed at the equator, and the extreme cold at the poles, the annual variations of temperature which accompany the changes of season, as well as the diurnal alternations of heat and cold, are all such obvious consequences of those astronomical arrangements, in consequence of which the sun, at any geographical station, attains a greater or less meridian altitude, and continues a longer or a shorter time above the horizon, as to need no lengthened explanation. The same sunbeam which, at a vertical incidence, acts on a surface equal to its own sectional area, when incident obliquely on the earth (including its atmosphere), is spread over a surface larger in the inverse proportion of radius to the sine of the obliquity. It needs little consideration, then, to perceive that at the poles, where the sun is below the horizon for half the year, and where during the other half it never attains a greater altitude than $23\frac{1}{2}^\circ$, and that only for a short time, its effective warming power on a given horizontal surface must be very far inferior to that which it exercises in the equatorial regions, where its meridional altitude never falls short of $66\frac{1}{2}^\circ$, and where the days and nights are always nearly twelve hours in duration; nor that in intermediate latitudes the increase of its altitude, and the length of the day as it advances along the ecliptic from the winter to the summer solstice, should bring with it that accession of general temperature which we observe.

(10.) This effect of obliquity of incidence is, however, enhanced by another cause. The sun's heat is partially absorbed in passing through the atmosphere, and *that* the more, the greater the mass of air it has to penetrate, or the more obliquely it traverses it. Professor Forbes, reasoning from observations made by himself and M. Kämtz on the Faulhorn in Switzerland, as compared with others at Brienz, 6844 feet lower in level, concludes that 46 per cent. of a vertical sunbeam is absorbed in traversing a *cloudless* atmosphere before reaching the sea level. A series of observations made in Paris by M. Pouillet (in 1837-38) at different zenith distances of the sun, gives only 24 per cent. One-third is probably not too low an estimate. The remaining two-thirds only (or less if the incidence be oblique) are directly effective in heating the earth's surface. The absorbed portion is employed in heating the air throughout its whole extent, and though not ineffective in maintaining the general temperature, acts to that end in a very different manner, as being more immediately transferable from one region to another by the action of the wind.

(11.) From experiments made at the Cape of Good Hope from December 23, 1836, to January 9, 1837, by the writer of this article, it results that the direct heating effect of a vertical sun at the sea level is such as would suffice to melt 0.00754 in. per minute in thickness, from a sheet of ice exposed perpendicularly to its rays. M. Pouillet's conclusions, reduced to a similar form of expression, give 0.00703 in. A mean of the two determinations, 0.007285 in. per minute, may therefore be pretty confidently stated as the measure of the sun's vertical heating power at the sea level in a perfectly cloudless sky. If visible cloud or haziness, even very trifling, be present, the effect is diminished. In a clouded state of the sky nearly the whole of the solar heat is expended in heating the air, and evaporating the clouds.

---

[1] While in the act of revising this sheet, we observe in the Royal Society notices for March 12, 1857, a letter from Professor Wolf announcing his discovery of an *annual sub-period* of the spots—a fact strongly corroborative of the view taken in the text.

(12.) Supposing, however, the sky clear, and all the rays of heat equally absorbable (which, however, is not probable), the melting effect per minute of *oblique* sunshine for a zenith distance $= z$ not exceeding 80° on a sheet of ice perpendicularly exposed to it, would be expressed by 0.01093 in. $(\frac{2}{3})^{\text{sec.}\,z.}$, and on a sheet *laid horizontally*, by the same function multiplied by cos. z. This latter effect is the measure of the direct power of sunshine to heat the general surface of the region on which it is incident (abstraction made of the specific nature of that surface). A table, in which the calorific efficacy of a vertical sun is represented by .750, and which gives its diminution for oblique incidences for every fifth degree of altitude, will be found in our article on CLIMATE, vol. vi. p. 776.

(13.) *Actinometry.*—The direct heating power of the sun's rays may be measured in two different ways—statically and dynamically. The statical method consists in equilibrating the heating power of sunshine on some body (as a blackened thermometer) with some external cooling influence which is itself measurable, or which we have reason to believe invariable. It has been usual to suppose this accomplished by simply noting the degree marked by such a blackened thermometer in the sun (exposed till it ceases to rise), in excess of that marked by a similar one in the shade. This is much as if a man should measure his strength by the depth to which he could thrust a pole into the ground, in the absence of any knowledge of its sharpness, or the resistance of the soil. The cooling influences (conduction and radiation) are dependent for their effects on local and temporary circumstances too numerous and too variable to estimate. The measure itself requires to be measured. The objection is palliated but not removed, by enclosing the thermometer in an exhausted glass tube, which eliminates conduction by cutting off the contact of air, and by other methods designed to deaden, or equalize external influences. It is, however, insuperable in principle.

(14.) The dynamical method consists in ascertaining the amount of physical change of a nature susceptible of definite measurement, effected on some object by a given sectional area of sunbeam in a given time, such for instance as the dilatation of a liquid, the melting of ice, or the raising of the temperature of a given quantity of water a certain number of degrees. The first attempts at obtaining such a measure, so far as we are aware, were made by the writer of this article in a tour through Sicily in 1824. A glass vessel full of inked water was exposed alternately 5 m. in sunshine and in shade, the change of temperature being noted by a very delicate thermometer immersed in the liquid, and the solar effect per minute measured by the difference of the minutely changes observed to take place in sunshine and in shade. A similar method was employed in the experiments at the Cape of Good Hope, cited in art. 11; the sun, nearly vertical, being allowed to shine directly on the water. M. Pouillet's "pyrheliometer" is constructed on this principle—a cylindrical body of water, of large diameter in proportion to its height, being enclosed in a metallic vessel of that form with a glass face, which is exposed perpendicularly to the sun. In the "actinometer"[1] a blue liquid (ammonio-sulphate of copper) is enclosed in a glass cylinder, one end of which is closed by a silver screw working in a tight collar, to admit of a small change of capacity when the liquid becomes too much dilated by heat, while the other end is soldered on to a thermometer tube, by which the liquid measures its own dilatation, the cylindrical portion acting as the bulb of the thermometer. The actual temperature of the liquid (on which its dilatability depends) is ascertained by an interior thermometer occupying the axis of the cylinder, and whose stem penetrates the axis of the adjusting screw, and is read off along its exterior prolongation. This instrument being several times alternately exposed for one minute in the sun and shade, and the changes of volume in each case read off on the scale, the differences or sums of the mean changes, according as the action has been in the same or in a contrary direction, gives the dilatation produced by the sunshine alone (freed from the disturbing influences), corresponding to the actual temperature of the liquid, which being reduced by an appropriate table to give the temperature acquired, affords a measure of the effect of a given sectional area of sunbeam in heating a definite volume of liquid. Finally, the result is reduced to "actines," or units of solar radiation, each actine denoting that amount of radiation which would suffice to melt one millionth part of a metre from the thickness of a sheet of ice perpendicularly exposed, in one minute, supposing it wholly absorbed. For the details of the description, the tables to be used for reducing the observations, and the general management of the instrument, our narrow limits compel us to refer the reader to the "Manual of Scientific Enquiry," published by the Board of Admiralty, which contains, moreover, practical directions for making and registering every description of meteorological observation. The portability and facility of use and reduction of this instrument, as well as the consistent results it affords, leave nothing to desire, and afford a perfect measure of solar radiation.

Of the Nature and Constitution of the Atmosphere. Its Pressure, Mass, and Extent.

(15.) We live under what may not improperly be called an ocean of air, which covers the sea and land, and extends far beyond the summits of the highest mountains. Like the sea, this ocean has its currents, which are winds, its waves of vast extent and magnitude, not visible indeed to the eye, but capable of being made so to the intellect by means of the barometer, and its tides, due to the action of the sun and moon. But here the analogy ceases. The air is a permanent gas, incapable of being reduced to the liquid state by any degree of cold or pressure yet applied. As such it is highly and perfectly elastic; condensible by pressure, when confined, into any fraction, however minute, of its ordinary volume, and dilating itself, when relieved, so as to fill any space, however large. Its elastic force, like that of all gases (see PNEUMATICS), is in the direct proportion of its density, its temperature continuing unaltered, but increases, if the temperature be raised at the uniform rate of $\frac{1}{273}$, or 0.00366 of its amount, for every degree centigrade (or 5-9ths of this quantity $=$ 0.002033 for every degree of Fahrenheit's thermometer) of additional heat, and diminishes at the same rate if cooled.

(16.) As the air reposes on the earth, and the whole weight is distributed over the whole globe, each portion (suppose a square inch) of its surface supports the weight of the column of air vertically above it, to whatever height it may extend, and therefore, by the law of reaction, presses upward that column with a force equal to its weight. Hence it follows, that the pressure per square inch, which equilibrates, and therefore measures the elasticity of the air at the earth's surface, must be equal to the weight of such a column. This the barometer enables us to ascertain, at any instant and at any place, by balancing it (see BAROMETER) against that of a column of mercury just sufficient in height to counteract it. It is subject to extensive fluctuations, but observation has shown that the mean or average length of such a column in the latitude of Paris, and at the level of the sea, may be taken at 0.760 met. (French measure) (29.922 in.), the mercury being of the density which it has at the temperature of melting ice, which is 13.596 times that of distilled water at its maximum. If the temperature of the mercury be 62° Fahr., which is the standard temperature of the English metrical system, the dilatation of mercury for 1° Fahr. being almost precisely 1-10,000th of its volume, the corresponding length of the mercurial column is 30.012 in., which is so nearly 30 in. that it is customary for English meteorologists to consider 30 inches as the mean or standard height of the barometer. In all meteorological reductions and discussions, however, wherever the term "*barometric pressure*" is used, it expresses the length of a column of mercury *at the temperature* 0° C. *or* 32° *Fahr.* which balances the aerial pressure.

---

[1] First used in the field by the author in 1826, in Cantal, on the Puy de Dome, and at Montpellier.

(17.) The weight of such a column of mercury having a square inch for its base is 14.7304 lbs. avoird., which is therefore the weight of atmosphere incumbent on each square inch of the earth's surface, supposed a perfect sphere. Hence, from the known diameter of the earth (7926 miles), we calculate the total weight of an atmosphere so uniformly covering it at 11.67085 (about $11\frac{2}{3}$ trillions of pounds; so that, making allowance for the space occupied by the land above the sea-level, we may take 11×10^{18} lbs. as an approximate value, which is about 1-188,000,000th part of the mass of the earth itself. Of this, about $99\frac{1}{2}$ per cent. has been ascertained to consist of a mixture of oxygen and nitrogen gases in the proportion of 21 : 79 in volume, or about 23 : 77 in weight. An atomic compound of these gases in the proportion of 2 atoms of nitrogen to 1 of oxygen, would give a ratio of 20 : 80 in volume. Some chemists, therefore, have considered the air as such a compound, and not a mere mixture. But, besides that the deviation of the ratios from each other is beyond the limit of error which chemical analysis tolerates, M. Regnault (Chem. i. 144) has adduced arguments which must be considered decisive against such a conclusion. Still the near approach to an atomic proportion is remarkable. Of the remaining 0.5 per cent, about 0.05 consists of carbonic acid, and 0.45, on an average, of aqueous vapour.

(18.) The specific gravity of dry atmospheric air is to that of mercury (at 32° Fahr., and 0.76 m. pressure), as $1 : 10513\frac{1}{2}$, and a cubic foot of such air weighs 1.29056 oz., so that were the air of that uniform density from the surface upwards, in order to exert the same pressure, it would require to be 26214 feet, or a trifle less than five miles in altitude. This is what is understood by the *height of a homogeneous atmosphere.*

(19.) Such, however, is not the real constitution of the atmosphere. There are mountains higher than this, which yet are covered with perpetual snow, and have clouds above them; and if we consider that each stratum of air, as we ascend from the earth's surface, bears only the weight of those above it, and being therefore less and less pressed, occupies a larger and larger volume in proportion to its weight, we shall perceive that (supposing air infinitely divisible and expansible), there would be no assignable limit to the height of the atmosphere. Theory demonstrates (see PNEUMATICS), that *supposing the temperature uniform* throughout, the density would decrease in geometrical progression as the altitude increases in arithmetical, and assigns for the relation between them the following equation, (in which P, p, represent the densities (measured by the barometric pressures), at the sea level and at the height h, and H the height of a homogeneous atmosphere), viz. $h = \mathrm{H}\,(\mathrm{Log.\ P} - \mathrm{Log.}\ p)$, the logarithms being hyperbolic; or if h and H be expressed in feet, and the hyperbolic reduced to common or tabular logarithms, $h = 60309\,(\mathrm{Log.\ P} - \mathrm{Log.}\ p)$. At the height, then, of 60,000 feet in round numbers, or about $11\frac{1}{2}$ miles, the density of the air on this supposition would be one-tenth of that at the sea level; at 23 miles, one-hundredth; at $33\frac{1}{2}$, one-thousandth, and so on. At an altitude of 103 miles, the density would be reduced to the thousand-millionth part of its superficial amount. Actually (for reasons which will presently appear), the decrease is still more rapid.

(20.) The question, whether or not there be any absolute limit to the atmosphere, has been considered to depend on the view we may take of the intimate constitution of matter. If it consist of ultimate, finite atoms, a limit must at all events occur where the gravity of one atom to the general mass of the earth exceeds the repulsive power exerted on it by the air below it, a question which defies calculation, since we know nothing of the law of force with which the particles of air repel each other, the usual opinion that it is inversely as their distance being quite untenable. If, on the other hand, matter be infinitely divisible, it has been argued by Dr Wollaston that the celestial spaces must be full of attenuated air, and that the sun, planets, and satellites, standing in communication with this general reservoir, would each, in the course of ages, have drawn to itself such a share, that equal densities in their vicinity should correspond to equal forces of gravitation. Calculating on this datum, the sun's atmosphere should have the density of the earth's at the sea level, at about $4\frac{1}{2}$ times *its own radius* above its surface, and Jupiter at above $\frac{8}{11}$. At these distances from the respective luminaries, the rays of light should suffer a deviation by refraction equal to twice our horizontal refraction, or more than a degree, a result directly refuted by observation, which indicates no refraction whatever. This argument, however, takes no account of the effect of centrifugal force. Apart from all considerations of molecular repulsion, it is certain that at about 26,000 miles' distance from the earth's equatorial surface, the centrifugal force would equal gravity, and beyond that distance would exceed it; so that were there no physical cause producing a positive and definite limit, all the air beyond that level must be flirted off into space; and there being no pressure, other air would rise from below to replace it, and share the same fate, so that the whole atmosphere would be drained away, to form a ring like that of Saturn. In fact, however, the excessive tenuity which must, under any hypothesis, be ascribed to the interplanetary air (to express which in fractional parts of its density at the earth's surface would require the denominator to consist of at least 1370 figures), dispenses with giving such reasonings any serious discussion. If, indeed, there were the least ground for believing that atmospheric air could be liquefied by cold of —120° Fahrenheit, the existence of a limit at a very moderate height would follow as a matter of course, as will presently appear. Supposing the law of dilatability to hold good rigorously for all temperatures, the elasticity of air at —273° centigrade would be *nil*. But we have no means of producing this degree of cold, and therefore no experimental examination of the case is possible; and we must therefore be content with the assurance, that at no elevation which can ever be attained by man, or in which animated life could be supported, does the law in question suffer any impeachment; and that at 80 or 90 miles above the earth's surface a vacuum exists, inconceivably more perfect than any which we can produce with our air pumps. At 45 miles the air is already rarified about 25,000 times, at which elevation it would seem, from the duration of twilight, that some feeble reflexion of light still subsists.

(21.) According to Dalton's views respecting the mixture of gases, two or more bodies of this nature mixed together exert no elastic force on each other mutually, though they obstruct and impede each other's free movement. Each *tends* to diffuse itself among the others, and to arrange itself as if the others had no existence, and if left long enough undisturbed would do so. In consequence of this property in a mixed atmosphere, if perfectly quiescent, each gas would constitute a separate and distinct atmosphere, arranged according to the above laws of equilibrium, and each sustaining its quota of the total pressure in the exact proportion of its own volume present in the mixture at the point where the pressure is estimated. But these volumes would be proportionally different at different elevations, the density of the oxygen atmosphere decreasing in a more rapid geometrical progression than that of the nitrogen, and that of the carbonic acid than either. But owing to the obstruction each offers to the free permeation of the others, and to the extreme mobility and continued agitation of the air, the state of equilibrium is never even approached; and experiment has shown that air collected at all elevations above the surface in balloon ascents (in one instance by Gay Lussac, in his memorable ascent in 1804, at the height of 22896 feet), contains these two elements in precisely the same proportions. With the carbonic acid, the case is somewhat different, that gas being subject to local variations consequent on its peculiar uses in the economy of animal and vegetable life; but the differences are so trifling, that for meteorological purposes they may be altogether neglected, and the atmosphere (at least its gaseous portion) regarded as one homogeneous gas.

Of the decrement of Temperature on ascending into the atmosphere, and on the barometric measurement of heights.

(22.) All who have ascended high mountains and all aëronauts are agreed on the fact of a decrease of temperature, which is conspicuously evident from the existence of perpetual snow on elevated summits even in the hottest regions. Respecting the rate of this decrease and its law, much uncertainty still prevails. We possess, it is true, a great accumulation of observations of mountain temperature, both barometrically and trigonometrically determined by De Saussure, Cordier, Ramond, Humboldt, Colonel Sykes, Eschmann, Boblaye, and many others, on the Alps, Pyrenees, Etna, Teneriffe, the Andes and Himalayas, and in Greece; but the results are only loosely accordant, and appear to indicate that the rate of decrease depends in some considerable degree on the season of the year and the local situation of the place of observation. If we assemble the most accordant, and especially those cases where the heights ascended have been considerable, and trigonometrically determined, we find an average decrement of 1° of Fahrenheit's thermometer for every 100 yards of ascent, or 1° per cent. for every 180 yards. The most unexceptionable mode of determining this important element would no doubt be by balloon ascents; but as the heights in such ascents are necessarily determined barometrically, they involve in their calculation (as will presently be shown) the very element in question, and the results deduced from such ascents seem generally to indicate a materially slower rate of decrease. Thus we find, indeed, from Gay Lussac's voyage, as calculated from a decrease of 72·5° Fahr. in ascending 22896 feet, a decrement of 1° in 316 feet, agreeing pretty well with the average above stated. But on the other hand, a mean of four ascents by Mr Green and Mr Rush in the Nassau balloon in 1838 and 1850, to altitudes between 19185 and 20352 feet, gives 485 feet, and a similar mean of four ascents by Mr Welsh in the autumn of 1852 from London, under the direction of the committee of the Kew Observatory, one of which was to the height of 22930 feet, and in which all the observations were conducted with scrupulous precision, and the reductions very scientifically made, afford the result of 386 feet. As a general average deduced, then, from balloon ascents, 400 feet per degree of Fahrenheit would seem to be preferable to 300.

(23.) For the cause, or rather causes, of the general fact of the decrement in question, we have not far to seek. There are several, all probably more or less efficient.

The first is, that in receding from the earth's surface, we are quitting the proximity of a heated body, approaching a region where no such body exists, and interposing more and more of a medium obstructive of heat. If we put any confidence in the theories of Fourrier and Pouillet, the temperature of the interplanetary spaces is probably not higher than −226° Fahr. Consequently, a thermometer exposed at a height where, practically speaking, there is no air, ought at all events not to stand above an arithmetical mean between this and the temperature of the earth's surface below it, that is, −72° at the equator, and −113° at the poles, taking 82° Fahr. and 0° Fahr. as the mean temperatures at those places. Between these two latitudes and levels, then, it would mark, of course, every intermediate degree.

Again, secondly, As the earth's surface receives on the average (art. 10) twice as much solar heat as the air, it is, generally speaking, habitually warmer, and warms the air by constant communication. The heat so imparted is entirely, in the first instance, diffused through the lower strata, only that radiated off going to heat the upper

Thirdly and lastly, there exists a powerful cause, first pointed out by Leslie, of quite a distinct nature, which will need a little more explanation.

(24.) Suppose the atmosphere of equal temperature throughout and at rest. Now let any mass of air at the surface receive an impulse upwards by some external force (not by heating it). It will rise, and in so doing, displace quiescent air above it, which will descend to fill its place, and this process will continue till the upward impulse is extinguished by friction and resistance. In rising, air expands, but as the descending air contracts, *pari passu*, the whole disturbed space when quiet is restored, will be occupied by air as before, and the total pressure will be unaltered. But as regards the distribution of *sensible* heat, a great change will have taken place. The air which has expanded in ascending has absorbed caloric (see HEAT), and grown colder, while that which has contracted in descending has given out just as much, and become hotter. The total heat and the total mass remain unchanged, but the equilibrium of temperature is destroyed. The lower strata have become warmer than the upper, the density adjusts itself accordingly, and the undisturbed column superincumbent on both is supported as before. Precisely the same consequence will result from forcing down by mechanical means (not by cooling) any mass of air from a higher to a lower level. The descending air in condensing becomes heated, while that which ascends to replace it is cooled by its own expansion.

(25.) Now this is no imaginary case. It will be shown hereafter (art. 52) that when aqueous vapour ascends by its levity, it drags air up with it; not by heating it, but by mere mechanical impulse; and thus we see that the mere fact of a circulation of air in the atmosphere, *in so far as that circulation is due to the generation and condensation of vapour, or even to the downward mechanical impulse of the fall of rain or snow*, must of necessity cause a deficiency of *sensible* heat in the higher as compared with the lower regions.[1]

(26.) As regards the law followed by this decrement, little decisive can be said. A uniform rate of decrease, such as that described in art. (26.) as a physical law coextensive with the atmosphere, is not probable, though for heights below 15000 or 20000 feet it is perhaps as exact as any which can be briefly stated in words. Assumed as a basis of calculation, it leads to the following very remarkable relation betwen the height (x) in yards, and the ratio of barometric pressures $\left(\varpi = \frac{p}{\mathrm{P}}\right)$ at the higher and lower levels, viz.—

$$\varpi = \left(\frac{\mathrm{X}}{a}\right)^{5.584}$$

when $a = 180$ yards $(273+\mathrm{T})$, T being the reading of the centigrade thermometer at the lower station, and X the *depression* of the upper station *below* the height a, (reckoned from the lower station) $(\mathrm{X} = a - x)$, which must be considered a limit to the atmosphere, or rather as a limit beyond which the formula is uninterpretable, or, physically speaking, absurd. Nevertheless, within the limits above specified it affords results not very remote from the truth. Thus it gives for Gay Lussac's ascent, calculated on his own data (in which T = 30°.8 C. and $\varpi = 0.42966$), a height of 7678 yards, differing only 46 yards from that assigned by himself. Meteorologists in general, we apprehend, are hardly aware how completely the law of equable decrease is subversive of the received notion of a diminution of pressure in geometric progression upwards from the sea level. This our formula above renders very apparent.

(27.) The law of decrement of temperature is a subject to which great interest is attached, and around which a vast amount of laborious research has accumulated, with a result not unusual in such cases—a great deal of thought and calculation wasted, and no very positive conclusion arrived at. The fact is, the problem has been attacked in the wrong direction. Speculation has been busy in assigning hypothetical laws, either simply tentative, or resting on no solid foundation of physical consideration, to exhibit the relation of the temperature to the height *directly*: to verify which supposes a series of heights and temperatures corresponding to each other to be given by direct observation, the whole series being *comparable*. Now we possess not, and never can possess, any such series; and it is therefore purely and simply groping in the dark to assemble a mass of miscellaneous observation from all quarters, in all climates and seasons, in which insulated decrements of temperature are concluded from mountain ascents; and put them together with the expectation that any intelligible result should emerge. We pass, therefore, without discussion, the theory of M. Biot (Kämtz, ii. 130) which assigns a decrement in geometrical progression for heights in arithmetical, and which sets out with the assumption that the whole heat of the air at any place is due to the extinction of heat radiated or conducted immediately from the earth at that place; or that of Lambert, followed by Baron Zach and Mr Atkinson, in which it is assumed (on a mere general impression that the decrement decreases with the height) that equal decrements of temperature shall correspond to *uniformly increasing increments* of altitude. In fact, no law of decrement, which would not make the density *increase* upwards, would be incompatible with the equilibrium of the strata; and for heights under 10000 feet almost any law and rate which satisfies this condition, and represents the temperatures at the highest and lowest levels correctly, will do so at the intermediate ones. The great defect of all such hypotheses is, that they cannot be fairly tested unless we possessed a scale of heights, trigonometrically determined, up to 20000 or 30000 feet, all in one geographical situation, and readily accessible from the sea level. Balloon ascents, indeed, amply satisfy the latter requirement—but as the heights must be concluded barometrically, they fail to afford what this mode of looking at the subject absolutely requires. A most valuable piece of positive information is, however, afforded by a balloon ascent, viz., that in a given very limited locality, out of the reach of surface inequalities and up-turned currents of heated air, on a given day, and with every facility for obtaining simultaneous observations on the surrounding region, a *definite relation, depending on no hypothesis, but absolutely given by observation, prevails between the temperature and pressure*, as read off at as many different instants, throughout the ascent, as the observer pleases—which relation is capable of being exhibited to the eye with all its capricious incidents by graphical projection in a curve, and of being freed, by a mode of treating such projections which has elsewhere (*Mem. Ast. Soc.* v.) been largely exemplified by the writer of these pages, from the greater part of the errors arising from casual influences or imperfect observation. In the view of the subject we are about to take (which it is something astonishing should have been overlooked by all who have treated of it), this information is all that is necessary for a rigorously exact determination of the heights of the several points of observation themselves, and of the law of decrement which actually subsisted *at the time and place.* By the comparison of such laws at different times and places, it will then be seen whether they are such as really to admit of any uniform or general expression.

(28.) To show this, let p be the barometric pressure, t the temperature (centigrade), and δ the density of the air at any altitude, x and P, T, Δ, those at the sea level, h the height of a homogeneous atmosphere at the temperature 0° C. and H at temperature T. Now if $k = 0.00366$, we shall have by what was shown in art. (15),

$$p = \frac{\delta\,(1+k\,t)}{\Delta\,(1+k\ \mathrm{T})}\mathrm{P}\,; \qquad (1)$$

and since the differential of the pressure $(d\,p)$ is the weight of the column $d\ x$, whose density is δ, $d\,p = \delta.\ d\,x$; (2.) Dividing, then, equation (2) by (1), and observing that $\dfrac{\mathrm{P}}{\Delta\,(1+k\,\mathrm{T})} = h$, we shall have

$$-\,\frac{dp}{p} = \frac{d\,x}{h\,(1+kt)}\,; \qquad (3)$$

If t be known in functions of x, this equation gives at once the relation between the altitude x and the barometric pressure p; and this is the mode in which the analysis of this question has always been conducted. But if put under the form

---

[1] If instead of being urged upwards by external impulse, a body of air dilated by heat ascend in consequence of such dilatation, it will rise until its expansion reduces it to the temperature of the surrounding air; but it cannot do so without depressing other air to a lower level, which thus becomes heated, so that in this case also the equilibrium of sensible heat is subverted, though in a somewhat different way.

$$d\left(\frac{x}{h}\right)=-\frac{(1\quad kt)\,dp}{p.},\quad\text{or }\frac{x}{h}=\int-\frac{(1+kt)\,dp}{p};\qquad(4)$$

it becomes available for a different mode of procedure. If the law of temperature, as depending on the *pressure*, be analytically expressible, or if t be an explicit function of p, we have x given at once by integration. But what makes this way of putting the matter peculiarly valuable is, that if this be not the case, but t only given *numerically* by the registered observations of the thermometer, and the reading-off of a graphical projection of them as above described, the integral in question *may be obtained graphically* with quite sufficient precision (practically speaking), and in an infinitely shorter time, than by any system of calculation; so that the determination of the altitudes in balloon ascents is made to depend *on no hypothesis whatever*, but to result purely and absolutely from the series of observed temperatures and pressures in the ascent and descent.

(29.) We have been able to collect no more than nine balloon ascents to sufficient altitudes (which should not be less than 10,000 feet), in which a series of corresponding readings of the two instruments have been taken consecutively enough for discussion, viz., those of Gay Lussac (art. 22), of Messrs Green and Rush in 1838 and 1850 (19185, 20352, 19904, 19440 feet), and of Mr Welsh in 1852 (19510, 19100, 12640, and 22930 feet), these latter leaving nothing to desire in point of instrumental appliances and scientific precision in their use. Plate XVIII. exhibits the graphical projection of the observations registered in each of these ascents, the dots being the points laid down, the continuous curve lines swept among them *liberâ manû*, without reference to any theory, but that one condition without which no general speculation on the subject is possible, viz., that their curvature shall be, generally speaking, similar in character, and have its concavity throughout towards the same side, and the dotted lines analogous curves in which this condition is not adhered to, but in which the most essential peculiarities of each ascent are brought into evidence. Each set of dots is referred to the curve to which it belongs by a light connecting line. The readings-off of these curves are stated in cols. 2, 3 .... 10 of the following table, and are set down *just as they were read from the actual projections used without any subsequent equalization of differences or correction whatever.*

Col. 11 contains the means of all the readings in the other columns, and from these a curve (the last of the plate referred to) is laid down which exhibits an average form of the curve, and embodies all the other results. That this proceeding is legitimate will appear from the following consideration:—Suppose t the temperature (or ordinate of any one of the curves) corresponding to the pressure p (the abscissa), and suppose any general relation such as $t=\alpha.\phi(p)+\beta\psi(p)+\&c.$ to subsist, α, β, &c. being parameters peculiar to each curve. Then if there be several such curves in which (corresponding to *the same pressure*) α, β, α', β', α'', β'', &c. are the parameters, and t, t', t'', &c. the ordinates, since $t=\alpha\phi+\beta\psi+\&c.$, $t'=\alpha'\phi+\beta'\psi+\&c.$, we have $\frac{t+t+\&c.}{n}=\frac{a+a'+\&c.}{n}\phi+\frac{\beta+\beta'+\&c.}{n}\psi+\&c.$, which shows that a similar relation subsists between the *mean* of the temperatures and the pressures, provided *mean* values of the parameters are used.

(30.) This essential point premised, we may now observe that the course of all the curves is evidently systematic; that the tendency to fluctuate in one direction in the early part of their course, as marked by the dotted curves in some of them, is contradicted by a similar tendency in the opposite direction in others, and that they agree in speaking a language to the eye which we have to interpret into a formula. Thus a good deal depends on the view we may take of the nature of heat itself and of temperature. Is there an absolute zero? And if so, does matter occupy space in virtue of the presence of heat? If we reply in the affirmative to both these questions, and suppose moreover, empty space absolutely devoid of heat, we must take the extreme lowest thermometer reading, as $t=-\infty$ corresponding to $p=0$. In that case the speculative prolongation of our curve would give it a vertical asymptote at $p=0$, and as its aspect so prolonged bears some general resemblance to a logarithmic curve, we will give that curve a trial. Taking, then, $\log. p = \alpha + \beta t$,[1] (5), we have $\frac{dp}{p} = \beta dt$, and by equation (4) art. (28), $x = h\int -\beta dt(1+kt)$

$$= \beta h\left\{(\mathrm{T}-t) + k\frac{\mathrm{T}^2-t^2}{2}\right\} = \beta h\,(\mathrm{T}-t)\left\{1 + k.\frac{\mathrm{T}+t}{2}\right\}; \quad (6)$$

But by equation (5) we have $\log. \mathrm{P} = \alpha + \beta\,\mathrm{T}$, whence we get $\beta(\mathrm{T}-t) = \log. \mathrm{P} - \log. p$; substituting which in (6) it becomes

$$x = h\,.\,\log.\left(\frac{\mathrm{P}}{p}\right)\left\{1 + k.\frac{\mathrm{T}+t}{2}\right\}; \quad (7)$$

(31.) This is the formula given by Laplace in the tenth book of the *Mécanique Céleste*, abstraction made of two factors in his expression for x, viz. $\left(1 + 0{\cdot}00228\cdot\log.\frac{\mathrm{P}}{p}\right)$ which takes into account the diminution of gravity in receding from the centre of the earth, and $(1 + 0{\cdot}00265\cdot\cos. 2\,\lambda)$, λ being the latitude of the place, which expresses the influence of the centrifugal force arising from the earth's rotation. The value of h, if the logarithms used are the common tabular ones, may be taken at 60309 British feet; if hyperbolic, at 26254 feet. This is the formula (including these factors) now universally adopted for computing heights from barometric observation. Its reduction to numbers is facilitated by tables which are given in the "Annuaire" of the French Board of Longitude, in Galbraith's Barometric Tables (Edin. 1833), and in that very useful collection by Arnold Guyot, published by the Smithsonian Institution, U.S. (Washington, 1852), to which, as containing almost every table a meteorologist can require, we once for all refer our readers. From this formula it appears that, according to the best estimate we can form of the temperature at great elevations, the extreme rarefaction specified in art. (19) as existing at 103 miles, on the supposition there made, would really be found about 11 miles lower, or at about 1-85th part of the earth's diameter above its surface.

(32.) Laplace's investigation of this formula is based on an assumption (avowedly introduced by him for the sole purpose of simplifying his analysis) of a variation of temperature with altitude which amounts to supposing equal decrements of temperature to correspond to increments of height, *decreasing* progressively in arithmetical progression. This is in fact the law of decrement which would result from our equation (6). It is therefore precisely the reverse of that of Lambert, Zach, and Atkinson, and, we may add, not in accordance with the general impression among meteorologists (in which, however, we do not participate), that the decrease is *slower* the higher we ascend. It is somewhat singular that Laplace does not appear to have noticed the logarithmic relation (5) which his hypothesis implies between the temperature and pressure; and still more so (and we are surprised that the remark should not have occurred either to Laplace himself, or to any of those who have used his formula) that his expression *is identical with that which would result from assigning to the whole atmosphere a uniform temperature, the mean of those actually observed at the higher and lower levels.*

(33.) When we come to examine our curve of decrement more particularly, however, it becomes evident that it is *not* a logarithmic curve, but a most undeniable parabola. The errors in the former case are systematic, and far beyond bearable limits. Supposing the curves to agree at the 15th and 30th inch of p, the errors are at 13, 17, 20, 23, 27, and 30.5 inches respectively $+2{\cdot}2°$, $-1{\cdot}8°$, $-3{\cdot}3°$, $-4{\cdot}2°$, $-2{\cdot}2°$, and $+1{\cdot}2°$. The logarithmic curve, therefore, is not in satisfactory accordance with the average course of nature as collected from these observations.

(34.) If we take for Fahrenheit's scale $\alpha = -87°$, $\beta = +9{\cdot}0667$, and $\gamma = -0{\cdot}1333$, or for the centigrade $\alpha = -66{\cdot}1111$, $\beta = +5{\cdot}0370$, and $\gamma = -0{\cdot}0741$, we shall find the numbers in col. 11 to be perfectly well represented by the equation $t = \alpha + \beta\,p + \gamma\,p^2$, substituting which in equation (4), integrating from P and T to p and t, eliminating γ by the equation $\mathrm{T} - t = \beta\,(\mathrm{P} - p) + \gamma\,(\mathrm{P}^2 - p^2)$, taking 60309 ft. for the value of h (as adapted for the use of *common* logarithms), putting for k its value 0·00366, and using the centigrade values of α and β, we shall find

$$x = h\left\{(1 + 0{\cdot}00366\,\alpha)\log.\frac{\mathrm{P}}{p} + 0{\cdot}000795\left\{(\mathrm{T}-t) + \beta\,(\mathrm{P}-p)\right\}\right\}; \quad (10)$$

(35.) To apply this formula to any proposed ascent, the readings of the instruments having been graphically projected, two extreme and one intermediate pair of corresponding values of t and p are to be fixed upon, and thence by resolving the three simple equations of the form $\alpha + p\,.\,\beta + p^2.\,\gamma = t$ which these afford, the values of α and β are obtained, which may then be substituted in (10), and the value of x determined. As an example we shall take Mr Welsh's ascent of Nov. 10, which gives $\mathrm{P} = 29{\cdot}972$, $p = 12{\cdot}240$; $\mathrm{T} = 46°{\cdot}7$ F. $= 8°{\cdot}16$ C.; $t = -11°{\cdot}3$ F. $= -24°{\cdot}06$ C.; $\alpha = -94°{\cdot}804$ F. $= -70°{\cdot}44$ C.; and $\beta = +8°{\cdot}4848$ F. $= +4°{\cdot}7136$ C., and executing the calculation we obtain $x = 22983$ feet, which corrected (by the factors in art. 31) for latitude and decrease of gravity, finally gives $x = 23027$ feet, being 97 feet in excess of the height assigned by Mr Welsh from Laplace's formula; by which it appears that, whatever be the objections to which the law of temperature implied in that formula may be liable, it may still be safely used even for such altitudes.

(36.) If $p = 0$, or so nearly such as would be the case in ascending some 25 or 30 miles, $t = \alpha$, which is therefore the temperature a thermometer would mark exposed to the total joint radiation of the earth and air from beneath, and to that into space from above. If then we call S the temperature of space *beyond the influence of terrestrial radiation*, we have, at least approximatively, $\alpha = \frac{1}{2}(\mathrm{T} + \mathrm{S})$. Now we have seen that in our mean curve $\alpha = -87°$ F. and $\mathrm{T} = +65°$ F., and that in Mr Welsh's last ascent $\alpha = -95$, $\mathrm{T} = +49$. Both agree in giving $\mathrm{S} = -239°$ F. Hence we may conclude generally, that taking for S this value, α may be at once assumed as $= \frac{\mathrm{T}}{2} - 119\frac{1}{2}°$ F. At the equator, then, the limiting temperature of the atmosphere would average $-77\frac{1}{2}°$ F., and at the poles about $-119\frac{1}{2}°$ F., with a range of temperature from the surface of $161\frac{1}{2}°$ in the former case and $119\frac{1}{2}°$ in the latter.

Of land and water as recipients and communicants of heat.

(37.) Of the solar heat which actually reaches the surface of the globe, that which falls on water penetrates it to some moderate depth and is absorbed internally, while that which is incident on land is wholly absorbed superficially, or within a very minute thickness. Water, moreover, is eminently a non-conductor of heat, so that once received into its substance it is only diffusible by agitation; and since this, however violent at the surface of the ocean, diminishes rapidly with the depth, the ultimate communication of heat downwards to any considerable depth is a very slow process. By far the greater portion of the daily supply of heat to water then may be said to float within a moderate depth of the surface, forming a kind of reservoir of heat. On the other hand, water is a *good radiant,* and as such is continually both day and night giving off radiant caloric, which is absorbed in traversing the air, and thereby tends to raise the temperature of the latter medium. It is a property of caloric radiant from bodies heated below incandescence to be eminently absorbable by transparent media. (See HEAT.) Hence it is most probable that much of the heat so radiated off is detained in the lower strata of the air. Meanwhile a balance is struck in the water itself of the quantities received and parted with, by the preponderance of one or the other of which it gains or loses in average temperature on the 24 hours. Thus, in the warm season, when days are long and nights short, the general temperature of the sea is slowly rising above its annual average, and *vice versa* in the opposite season. Below a certain depth, however, the temperature of the ocean would appear to be determined by other causes, and to be very little dependent on its superficial amount or fluctuations. It results from the observations of Kotzebue, Beechy, and Sir James C. Ross, as a general fact ascertained by thermometric soundings, that the deep sea water below a certain level, determined by the latitude, is of invariable temperature throughout the globe, and that a very low one; the calculations of Lenz, founded on Kotzebue's results, giving 36° F., and those of Ross 39°.5 (which last is the temperature at which pure water attains its maximum of density). The depth at which the fixed temperature is attained is about 7200 feet at the equator, diminishing to lat. 56° on either side of that line, where it attains the surface, and the sea (superficial currents apart) is of equal temperature at all depths. Thence, again, the upper surface of this uniform substratum descends, and at 70° of latitude has already attained a depth of 4500 feet. Thus the ocean is divided into three great regions; two polar basins in which the surface temperature is below 39°, and one medial zone above it, attaining 82° at the equator, and at the poles of course the freezing point of sea water. It is within these respective regions only, then, that superficial currents can act as transporters of *meteorological* temperature.

---

[1] t here expresses centigrade degrees, the same form applying equally to either mode of expression.

(38.) The habitudes of dry land with relation to incident heat are very different. There is no mobility of parts, and the communication of heat downwards is therefore entirely a process of conduction. But what is most influential, is the fact that the absorption is performed strictly on the exposed surface, which therefore in the instant of absorption fixes upon itself within a very minute depth all the heat which, falling on water, would in the same instant be disseminated through many feet or yards of its substance. The mere superficial film, then, becomes much more heated, and, since it is a law of radiation that its intensity increases rapidly with the temperature of the radiant surface, it radiates out on the very instant a much larger fraction of the total incident heat than in the case of water, besides imparting to the air by contact-communication a proportionally greater amount. In water the absorbed heat is for the most part withdrawn from the radiant action, enveloped and husbanded. In dry land it is instantly and wholly exposed to such action in its most intense form. It is no uncommon thing in dry and light (*i. e.* badly conducting) soils, in hot climates, to find a superficial temperature of 120°, 140° F., and even more. We have ourselves observed it at 159° F. at the Cape of Good Hope. In the arid regions of Australia, Captain Sturt reports that a lucifer match dropped on the ground takes fire. The surface water of the equatorial seas is scarcely ever known to range higher than 83° in the day, and 82° in the night.

(39.) That portion of the heat which enters the soil is conducted downwards, and so long as the surface is gaining in temperature a wave of heat is continuously propagated downwards into the earth. When the surface, however, by the decline of the sun, begins to lose heat, this ceases, and (the radiation still continuing) what may be called a wave of cold (less comparative heat) begins to be propagated, and so on alternately during the day and night. These waves as they run on spread forwards *and backwards*, and so by degrees neutralize and destroy each other. Thus the diurnal fluctuations of temperature beneath the surface grow continually less as the depth increases; the rate of diminution depending on the "conductibility" of the soil. In ordinary soils the difference between the diurnal and nocturnal extremes becomes imperceptible at four feet below the surface. (Quetelet, *Mem. Acad. Brux.*, 1836). In like manner, the general increase of heat due to the summer season, and of cold during winter, are propagated in similar but larger and feebler annual waves, which in their turn neutralize each other at more considerable depths, and become imperceptible at 40 or 50 feet. Professor Forbes has shown in an elaborate memoir on this subject (*Trans. R. S. Edin.*, xvi.) that at depths varying from 57 to 99 feet, according to the nature of the soil, the annual variation does not exceed 0°.01 C.

(40.) The absorption of incident heat *as solar heat*, and its radiation outwards *as terrestrial heat* (*i. e.* heat of a much more absorbable nature) by the solid surface, depends very much on the nature of its substance; but if the ground be covered with vegetation, *the whole* of the *incident heat* is returned back either by radiation or contact-communication to the air; and the soil receives no heat where so covered, otherwise than circuitously through the medium of heated air. All these causes acting together produce a vast difference as respects the temperature *of the air* in regions of the globe covered by the ocean and those occupied by dry land. In the former its fluctuations, both diurnal and annual, are confined within very much narrower limits than in the latter; and this contrast, which theory indicates, is confirmed by universal observation, as the expression of the distinction between an *insular* and a *continental* climate, or that of a small island remote from all other land and of the central regions of an extensive continent. If there be one general feature in meteorology more prominent than another it is the uniformity of temperature over great bodies of water, as compared to that under similar exposures to the sun on land.

(41.) *Terrestrial Radiation.*—The theory of radiant heat promulgated by Prevost, which all experimental inquiry into the subject has tended to confirm, lays it down as a principle, that a mutual interchange of heat is continually taking place between all bodies freely exposed to view of each other, the hotter radiating more than the colder in the ratio of some function increasing with the temperature. The experiments of Dulong and Petit on the radiation of bodies in vacuo, have shown that this function, within the limits of their experiments, is of the exponential form, or in other words, that the force of radiation in vacuo increases in geometrical progression as the excess of temperature of the radiant body above that of its envelope increases in arithmetical.[1] Hence, when a hot body is placed in presence of bodies, some colder some hotter than itself, an equilibrium will rapidly be established, in which its momentary gains and losses of heat to and fro among them all will balance each other, and its temperature will thenceforward be unchanged.

---

[1] There must be some natural limit to such a law. Radiation in absolute vacuity *cannot be infinite.*

(42.) Such will be the case if the body be completely surrounded or enclosed by others. But if only partially so, if there be an opening out into perfectly free space, through which rays of heat can escape, and from which none are returned, heat will constantly flow out from such a system, and the body will be maintained at a temperature lower than that of such partial envelope, and the more so the larger the *angular area* of the opening.

(43.) If it were certain that the vacuum, or ætherial medium in which the planets move, and which conveys light, had absolutely *no temperature* of its own capable of being imparted to matter, and if the air were perfectly transcalescent and incapable of radiation from its own particles, or from those of impurities floating in it, a thermometer placed a very small distance from the ground, with an unobstructed view of the sky, would receive from the hemisphere above it no heat but that radiated from the stars and moon; or (putting the moon out of the question, as it is almost certain that no portion of her heat escapes absorption in the air), none bearing a greater ratio to that it would receive from the sun, than the light of a starlight night to direct sunshine, which cannot exceed that of 1 to 100000000. It may therefore be regarded as *nil*.

(44.) The mean temperature of the earth remaining unchanged, it necessarily follows that it emits by radiation *from* and *through* the surface of its atmosphere, on an average, the exact amount of heat it receives from the sun, *i.e.*, as much as would melt 0·01093 in. in thickness of ice per minute over the area of one of its great circles, or one-fourth of this thickness (0·00273 in.) over its whole surface (art. 11, 12), which is equivalent to 135-960ths of that quantity, or 0·000374 in. depth of water per minute (or 1-40th in. per hour), condensed from its dew point. Taking this as the measure of the total average radiation, one-third of it, or 1-120th in., may be taken as radiated off from the atmosphere without ever reaching the earth, and the remaining two-thirds (1-60th in.), may be considered as got rid of by radiation, direct or indirect, from the surface of the earth. In complete absence of any means of estimating the ratio of these portions, we may suppose the latter to be one-half of 1-60th or 1-120th in. Let us now consider the manner in which this part of the process takes place, supposing a clear sky to prevail.

(45.) Conduction through the soil is a very slow process, radiation a very rapid one. So soon, then, as the sun has sunk so low as not to counteract the earth's radiation, the immediate surface begins to part with its heat, at first, of course, slowly, but as night advances more rapidly, and at length much faster than it can percolate from the interior to supply the waste. The surface, therefore, becomes greatly chilled, and a wave of cold (to use the mode of expression adopted in art. 39) is propagated downwards, neutralizing and destroying the heat-wave rising to meet it, a process which goes on leisurely, and takes its own time. Meanwhile the chilled surface now borrows heat from the air also, to supply its waste, 1st, by contact-communication; 2d, by downward radiation; *and, 3d, by condensation of vapour when the temperature of the surface-air is reduced to the dew point*, and thus attains that state of equilibrium which the circumstances admit of. The process is in fact in every respect the converse of that described (art. 38), by which heat penetrates the soil, the immediate surface exhibiting in both cases the most sudden and violent effect of the acting causes.

(46.) The most consecutive series of experiments and observations we possess on terrestrial radiation, are those of Professor Daniell, Captain Sabine, and more recently Mr Glaisher, the author of a very elaborate memoir on the subject (*Phil. Trans.*, 1847). Our limits will only permit us to mention some of the more prominent results obtained. The maximum of terrestrial radiation takes place when a perfect calm and cloudless sky prevail during a long night, in a level country. Under these circumstances, there is nothing to disturb the air immediately resting on the soil, so as to replace the air cooled by contact with the chilled surface by warmer air from above; and if a series of thermometers be exposed at various heights above the surface, that which is just not in contact will be found to mark several degrees lower than the general temperature of the air, and the others at greater altitudes, will stand progressively higher up, to about 10 or 12 feet, the difference, however, above 4 feet being very trifling.

(47.) The depression of the thermometer exposed to radiation in contact with any horizontal surface is greater as the radiating power of the substance of which that surface consists is greater, and as its power of conducting heat is less. The greatest depression observed by Mr Glaisher below a thermometer freely suspended at 12 feet above the ground, was no less than 28°.5 Fahr.! the lower thermometer being placed on raw cotton wool on long grass. The relative depressing powers of this and other supporting substances, assigned by him from a mean of all his observations, are given below; long grass being taken as a standard.

Hare Skin,	1316	Charcoal Powder	776
Rabbit Skin,	1240	Jet-black Lambs' Wool,	741
Raw White Wool,	1222	Sheet Zinc,	681
Flax,	1186	White Tin,	667
Raw Silk,	1107	Snow,	657
Unwrought White Cotton Wool,	1085	Sheet-Iron,	642
Long Grass,	1000	Paper,	614
Lamp-black Powder,	961	Slate,	573
Flannel,	871	Garden Mould,	472
Glass,	864	River Sand,	454
Sheet Copper,	839	Stone,	390
Coloured Lambs' Wool,	832	Brick,	372
Whiting-powder,	827	Gravel,	288

(48.) When a thermometer is exposed with its bulb in the focus of a concave silver hemisphere [1] or paraboloid, highly polished both internally and externally, and deep enough, when exposed with the concavity upwards, to cut off from the thermometer all view of the earth, and as it were to continue the sky beneath it, it can only receive heat by condensation and radiation from the air, and from the condensation of moisture. A thermometer so exposed under a clear sky, and shaded from direct sunshine, always marks several degrees below the temperature of the air, and its depression affords a rude measure (of the statical kind, and open to all the objections to which that kind of measure is open.—See art. 13) of the facility for the escape of heat by radiation afforded under the circumstances of exposure. As compared with exposure on any of the supporting substances above enumerated, the depressing power of such a reflection by Mr Glaisher's experiments appears to be 888, that of long grass being 1000, which is almost identical with that of the glass of which the bulb is formed. If the axis of such a reflector be directed to a cloud, or to any terrestrial object, the thermometer immediately rises, even should that object be the summit of a snow-covered mountain (as we had ourselves occasion to observe on April 18, 1824, from the roof of the observatory at Turin, the snowy range of the Alps affording an excellent object for trial). If directed to a cloud, the height of the cloud is not indifferent—Mr Glaisher's observations clearly showing that the higher the cloud the greater the radiation upward, whether estimated by the reflector, or by the depression of a thermometer laid on grass. Thus, in nights uniformly and totally cloudy, the mean height of the clouds being respectively 1900, 2800, and 3700 feet (which his peculiar situation enabled him to ascertain), the depressions were found to average 1°.6, 2°.5, 3°.9, clearly indicating the lower temperature of the higher clouds.

---

[1] The figure is absolutely of no importance. A paraboloid is generally used, for no reason that we can perceive but to increase the cost.

(49.) As an instance of the effect of terrestrial radiation applied to a practical purpose, may be mentioned the manufacture of ice in the East Indies. The process, as described by Mr Williams (*Phil. Tr.*, vol. lxxxiii. p. 56) practised in Benares on an immense scale, consists in exposing shallow porous earthen pans on straw in a level area, divided into compartments four or five feet square. The pans are filled in the afternoon; and the temperature being much reduced by evaporation before night, the freezing process is completed by radiation at night. In this way Mr Williams has often seen ice $1\frac{1}{4}$ inch in thickness produced in December, January, and February, the thermometer at $5\frac{1}{2}$ feet above the ground, marking from 41° to 46° Fahr. In a night of 12 hours, it may be remarked, the mean emission of heat from the earth's surface, taken as two-thirds of the total mean radiation, would suffice for the conversion of 480×0·00273 or 1·31 in. into ice. (art. 44.) So that there can be no necessity to recur to other causes than radiation (as has been done by some) for a full account of the effect observed.

(50.) *Of the evaporation and condensation of water, and the dilatation of air, as elements of power in Meteorological Dynamics.*—Water, freely exposed to the air, evaporates at all temperatures, even *when in the state of snow or ice.* The rapidity of evaporation is, however, much increased by warmth. Thus, in a calm atmosphere, under the ordinary pressure, Dalton found that when, from a certain surface, the evaporation from boiling water proceeded at the rate of 40 grs. per minute, it was 20 grs. at a temperature of 180° Fahr, 13 grs. at 164°, 10 grs. at 152°, and so on. *Cæteris paribus*, in dry air the rapidity of evaporation is proportional to the elastic force with which the generated vapour tends to escape from the evaporating surface; *i. e.*, to the tension of vapour due to the temperature of that surface (See Evaporation). If the air be already moist, evaporation is proportionally retarded, the force of escape being the difference between the elastic tensions of the generated vapour and of that already existing in the air. Under a low atmospheric pressure, also, it is far more rapid than under a high one, owing to the comparative absence of obstruction to the diffusion of vapour by the aerial particles—vapour being subject to the same laws of diffusion and non-reciprocity of pressure as other gases, and indeed, *while maintained in the vaporous state*, to all the other laws of gaseous statics and dynamics (See Heat). Owing to the same reason, evaporation is accelerated by wind blowing over the evaporating surface, which removes the generated vapour as fast as it is produced, and dispenses with the slower process of diffusion upwards. *Cæteris paribus*, moreover, the amount of water evaporated is proportional to the surface exposed to air. It is much greater, therefore, from rough and porous solid substances kept wetted (as, for instance, from moist soil or from vegetation wetted by rain), than from the surface of water itself; and from the latter, when agitated by winds or dashed in spray, than when tranquil.

(51.) Evaporation never takes place without the abstraction of heat from the evaporating surface. Every grain of water evaporated carries off with it sufficient heat to raise 960 grains, 1° Fahr., to supply which, that quantity of the residual water must have been cooled 1°. This heat, however, is *latent*, *i.e.*, does not appear as *temperature* in the vapour produced, which is no warmer than the surface from which it emanates. On condensation, however, the absorbed heat is given out again; and thus aqueous vapour becomes an agent in the transfer of heat, in its latent state, from one part of the globe, or from one region of the atmosphere to another, just as a moving body transfers the impetus which created its velocity to the place where it encounters an obstacle.

(52.) Vapour introduced into the air acts as a moving power in two distinct ways. 1*st*, By a simple addition of volume. The tension of the vapour is added to the elastic force of the air, according to Dalton's law, and increases by the same amount the total power of the mixture to support pressure. Were the specific gravity of vapour the same with that of air, the effect of its introduction would be simply one of distension. It would tend to relieve itself by lateral diffusion, or removal of obstructing air; and if prevented from so doing, would simply heave up the incumbent aerial column in struggling to diffuse itself, and so increase its total vertical altitude. 2*d*, But a far more efficacious motive power originates in the less specific gravity of the vapour of water than of air of the same temperature (0·6235 : 1). It is the lightest of all known "vapours," and, with exception of hydrogen and ammonia, the lightest of gases. In consequence, as soon as generated, it tends to rise in the air by its buoyancy, and in so doing, carries up with it much of the air with which it is intermixed, disengaging itself no doubt from it, in its upward progress, to become entangled, however, with fresh particles, which again it carries upward, to abandon them for others. In this way, not only is its upward diffusion far more rapid than its horizontal, but in its struggle upwards it tends to produce an ascensional movement in the air itself, and thus (as we shall presently see) to act as a powerful agent in the production of wind.

(53.) Whenever vapour comes in contact with any body, or arrives at any locality whose temperature is lower than that due to its tension, a portion of it condenses into water, or, it may be, into ice. In so doing it gives out again its latent heat, which is communicated to the condensing body, raising its temperature, or else is disseminated throughout the region, together with the condensed particles. If the condensation be into water, the heat thus reappearing as temperature is precisely the same in amount as that taken up in evaporating the same quantity of vapour from water, or 960° Fahr.; if into ice, the additional amount of 135°, which is that which becomes latent on the conversion of ice into water, is set free. If the condensation take place at the surface of the earth, the result is dew or hoar-frost, according as the surface is above or below the freezing-point; if aloft in the air, the result is a cloud or mist, or, if abundant, rain, snow, or hail. But in every case the condensation of vapour is accompanied with a mitigation of cold *at the point where it actually takes place.* The same is true of the freezing of water, however contrary to ordinary notions. Were it not for this, our winters would be intolerable.

(54.) It is clear, moreover, that the generation of vapour, under any extensive region, *more rapidly than it is carried off* by diffusion or otherwise, must be attended with an increase of barometric pressure, since the total weight of the atmosphere vertically over any region must be supported by the total area of surface, and equally so that its condensation, *provided the condensed water* be abstracted from the atmosphere, must lead to a diminution of pressure. The contrary will happen if the vapour generated be carried off as fast as produced by such a general upheaving of the aerial strata over any region as shall subvert their equilibrium, and cause them to overflow, upwards and laterally. In such a case, since air also will be carried off bodily from the region, and be replaced by vapour, the mean specific gravity of the whole aerial column, and its total weight, will be diminished, and the barometric pressure lowered. This takes place on a most extensive scale over the intertropical seas. The temperature of the surface water in them is habitually very elevated (from 78° at the tropics to 83° at the equator), and varies very little by the vicissitudes of season, or the alternation of day and night. A steady and copious evaporation is therefore continually going on. Vapour, carrying with it air, is constantly thrown up beyond the levels of equilibrium, where it flows over and spreads itself out over the upper regions of higher latitudes. The immediate consequence is a habitual deficiency of barometric pressure at the sea-level on the equatorial, as compared with that on the extra-tropical seas. In a voyage to the Cape of Good Hope in 1833-34, the writer of these pages found this decrease from the tropics to the equator, on either side, to amount to 0·24 in.

(55.) The dilatation of the air itself by heat, whether communicated to it from the earth, or radiated directly into it from the sun, acts in a somewhat different manner. Air is dilated only by about one-tenth of its volume by 50° Fahr. increase of temperature, so that, unless locally and violently heated, its effect in producing bodily uprushing currents is comparatively less than that of the introduction of vapour into its mass. When heated over large tracts, it acts rather by increased elasticity to upheave the superincumbent strata, and, by bulging them upwards, to destroy their equilibrium, and cause the upper atmosphere to flow over on less heated regions. The general effect, however, is similar; and as the sun cannot generate vapour without at the same time heating the air, it is impossible to separate their dynamical effects. Whether the air go forth from its place *proprio motu*, or be jostled out of it by the introduction of a lighter medium, the local relief of pressure is equally produced.

(56.) *Of the winds.*—Among the proximate agents in meteorology, the winds hold the first place. To their agency is owing the subversion of what Humboldt has termed the *solar climate* of the world (or that which would exist were the atmosphere motionless), and the production of its *real climate*. This they effect in two ways, viz., 1st, *Directly*, by transferring into regions remote from their origin the heated air and aqueous vapour (charged with latent heat) which the sun's direct action generates; and, 2dly, *Indirectly*, by causing currents in the ocean, which convey to one locality the surface water heated in another. In both ways they effect a constant circulation, both of heat and moisture, the two great elements of climate, which cannot therefore be understood till we know something of the habitual force and direction of these great aerial movements, considered on an extensive scale.

(57.) A very small difference of atmospheric pressures, as a moving power, suffices to generate a considerable wind. Calculating from a formula given by D. Bernouilli to express the velocity of a gas issuing through an orifice in a vessel in which it is compressed into surrounding air of less elasticity, it appears that, to generate in atmospheric air, velocities of efflux equal respectively to 10, 20, 30; 60, 90, 120; and 150 feet per second (or of 7, 14, 21; 41, 61, 82; and 92 miles per hour), would require corresponding effective differences of pressure of 0·006 in., 0·010 in., 0·016 in., 0·06 in., 0·14 in., 0·25 in., and 0·41 in., which may be taken as the velocities of wind in a gentle air, a light breeze, a good sailing breeze, a gale, a great storm, a tempest, and a hurricane producing universal desolation, sweeping away buildings, and tearing up trees. The corresponding pressures of the wind per square foot on a plane surface, perpendicularly opposed to it, are respectively in pounds 0·2, 0·9, 1·9; 7·5, 16·7, 30·7; 37·9. It must be borne in mind, however, that for such pressures to produce the velocities ascribed to them, they must be supposed to act unmitigated by any graduation, which is never the case in nature, the transition from a higher to a lower pressure at stations remote from each other being always extremely gradual, so that barometric elevations and depressions to a much larger extent may and do exist without giving rise to great winds. It is only when sensible differences subsist between the pressures at places near each other that violent phenomena arise.

(58.) We have seen that the immediate effect of the application of heat to any region is to generate an ascensional movement in the incumbent atmosphere, a bodily overflowing of its material above, and a relief of barometrical pressure below. The air of the cooler surrounding region not being so relieved (but rather the contrary, owing to the increase of weight poured on it from above), will be driven in by the difference of hydrostatic pressures so arising, and thus originate two distinct winds, an upper one setting *outward* from the heated region, a lower *inward*. If the region heated be a limited one, these currents will radiate from and to it as a centre; if a linear tract, or a whole zone of the globe, such as the generally heated intertropical region, they will assume the character of two sheets of air setting inwards on both sides below, uniting and flowing vertically upwards along the medial line, and again separating aloft, and taking on a reversed movement.

(59.) In this account of the production of wind, however, no account is taken of the earth's rotation on its axis, which modifies all the phenomena, and gives their peculiar character to all the great aerial currents which prevail over the globe. The first clear perception and announcement of this cause, as affording an explanation of the trade winds (otherwise inexplicable), is due to Hadley (*Phil. Tr.*, 1735), and affords a beautiful demonstration of that great astronomical principle as a physical fact. To form a right estimate of its importance, it is only necessary to observe, that of all the winds which occur over the whole earth, one-half at least, more probably two-thirds, of the average momentum is nothing else than force given out by the globe in its rotation in the trade currents, and in the act of reabsorption or resumption by it from the anti-trades.

(60.) Since the earth revolves on an axis passing through its poles from west to east, each point in its surface has a rotatory velocity eastward proportional to the radius of its circle of latitude, and any body of air relatively quiescent on that point will have the same. Conceive now such a body to be urged by any impulse in the direction of a meridian towards the equator. Since such impulse communicates to it no increase of easterly velocity, it will find itself, at each point of its progress, continually more and more deficient in this element of movement, and will lag behind the swifter surface below it, or drag upon it with a relative westerly tendency. In other words, it will no longer be a direct north or south wind, but, relatively to the surface over which it is moving, will assume continually more and more the character of a north-easterly or south-easterly one, according as it approaches the equator from the north or south.

(61.) Meanwhile, however, the earth is continually acting on the air by friction, and communicating to it rotatory velocity. As it approaches the equator, in whose vicinity the diurnal circles increase more slowly, the relative westerly tendency is continually less and less reinforced by the cause which produced it, and the counteraction arising from friction acquires energy, till, on arriving near the equator, the wind loses its easterly character altogether; while the northern and southern currents, here meeting and opposing, mutually destroy each other, producing a calm; and become deflected upwards, to form an ascensional current, replacing the air abstracted. The result, then, is the formation of two great tropical belts, in the northern of which a north-easterly, and in the southern a south-easterly wind prevails, while the winds in the equatorial belt which separates them, are comparatively feeble and free from any steady prevalence of easterly character. This is the general description of the trade winds as actually observed.

(62.) A precisely contrary set of re-actions takes place on the upheaved or displaced equatorial air. In flowing over to regain its level, it commences its course relatively in a meridional direction, but really with the full amount of easterly velocity which the earth's equator has; and since this, as it proceeds north or southwards, is in excess of what would suffice to keep it on the same meridian, it continually deviates to the westward; and when it again returns to the earth in its circulation, which it does on both sides beyond the tropics, it does so with a powerful westward tendency, and the more, as in its course it has been less under the influence of surface friction, owing to the elevated region in which it has travelled. It thus restores to the mass of the earth the momentum abstracted by it in the former phase of the cycle. We have here the origin of the SW. and westerly gales, so prevalent in our latitudes, and of the almost universally westerly winds in the northern and southern extra-tropical seas. The existence of an upper current, opposite in direction to the under, is a matter of frequent observation, as shown by the courses of a lower and higher stratum of clouds.

(63.) Were the whole globe covered with water, and the sun always in the equinoctial, the system of the trades and anti-trades (for so the compensating westerly winds may conveniently be designated) would be perfectly symmetrical about the equator, as their medial line. Two causes tend to derange this symmetry, viz.:—1*st*, The movement of the sun in declination, which carries it alternately away from the equator to 23½° on either side; and 2*d*, The existence and peculiar form of the continents.

(64.) Suppose the sun at the northern tropic. At that time, the region beneath the southern being 47° from the circle of vertical sunshine, will be receiving little more than half its maximum of solar heat (art. 12), and the circle of 47° latitude will be receiving as much heat as the equator itself, or more, the days being longer. If this state of things were permanent, the neutral line would shift from the equator to the northern tropic, carrying the whole system of the trades with it. But the sun approaches the tropic gradually, and does not remain there, but returns to the equator; and as, moreover, the general temperature of the ocean follows very slowly the action of its rays (art. 40), these effects cannot be fully wrought out, or nearly so, and the utmost that could arise would be a very moderate northerly transfer of the medial line, and with it, of the inner and outer limits of the trades; and as the reverse effects will of course arise when the sun gets into south declination, the result altogether will issue in a periodical annual oscillation of the wind system to and fro on either side the equator; the maximum excursions falling later in the year than the precise epochs of the solstice, on the general principle *that cumulative effects necessarily attain their maximum later in point of time than their causes.*

(65.) This is very nearly an accurate account of the real state of things in the Pacific Ocean, whose vast extent brings it within the general scope of our hypothesis, and in which the north-eastern trade extends from about 2° to 23° north latitude, in its mean situation, and the south-eastern from about 3° to 21° south latitude. Between them lies an equatorial belt of about 5° in breadth, of such habitual calm as to have given a name to the ocean itself. The annual oscillation is confined within very moderate limits.

(66.) In the Atlantic the disturbing influence of the continents is very sensibly felt. The great mass of Africa, and especially of its sandy and burning deserts, lies considerably north of the equator. These become intensely heated, and their temperature *follows the sun* much more closely than that of the sea. There can be no doubt that the medial line of the trades crosses Africa considerably to the north of the equator, nor that the annual oscillation of the northern trades at least is very great, and the influence extends to the neighbouring Atlantic. In this ocean the equatorial limit of the north-east trade shifts with the season from 5° 15′ to 11° N. lat., and that of the south from about 2° to 3° 15′ N., so that the medial line lies always a little north of the equator.

(67.) It is in the Indian seas, however, and especially in the vicinity of the great Asiatic continent, that the disturbing influence of the land is most clearly exhibited, issuing in a complete reversal of the north-east trade during a considerable portion of the year, and the production of monsoons, *i.e.*, of winds which blow half the year in one, and the other half in the contrary direction. When the sun is south of the equinoctial, it being the cold season in those continental regions, the regular trade winds prevail throughout those seas, and what is called the north-east monsoon is in fact no other than the undisturbed north-east trade wind. But where the sun has north latitude, and especially about the northern solstice, it is vertical over a very large region of Arabia, Hindostan, Bengal, Burmah, and Cochin, which become, of course, intensely heated. Under these circumstances, besides the permanent line of maximum temperature in the equatorial sea, there is developed another more intense and less regular line of the same nature, under or near the northern tropic, towards which, and not towards the equator, a large proportion of the intermediate air is drawn. Receiving thence a *northern* impulse, and that impulse carrying it into a region of less rotatory velocity than that which it has left, it assumes a relative south-west direction, and is called the south-west monsoon. Meanwhile, south of the equator, the south-east trade continues to prevail from May to October over all that part of the Indian Ocean which is not skirted with large tracts of land to the south; but where this is the case, as in the Java seas, as far as New Guinea, which are skirted to the south by the great Australian continent, we have again a double maximum, and the phenomenon of a NW. monsoon taking the place of the SE. trade. Our limits will not allow us to pursue this subject into details, for which we must refer to Dove's Meteorological Researches, Kämtz's Meteorology, and Horsburgh's India Directory. The setting in of the monsoon is generally accompanied by deluges of rain and thunder storms of excessive violence.

(68.) *Sea and land winds.*—The uniformity of temperature over a surface of sea, compared with that over land, gives rise to winds alternately setting to and from the land, at those seasons when it is powerfully heated in the day time, while at night its temperature sinks to an equality, or even sometimes below, that of the sea surrounding it. As the hottest and coldest hours of the day are about 2 P.M. and a little before sunrise, the winds in question necessarily attain their greatest power at somewhat later epochs in the day.

(69.) *Dove's law of rotation of the wind.*—It is not, however, merely in the great system of aerial movements which affect the whole atmosphere, that the influence of the earth's rotation is felt. Even very limited local movements are modified by it. It is a remark as old as Lord Bacon (*de Ventis*, 1600), and since confirmed by Mariotte in France, Sturm in Germany, Toaldo in Italy, and many other writers both in Europe and North America, that the wind has a decidedly preponderating tendency to veer round the compass according to the sun's motion, *i.e.*, to pass from N. through NE., E., SE., to south, and so on round in the same direction through west to north; that it often makes a complete circuit in that direction, or more than one in succession (occupying sometimes many days in so doing), but that it rarely veers, and very rarely or never makes a complete circuit in the contrary direction. M. Dove in his "*Meteorologische Untersuchungen*," was the first to show that this tendency is a direct consequence of the cause above mentioned.

(70.) Suppose that at any station in north latitude, after a calm, the air over and around the place, for some considerable distance, to receive an impulse in the direction of a meridian, carrying it towards the equator. The first air which passes over the station, coming from its immediate neighbourhood, has the same rotatory velocity as the station, and therefore passes it as *a north wind.* But the movement continuing, that which arrives subsequently having set out from a continually higher and higher latitude, arrives with continually less and less rotatory velocity, and therefore in its passage over the station, will relatively decline more and more to the east, and pass as a north-east wind. If now the southward movement relax, and at length cease, the relative motion from the east will continue for a while, till destroyed by friction, and the wind will for the moment have become a direct east wind. Now, suppose a contrary impulse given, or that the mass of air begins to travel again northward, the east wind will evidently begin to be deflected towards the north, and will become a south-east wind. As the northward movement continues, the fresh arrivals will bring with them an excess of rotatory velocity, or a tendency to blow relatively *from the west*, and will thus first neutralize the easterly character, changing the wind from SE. to S., and finally overcome it, passing into a south-west wind. If, then, the other oscillation take place, and the mass of air begin again to travel southward, the wind, by the very same reasoning, will gradually change to west, then by NW. to N., and finally come round again to the NE. It is obvious that for a station in south latitude, the conditions being reversed, a contrary law of rotation ought to prevail. Observations in south latitude are in great measure wanting by which to test this theory. In north, as we have seen, it is found conformable to fact.

(71.) In the tropical regions, where the superficial air always flows towards the equator, no such oscillatory movement northwards and southwards, as is above supposed, takes place. Where monsoons exist, there is but one such oscillation annually, and accordingly the wind makes one annual circuit; but in the temperate zones beyond the trades, as casual circumstances determine, equatorial and polar tendencies alternately preponderate, and every oscillatory movement so impressed is thus converted into a circulation in a fixed direction.

(72.) *Cyclones.*—The West Indian seas, those about Mauritius, and the China seas, are infested with *hurricanes*, or storms of wind, of excessive violence, productive of frightful devastation both on land and on sea, and which, in addition to the interest which such scourges must always command, have of late come to possess a peculiar one in the eyes of meteorologists, on account of the remarkable features in their history brought to light by the laborious researches of Professor Redfield, Colonel Reid, and Mr Piddington. By a collection of the log-books of ships which have encountered such storms, and the comparison of the recorded directions of the wind, at different periods of their progress on land, in regions devastated by them, the following general facts respecting them have been established, viz., 1st, That in any such hurricane, the movement of the air (regarding its whole extent) is vorticose. They are in fact whirlwinds, though often of vast magnitude, the diameters of some of them, which have been already traced, exceeding 500 miles, though for the most part not more than 200 or 300. Hence the name given to them of cyclones. 2d, The centre of the vortex is not fixed, but travels leisurely enough (from 2 to 30 miles per hour), along certain tracts. In the West Indies they are confined to a pretty definite area, their usual course being in a parabolic curve, having some point near Bermuda for its focus—originating in the Gulf of Florida—and running along the coasts of the United States, following generally the course of the Gulf Stream, and sweeping across the Atlantic, occasionally visiting our island. In the southern Indian seas, according to Mr Piddington (*Sailor's Handbook*), they follow also parabolic curves, the vertices of which often sweep round the isles of Mauritius, Rodriguez, and Bourbon, and whose average focus is a point about 25° S. lat. and 70° E. long. Along the arcs of these parabolas, in both regions, the initial movement of the centre of the storm is westward, so that the movement of the cyclone in its parabolic orbit is contrary to that of the wind in the cyclone itself. 3d, In cyclones which occur in the northern hemisphere, the rotation of the air is invariably in the contrary direction of the hands of a watch laid face uppermost ↶ ; in those of the southern hemisphere the reverse, ↷. 4th, They originate between the tropics, and run outwards from the equator towards the poles. But *on the equator itself they never occur.* 5th, They are announced by a rapid fall of the barometer, the depression being greatest in the centre (sometimes amounting to two inches!) 6th, The wind is most violent in the neighbourhood of the centre of the cyclone, but as the centre itself passes over any spot, a momentary calm is observed, the wind immediately recommencing in the reverse direction to what it had the instant before (a necessary consequence of the vorticose motion).

(73.) A complete account of all these characters is afforded by Hadley's principle, as developed by Dove in his "Law of Rotation," and applied to this specific class of aerial movements by Professor Taylor. Suppose (in the northern hemisphere), that owing to the application of local heat, a tendency in the air over some extensive locality C, to ascend in a vertical column should arise; to supply the place of the air so ascending, an indraught from all the surrounding region will commence. Let the equal lines N*n*, 1-1, 2-2, 3-3, E*e*, &c. (fig. 1) represent the forces and directions of currents drawn in from equidistant points, situated to the N., NNE., NE., ENE., East, &c.; then, were the earth at rest, these currents would all press towards C with equal force, and the lines N*n*, &c., would be terminated by concentric circles, and a mere vertical ascending current without gyration would result. But the earth revolving from W. to E., take to the westwards of *n*, *na* to N*n* as the difference of the rotatory velocities at N, *n* to the velocity of the indraught; join N*n*, which will then represent the *relative* force and direction of the current setting in from N; and a similar construction being made at every other point, the system of relative currents will be that represented by the arrows N*a*, 1 *b*, 2 *c*, 3 *d*, E *e*, &c. And it needs but a bare inspection of the figure to perceive that such a system terminating in an ascensional movement over the tract C can be no other than a vortex or spiral eddy in the direction of the internal curved arrow, *i.e.*, in a direction contrary to the motion of the hands of a watch laid face upwards. In the southern hemisphere it will be the reverse, as will appear on drawing the figure.

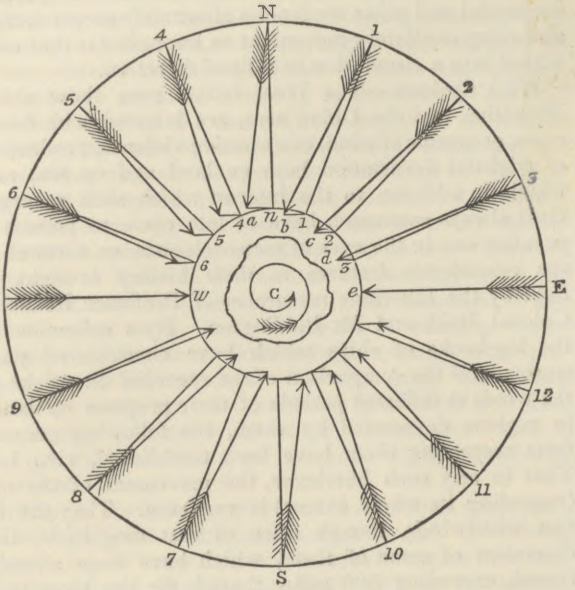

Fig. 1.

(74.) It is also obvious that the force of the vortex so arising must be in proportion to the strength of its efficient causes. In high latitudes there is a deficiency of solar heat and aqueous evaporation to produce a sufficiently powerful ascending current. On the other hand, on the equator, with abundant heat, the other efficient cause, viz., a difference of diurnal rotatory velocity, is absent.

(75.) *Atmospheric waves.*—The atmosphere, like the ocean, has its waves, which are rendered sensible by the increase or diminution of barometric pressure, as the crest or the trough of the wave passes over the place of observation. They are, however, on a much vaster scale than those of the sea, as might be expected, from the greater mobility of the medium, and the extent of surface over which their existing causes act simultaneously. But they are distinguished from the latter by features of a peculiar kind, which depend on two causes, viz., 1st, The varying density of the air from the earth upwards; and, 2d, The fact that the disturbances in which they originate are not (as in the case of the sea-waves) merely superficial, but extend through the whole depth of the atmosphere, and are most powerful at the ground level.

(76.) A very good general notion may be formed of the peculiar modification of waves which depend on a decreasing density of the medium in which they are excited, by pouring into a large glass vessel fluids of different densities which do not mix, and which have different colours. An undulatory movement impressed on such a system disappears very speedily from the surface of the uppermost fluid, but continues long after to agitate the lower strata; and moreover the latter, while possessing the inertia which belong to their *entire* densities, but the preponderant weight which corresponds only to their *differences* of density from those above them, are less controlled by gravity in proportion, and their excursions above and below their planes of equilibrium are therefore vastly exaggerated. Again, if there are several such strata, which is easily managed by carefully pouring, one over the other, several fluids (even if *miscible*, provided actual *mixture* be avoided), their undulations are far from maintaining any parallelism or correspondence; and it will be found practicable to propagate in them waves of independent origin, and differing in direction, mutually reacting on each other. The aerial waves are, besides, exaggerated by the elasticity of the medium, the portion thrown up, *ipso facto*, dilating itself, and therefore swelling into a higher convexity than it would assume if inelastic.

(77.) As the attraction of the sun and moon tend to produce an elliptic distortion in the spherical outline of the ocean (whose vertex follows the luminaries), and which thus becomes converted into a great circulating tide-wave, with two maxima and two minima in the luni-solar day; so the heat of the sun producing a far more considerable elevation of the level lines, and a far greater disturbance of equilibrium in the aerial hemisphere beneath it, while the nightly chill on the other side acts *in a contrary sense* on the opposite hemisphere, a similar, but much more considerable circulating wave, or *heat-tide*, is generated, following the sun (as all cumulative and periodical effects follow their causes) at a certain interval, but which differs from the sea-tide wave in having only one elevation and one depression of the barometric column, and in having a mean solar day for its period. Of this, more hereafter. The gravitation-tide, depending on the joint attraction of the sun and moon, gives rise to no greater difference of level in the aerial strata than what the same causes produce in the ocean itself, viz., about six feet. Their effect on the barometer would amount at the maximum to less than 1-130th of an inch.

(78.) Were the sun constantly vertical over the equator (exactly as in the astronomical theory of the tides), no annual fluctuation would arise; but as the point of maximum heat oscillates from tropic to tropic, an annual transfer of air from hemisphere to hemisphere takes place, producing a fluctuation analogous to the menstrual inequality of the tides arising from the moon's change of declination—only as there is more time given for this cause to work out its effect, and the obstructing causes are comparatively feeble, the extent of the annual variation in the barometric pressure bears a much greater ratio to the diurnal than in the analogous case: and for the same reason, as in the diurnal fluctuation, the wave which causes it is single, not double crested.

(79.) It is not with these fluctuations, however, that we are now concerned. They will be considered under another head. The atmospheric waves here considered are those which originate, not from the general movement of the whole body of the atmosphere, but from internal displacements, the result of winds diverted from their course, or of great local disturbances of temperature, due to a concurrence of circumstances which may be termed casual, forasmuch as we cannot trace their laws. Such waves have been traced by comparing hourly observations of the barometer made by numerous observers, on certain days determined by preconcerted arrangement, in distant places, the progress of the waves, their general direction, their height, and velocity, being concluded from the rise and fall of the barometer as noted in each. Thus, to cite some instances, it has been found that on the 21st of September 1836, by observations made at Markree, Limerick, Halifax, Oxford, London, Brussels, Hanover, Geneva, Turin, Gibraltar, and Cadiz, a wave having a barometric depth of 0.2 in., was ascertained to have passed over the British Isles and the west of Europe, having its crest nearly in the direction NNE. or SSW., and the direction of its progress nearly from WNW. to ESE. The half breadth of this wave, which occupied nearly 26 hours in its passage, extended from Oxford to near Halle in Würtemberg (about 540 miles). Its velocity of advance was about 26 miles per hour. Again, on the 21st of December 1837, a very well defined wave travelled in a direction from 10° north of W. to 10° south of E., at the rate of 18·62 miles per hour. The total depth of this wave from crest to trough was measured by fully $\frac{3}{4}$ inch of barometric pressure, so that the level strata must have fluctuated through a vertical height of at least 700 feet. The area over which this wave was traced, is marked by fifteen stations of observation, extending from Markree in Ireland, to Parma in Italy.—(*Brit. Ass. Rep.* 1843.)

(80.) It would appear from the researches of Mr Birt, that a very remarkable wave of this kind (to which he has given the name of "the great November wave") passes annually over these islands and the adjacent regions (embracing probably the whole of Europe and the seas on its north-west coasts in its range), the crest extending in a direction from NE. to SW., the direction of progress (at right angles to this or) from NW. to SE., the velocity about nineteen miles per hour. Both the breadth and depth of this wave are on a vast scale. The whole wave occupies about fourteen days in its transit, the crest passing over London about the middle of November, so that its total breadth cannot be less than 6000 miles, while the extent of barometric elevation from its trough to its crest seldom falls short of an inch, and occasionally amounts to double that quantity. What is no less remarkable, there is a certain region (in which London is included), over which the rise and fall of the barometer during the transit of the wave exhibit a considerable resemblance, so that a section of it, in the direction of its advance, would be a symmetrical curve, the middle crest being preceded and followed at about five days' interval by two lower ones, and the beginning and the end marked by deep depressions. The researches of M. Le Verrier leave no doubt that the great Crimean storm of the 14th November 1854, of disastrous memory, was part and parcel of this phenomenon.

(81.) *Anemometry.*—The wind, regarded as a meteorological element to be measured and recorded, differs from other elements, inasmuch as it offers two distinct objects of measurement, viz., its direction and velocity; three, indeed, since the quantity of air passing over a given place of observation varies as the velocity and density jointly. This, however, is a nicety into which meteorologists have not yet thought it worth while to go, being content to regard the number of miles travelled over by the wind in a given direction as expressing the material transfer of the air in that direction. In fact, as different and often opposing currents co-exist at different levels, it would be a useless refinement to do so. The direction and velocity, however, are essential features. The former is readily determined by a well-constructed vane, erected high enough to be out of the reach of eddies, and either read off on a divided circle to degrees of deviation from the meridional direction, or so mechanically arranged as to register itself at every instant. The velocity may be measured (or self-recorded) in several different ways. As, for instance, first, by causing the wind to act perpendicularly (as in Osler's anemometer) against a square foot of surface, so as to drive back a spring of known elasticity, the extent of compression determining the number of pounds which equilibrate the momentum per square foot, and which (like the direction) may be self-recorded at every instant. Secondly, by causing it to drive round the fans of a light vane, presented always perpendicular to its direction, and registering the number of its turns by means of an endless screw and wheelwork, as in Whewell's construction (C. U. Phil. Tr. vi.; improved by Dr. Robinson, Mem. R. I. Acad. xxii.), which has the advantage of giving not merely the momentary velocity, but the total or integral amount of space run over, or the transfer of air per day, per hour, or per minute, as may be required.

(82.) Since the whole of the air in the region surrounding the place of observation participates in the movement so recorded, and must be considered as transferred bodily at each instant with a motion equal and parallel, the particle which was first over the spot will describe a curve whose elementary arc and direction are determined, and may therefore be traced, either by hand or by a self-acting movement in the mechanism of the anemometer on any scale. Suppose (fig. 2) A p q r B to be the trace of one day's movement, A S the direction of the meridian, p, q, r, the points attained at stated hours, t_1, t_2, &c. and let Q_1, Q_2, Q_3, &c. be the angles p A P, $q\,p\,a$, $r\,q\,b$, &c. or the directions of the wind, reckoned round the compass from the north, eastwards, and v_1, v_2, &c. its velocities; then since $p\,\mathrm{P} = v \,.\, \sin.\, \theta$, $\mathrm{AP} = v \,.\, \cos.\, \theta$; if dt be the element of the time, we shall have $\mathrm{AS} = \int v dt \,.\, \cos.\, \theta$, and $\mathrm{BS} = \int v dt \,.\, \sin.\, \theta$, from $t = 0$ to $t = 24$ h. in strictness; and approximately—

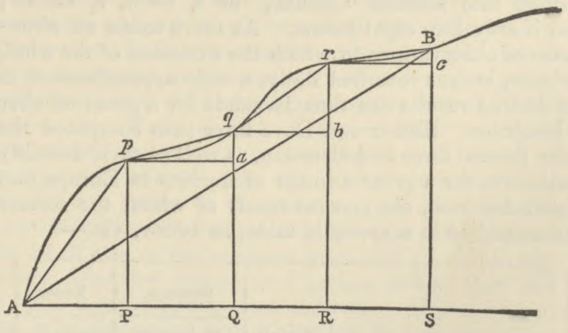

Fig. 2.

$$\mathrm{BS} = v_1 \,.\, \sin.\, \theta_1 + v_2 \,.\, \sin.\, \theta_2 + \&c. = \mathrm{A}$$

$$\mathrm{AS} = v_1 \,.\, \cos.\, \theta_1 + v_2 \,.\, \cos.\, \theta_2 + \&c. = \mathrm{B}$$

So that if AB be joined, AB representing the mean movement during the twenty-four hours, if AB = V, and BAS = φ, we shall have

$$V = \sqrt{A^2 + B^2}; \text{ tan. } \varphi = \frac{A}{V},$$

whence the mean velocity and direction, during the twenty-four hours, may be calculated from a series of registered numbers, or from the measurement of AB and BS on the self-registered trace.

(83.) If AB, BC, CD, DE, &c., represent the mean diurnal movements during a week, month, or year (fig. 3), so, by a similar system of calculation, may the mean weekly, monthly, or annual direction and velocity be computed. Hitherto it has not been possible to obtain the necessary data for any considerable number of stations, the instruments required being both costly and comparatively of recent construction. But no class of observations is calculated to afford more insight into the sequence of meteorological changes; and they cannot be too earnestly recommended to general attention. Meanwhile, in the absence of all information as to the velocity of the wind, it has been the practice to assume *all winds as of equal force*, or rather that the force of winds may be regarded, on the average, as measured by the frequency of their occurrence. The formula given by Lambert for the average direction and force of the wind, is founded on this supposition (a most misleading one), and consists in substituting for v_1, v_2, &c., in the general values of A and B above given, the numbers n_1, n_2, and in which the winds N., NNE., NE., &c., making angles $\theta_1 = 0$, $\theta_2 = 22^\circ\frac{1}{2}$, $\theta_3 = 45^\circ$, &c., supposing the circumference divided into sixteen "points;" or $\theta_1 = 0$, $\theta_2 = 45^\circ$, &c., if only into eight points. As there exists an abundance of observations in which the direction of the wind, *per vane*, is thus recorded daily, a rude approximation to the desired results can thus be made for a great number of localities. Kämtz and Dove have thus computed the mean annual force and direction, as well as their monthly variations, for a great number of stations in Europe and North America, the general result of which the former has embodied in a synoptic table, as below, viz.—

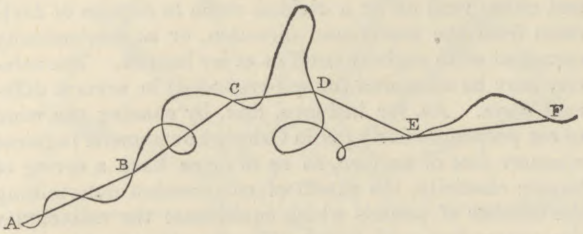

Fig. 3.

	Direction.	Force.
England	S. 66° W.	0.198
France and Holland	S. 88 W.	0.135
Germany	S. 76 W.	0.177
Denmark	S. 62 W.	0.170
Sweden	S. 77 W.	0.228
Eastern Europe	N. 87 W.	0.167
Northern part of United States	S. 86 W.	0.182

in which the numbers under the column headed Force express the values of V in the formula so modified.

(84.) *Oceanic Currents.*—The winds act indirectly as distributors of heat and moisture, by producing currents in the ocean. Were there a free communication round the globe, at or about its equator, the continuous action of the trades could not fail to establish a westerly circulation of the equatorial waters with little deviation to the north or south; and were the whole globe covered with water, the compensating SW. and NW. winds beyond the tropics would produce two extra-tropical easterly currents, surrounding the globe, and separated from the equatorial one by zones of still water, a lively picture in short of what is most probably the state of the planet Jupiter (the rotatory velocity of whose equator is 26 times greater than the earth's) as concluded from the appearance of its belts.

(85.) The continent of America, however, which presents an unbroken barrier as far as the 55th degree of south latitude, effectually prevents the equatorial current from making a complete circuit round the globe, its passage round Cape Horn being barred by the contrary southern compensating current. Its passage round the Cape of Good Hope, also, is materially impeded, though not prevented, by a similar cause, so that in the Atlantic two vast eddies are formed, in the southern of which the water, deflected along the Brazilian coast till it meets the opposite current at Cape Horn, joins that current, and is swept eastward with it. In the northern it is thrown upon the north-east coast of South America, through the Caribbean Sea, obliquely into the hollow of the Gulf of Mexico, where it is suddenly and violently deflected to the north-west, and issues in what is called the Gulf Stream, to which, as a very powerful agent in determining our own climate, we must devote some small space, referring the reader for further details on the subject of currents to our article HYDROGRAPHY, and to the chart of Oceanic Currents by Captain Beechy, in the *Admiralty Manual of Scientific Enquiry*, p. 106.

(86.) The Gulf Stream, where it quits the Gulf of Florida, has a velocity of from three to five miles per hour (varying with the season), a breadth of only a few miles, and a temperature of 83°. Thence it follows the coast of America to about the 36th degree of latitude, where it still possesses a temperature of 76° Fahr., and where it quits the coast about Cape Fear, and encircling the Azores, spreads itself in wide diverging streams over the basin of the Atlantic, between the coasts of America and Spain, forming a vast eddy, overgrown with the "sargasso" or Gulf weed. The main stream, however, continues to run north-westward, directed full towards the British Islands, to about the 46th parallel, in the 40th degree of west longitude, where its force is much weakened by subdivision. The surface water, however, continues to flow onwards in the same direction, and its presence on our western shores is evidenced by the warm vapours the south-west winds waft from above it, and by tropical plants and seeds thrown ashore on the west coast of Ireland, on the Hebrides, and even on Norway. Were the isthmus of Panama broken through, there is no doubt that the whole climate of our islands would undergo a most notable deterioration.

(87.) *Of the precipitation of vapour, and the formation of dew, fogs, clouds and rain, &c.*—Air and vapour, according to the views of Deluc (first distinctly announced in a very remarkable paper, *Phil. Tr.* 1792, p. 400), and the theory of the independent elasticity of gases in general, announced by Dalton in 1801, form two distinct and in great measure independent atmospheres; the one permanent in material and constant in quantity—the other in a continual state of destruction and renovation. Were the temperature of all regions of the globe alike, no precipitation of vapour in the form of rain or snow would ever take place. A certain definite amount of vapour once generated and diffused, would remain as a permanent constituent of the atmosphere, and each aerial stratum would exist in a state of habitual exact saturation, so that no further evaporation would take place from a moist surface at whatever level exposed. But owing to the equatorial heat, the polar cold, and the great system of circulation established by the winds, the atmosphere is converted into a great distilling apparatus, and the vapour raised in warmer regions is continually being precipitated in colder, according to laws which we are now to trace.

(88.) The most immediate, though assuredly not the most obvious result of this state of things, is a general fact avouched (like the cold of the higher regions) by all mountain travellers and all aeronauts, viz.—The habitual *hygrometric* or *relative dryness of those regions* IN CLEAR WEATHER. This is shown by very ordinary but very demonstrative facts. Thus Deluc remarked that the head of his walking stick always fell off in high mountain ascents, from the shrinking of the wood. We have seen that were there never any rain, &c., each stratum of the air would be in an exact state of saturation, and no evaporation would be possible from a moist surface at any level. "But[1] every act of precipitation, no matter how produced, unsettles this state of things and withdraws from the total mass of air some portion of its entire amount of vapour. As such precipitations, therefore, are constantly going on in some place or other, the atmosphere, as a mass, though incumbent on a wet and evaporating surface, is necessarily always deficient in moisture; and for the very same reason, every superior stratum is relatively deficient in comparison with that immediately beneath it, from which its supply is derived. In point of ultimate causation, then, there is a constant drain on the aqueous contents of the atmosphere, arising from changes of temperature. This drain extends to all its strata; but while the lower renew their losses from a surface hygrometrically *wet*, the upper draw *their* supply from sources more and more deficient in moisture." What the equatorial depression of the barometer at the sea level then is to the system of winds, such is the habitual hygrometric dryness of the air above the clouds to that of rains—at once an indication of a process in progress, and an efficient agent in continuing it. Wherever such relative dryness exists, vapour, by its own expansive *nisus*, is in the act of transfer *in an invisible state* from one atmospheric region to another, and the rapidity of that transfer is proportional, *cœteris paribus*, to the degree of dryness, as the velocity of a river at any point is to the inclination of its surface to the horizon. This by no means supposes a universally prevalent deficiency of vaporous tension. Complete saturation must exist at the points of evaporation and deposition, but at intermediate ones any amount of irregularity may prevail according to local circumstances.

(89.) *Hygrometry.*—To obtain a measure of this important element is the object of *hygrometry*, which consists in determining by instrumental means the absolute quantity of water existing, as vapour, in a given volume (suppose a cubic foot) of air, under any circumstances of temperature and pressure, and thence, from the known specific gravity of vapour, deducing its elastic force or tension. For the ways in which this may be accomplished, and for a description of the instruments used, the reader is referred to our article on HYGROMETRY. The method now adopted in preference to all others, as the most simple and convenient in practice, and leading to results which a very severe examination has proved to be quite satisfactory, is the simultaneous observation of the wet and dry thermometer. The formula of reduction, as it results from Dr Apjohn's elaborate investigations, is as follows:—Let t, t' be the respective readings of the *wet* and *dry* thermometers (in degrees Fahrenheit), h the barometric pressure in inches, f the elastic force of saturated vapour at the temperature t, and F its elastic force at the "Dew-point," or at that temperature which the air ought to have, so as to be exactly saturated with the quantity of vapour it actually contains. Then will

$$F = f - \frac{t'-t}{80} \cdot \frac{h}{30}; \ (a) \qquad \text{or, } F = f - \frac{t'-t}{96} \cdot \frac{h}{30}; \ (b)$$

the equation (a) or (b) being used according as t, the reading of the wet thermometer, is above or below 32°. f is found from a table of the elastic force of saturated vapour (see STEAM) at different temperatures, which will also be found in the *Admiralty Manual of Scientific Enquiry*, p. 321; and F being calculated from the above expression, the dew-point may be had from the same table, used reversely, *i.e.*, entering the table with F and finding the corresponding temperature. F known, the weight of water per cubic foot is found by multiplying the weight of a cubic foot of dry air at 30 inches (563·2124 grs.) by the specific gravity of steam for elasticity F, *i.e.*, by F × 0·6235, or by the formula F × 35·166. Copious tables for facilitating the whole process have been published by Mr Glaisher, (*Hygrom. Tables*, Lond. R. and J. E. Taylor. 1847.)

(90.) If the temperature of any given space containing vapour be higher than its dew-point, water exposed in it will evaporate. The air it contains is then said to be *relatively* more or less dry, or (in reference to the old chemical theory of solution advanced by Hutton, the language of which being convenient, is retained, though the theory is exploded), under-saturated. If lower, some portion of the vapour will begin to be precipitated, and this precipitate assumes various forms, according to the circumstances under which a sufficiently low temperature is produced.

(91.) I. *Dew.*—When the mass of moist air is simply brought into contact with a cold body, the result is *dew*, which is deposited in minute globules of water on the body, or if the temperature of the latter be below the freezing-point, ice or *hoar-frost*. The nature of these phenomena was, up to a late period, strangely misconceived,—the effect, by a mistake very common in meteorology, being put for the cause, the dew being regarded as *producing* the chill accompanying it, instead of the reverse. Dr Wells, in his "Essay on Dew"—a little work which deserves to be considered as a model of experimental inquiry—was the first to place in a clear light the true nature of the process. The chief facts to be accounted for are these:—1st. Dew (as distinguished from small rain or the moisture produced by visible fog) is never deposited except on a surface colder than the air. 2d. It is never deposited in cloudy weather; and so strict is its connection with *a clear sky*, that its deposition is immediately suspended whenever any considerable cloud passes the zenith of the place of observation. 3d. It is never *copiously* deposited in a place screened or sheltered from *a clear view of the sky*, even if the screen be of very thin material, such as muslin or paper suspended over it. 4th. It is most copiously deposited on all such bodies as are *good radiants and bad conductors of heat*, such as grass, paper, glass, wool, &c., but little or not at all on *bad radiants*, such as polished metals, which are also *good conductors*. And, lastly, it is never deposited if there be much wind. All these circumstances, as Dr Wells has shown, point to the escape of heat from the bodies exposed by *radiation out into space*, or into the upper and colder regions of the air, faster than it can be restored by counter-radiation or by *conduction* from contact with the warm air or with solid substances—wind acting in this respect with great efficacy, by continually renewing the air in contact. Hoar-frost differs only from dew by being frozen in the moment of deposition, and therefore accreting in crystalline spiculæ.

---

(92.) II. *Mist or Fog.* If a table of vapour tension, or the formula from which such a table is calculated, viz.

$$\text{Tab. Log.}\left(\frac{p}{30}\right) = -0.0085412197.t - 0.0000208109.t^2 + 0.000000058.t^3$$

where p is the elastic force of saturated vapour, corresponding to a temperature of 212°—t Fahr. (Biot, *Tr. de Phys.* i. 278), be projected into a curve, (fig. 4), taking t for an abscissa, and p for an ordinate, it will be found to have the form P D Q convex in every part towards its axis or asymptote A B. Hence, if between any two dew-point temperatures, A M, A N, an arithmetical mean A B be taken, and P, Q, the ends of the ordinates joined, B E will express the arithmetical mean of the extreme ordinates, or of the elasticities at the two temperatures, and B D (less than B E) that corresponding to their mean. Hence it is evident, that if two equal volumes of air, saturated at temperatures t and t' be mixed, since the mixture will have the mean temperature, water must be precipitated, the corresponding vapour tension being less than the mean. The form in which the moisture so precipitated first appears, will necessarily be that of very minutely divided particles, which, however, having the refractive power of water, reflect and refract light as such, and appear therefore as a mist, fog, or cloud of greater or less density and opacity, according to the amount precipitated in a given volume. It is a favourite dogma with many meteorologists, that the particles so precipitated assume the form, not of drops, but of hollow spheres or bubbles. De Saussure states, that he has seen such floating before his eyes in clouds and fogs on the Alps, and the dusty appearance of the vapour floating over a cup of coffee in the sunshine is adduced in proof. The strongest argument in their favour, however (for there is great room for optical illusion in such matters), is that adduced by Kratzenstein, that the sun striking on a cloud or fog produces no rainbow, which it ought to do were the water collected in spherical *drops*. This argument does not admit of a ready answer; but the difficulty, on the other hand, of conceiving any possible mode in which such bubbles can be formed, disposes us to believe that the extreme minuteness of the globules may perhaps be found to afford one, their diameters being probably of an order comparable with the breadths of the luminiferous undulations.

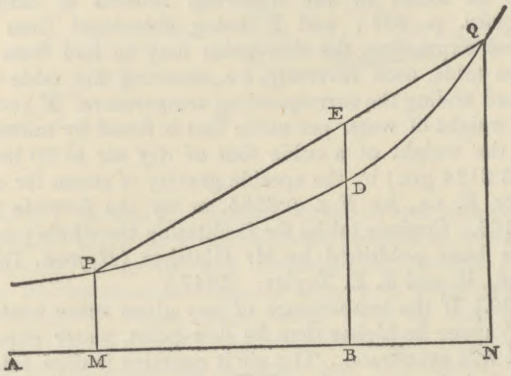

Fig. 4.

(93.) *Radiation Fogs and River Mists.*—When the air in contact with a radiating surface has been reduced in temperature to the dew-point, and has discharged its superfluous moisture in dew or frost, it remains saturated, and at the same time colder than that above it. If the ground be quite level, and the air quite calm, however, little or no mixture will take place, the upper air remaining uppermost, in the absence of any reason for its descent, or for the rise of that beneath. But if the ground slope ever so little towards a valley or hollow basin, the cold air will run downwards, and mixing with the air below, if sufficiently near to saturation, will depress the mean temperature of the mixture below its resultant dew-point, and produce fog. If the low ground be occupied by water or marsh, as the air reposing on it is sure to be saturated, copious precipitation will necessarily result. If dry, the mist produced will be less copious, and *may* not even take place at all. In the Weald of Kent, a district abounding in grassy slopes and winding and branching valleys, in the calm clear nights which are there so frequent, beautiful instances of radiation-fog are of perpetual occurrence. Immediately after sunset, in clear weather, dew commences—streams of cold air set downwards, following the lines of watershed (very sensible as descending currents), their course being marked with mist, thin and filmy at first, but acquiring density in its downward progress, and by degrees filling the valleys with fog, which, in the morning before sunrise, presents exactly the aspect of a winding lake or river of water, whose surface, perfectly even and horizontal, runs a sharply defined level line round every promontory and into every retreating nook. Descending into such a lake, under a full moon, a few yards below its upper surface, *a lunar rainbow is frequently seen* in the mist. We on one occasion resorted to a particular spot, well situated for the purpose, to look for one, and were not disappointed. (Here then, at least, the argument of Kratzenstein for vesicles is inapplicable; and we cannot forbear adding that by far the finest lunar rainbow we have ever been fortunate enough to witness (Nov. 12, 1848) was formed in a dense fog, *evidently close at hand*, and when not a drop of actual rain was falling. On this occasion the exterior or secondary bow was seen.)

(94.) It is a matter of ordinary remark, that the spring frosts are severer in hollows and low grounds than on slopes and heights. This is an obvious consequence of what has been said. The cold air flows downwards, and collects in the hollows, being replaced on the heights by the air of a higher stratum, unchilled by radiation.

(95.) A radiation-fog once formed tends to its own increase, by radiating off heat from its own particles, water in the liquid state being a good radiant of caloric.

(96.) When the warm current in the open ocean encounters a shoal, the lower water (of inferior temperature) is thrown up to the surface. The surface-water, therefore, on the shoal is colder than that of the surrounding ocean, and their atmospheres (saturated at the respective temperatures) mingling, produce those fogs which are observed to be prevalent in such localities. The fogs of Newfoundland are a remarkable instance in point. Fogs, too, are produced in the neighbourhood of floating icebergs, on a similar principle. The Arve, in its descent from Chamouni, occasionally presents the appearance of a river of warm water throwing up steam (though, in fact, many degrees colder than the air), from the mixture of the cold air above it with the saturated warmer air of the valley through which it flows (*Obs.* Aug. 1821).

(97.) *Barometric fogs.*—The temperature of a mass of air may be lowered beneath the dew-point, independent of radiation, contact of a cold body, or mixture with colder air, by the simple effect of its own expansion. This may take place in two ways, viz., 1st, By a rapid and considerable relief of barometric pressure from above; or, 2dly, By its own ascent into a higher region of the atmosphere. The first case takes place when the trough of an atmospheric wave (see art. 75) passes rapidly over the place of observation. The fog so produced comes on for the most part suddenly, and without any obvious cause. It is not rolled in from a distance by the wind, nor does a moderate wind dissipate it. It is not confined to the surface of the ground, but extends at once to great altitudes. It does not resolve itself into rain, but disappears, when the atmospheric equilibrium is restored, by the recondensation of the air, and the reappearance of its sensible heat. Such fogs are very common, and are precisely analogous to the cloud produced in the receiver of an air-pump by a rapid partial expansion of the air. They want a name, and that of barometric fogs seems not inappropriate.

(98.) III. *Clouds.*—When a body of vapour is generated from any warm evaporating surface, it ascends by its relative levity, losing sensible heat, as well by its own expansion as by its bodily transfer into and intermixture with colder air. Should the supply of vapour, however, not be very copious, and should it find itself, in its ascent, always in a region hygrometrically dry, it by no means follows that it will reach the point of precipitation; but should the reverse of these conditions obtain, viz., a copious and continued supply from below, and a state of vaporous tension already existing aloft approaching saturation, a portion will be precipitated, in visible cloud, on arriving at a certain level. When this process takes place in a calm state of the air, and the evaporating surface is limited in extent, or irregularly distributed in patches (as over marshy ground, rivers, lakes, &c.), or if any other cause dispose the vapour to rise in columnar bodies of greater or less extent, the summits of these are marked by protuberant masses or piles of cloud, with generally rounded outlines, which appear to repose on flat bases, indicating the "vapour plane," or that level where hygrometric saturation commences. To such clouds, in Howard's *Nomenclature of Clouds*, the name of Cumulus is assigned. They abound in the calm latitudes of the equatorial seas, and form a distinguishing feature in the meteorology of that region.

(99.) That the mere self-expansion of the ascending air is sufficient to cause precipitation of some of its vapour, when abundant, is rendered matter of ocular demonstration in that very striking phenomenon so common at the Cape of Good Hope, where the south or south-easterly wind which sweeps over the Southern Ocean, impinging on the long range of rocks which terminate in the Table Mountain, is thrown up by them (as marked by the direction of the arrows in fig. 5), makes a clear sweep over the flat table-land which forms the summit of that mountain (about 3850 feet high), and thence plunges down with the violence of a cataract, clinging close to the mural precipices that form a kind of background to Cape Town, which it fills with dust and uproar. A perfectly cloudless sky meanwhile prevails over the town, the sea, and the level country, but the mountain is covered with a dense white cloud, reaching to no great height above its summit, and quite level, which, though evidently swept along by the wind, and hurried furiously over the edge of the precipice, dissolves and completely disappears on a definite level, suggesting the idea (whence it derives its name) of a "Table-cloth." Occasionally, when the wind is very violent, a ripple is formed in the aerial current, which, by a sort of rebound in the hollow of the amphitheatre in which Cape Town stands, is again thrown up, just over the edge of the sea, vertically over the Jetty, where we have stood for hours watching a small white patch of cloud in the zenith, a few acres in extent, in violent internal agitation (from the hurricane of wind blowing through it), yet immovable, as if fixed by some spell, the material ever changing, the form and aspect unvarying. The Table-cloth is formed also at the commencement of a "north-wester," but its fringes then descend on the opposite side of the mountain, which is no less precipitous. Fig. 1, Pl. XIX., is a careful representation of such an exhibition of it on May 20, 1835.

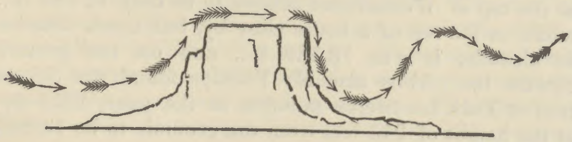

Fig. 5.

(100.) *Nomenclature of Clouds.*—The forms and aspect of clouds are very indicative of the circumstances under which they are in the act of forming or dissipating. Howard (*Askesian Lectures*, 1802) has endeavoured to embody their chief characters in a determinate nomenclature, which has been generally adopted. He divides clouds into three primary modifications: Cumulus, Stratus, and Cirrus, with intermediate forms graduating into one another under the names Cumulo-stratus, Cirro-stratus, Cirro-cumulus, and, lastly, a composite form, resulting from a blending or confusion of the others, under the name Cirro-cumulo-stratus or Nimbus.

(101.) *Cumulus* has been already described. Mr Howard defines it as *sursum crescens*, increasing upward from a horizontal base. This is in conformity with its origin. When sharply terminated by rounded spherical forms, which under sunshine appear as snow-heaps, the form clearly indicates the act of self-dissipation in invisible vapour into the upper relatively dry air.

(102.) *Stratus* consists of horizontal sheets. Its situation is low in the atmosphere, and may be considered as intermediate between cloud and fog, being chiefly formed at night, and under the influence of radiation either from the surface of a ground fog (as already described), or from impurities floating in the air itself. The latter is remarkably the case in great cities in which coal is chiefly consumed as fuel, and gives rise to those dense, yellow, suffocating fogs which infest London in the winter months. A very peculiar phenomenon exhibited by the London atmosphere has been described to us by the Astronomer-Royal, and appears to be referable to the same cause. In calm evenings after sunset, as seen from the Royal Observatory on Greenwich Hill, the vast irregular mass of smoke hovering over London appears to subside. Its heaped and turbulent outline becomes flat, and sinks rapidly into a low level cloud-bank, with a very definite outline, and fair sky above. It would seem that each particle of soot, acting as an insulated radiant, collects dew on itself, and sinks down rapidly as a heavy body. Stratus is also sometimes formed very suddenly on a higher level, when in a clear, calm night the general temperature of the air sinks by radiation, or by diminution of atmospheric pressure, till at some definite altitude above the surface the dew-point is attained. Thus, on the night of April 19, 1827, the sky, up to 16h. 16m. Sid. T, being perfectly cloudless, and not a breath of wind stirring, stratus at a high level commenced in the eastern horizon, and in eight minutes had extended to the western, obscuring the whole sky, the calm remaining unbroken. In this case the velocity of propagation of the edge of the cloud from east to west (or following the sun) could not have been less than 300 miles per hour (*Mem. Ast. Soc.* iii. 51.)

(103.) *Cirrus* consists of fibrous, wispy, or feathery clouds occupying the highest region of the atmosphere. The name of mares' tails, by which cirri are commonly known, describes their aspect well. Of all forms of cloud these present the greatest variety. Their filamentous structure clearly indicates them as either in the act of originating from the union of aerial currents running parallel to each other, or as the residues of dissolving cloud drawn out into fibres by wind. Mr Howard is disposed to assign to them an electric origin, or at least to attribute their fibrous appearance to electricity, but in this view we cannot coincide. From the great elevation of cirrus it is more than probable that its particles are frozen, and of course crystalline, and that to this constitution it is owing that halos, coronæ, and other optical appearances referable to reflexions and refractions in ice crystals, appear almost invariably in this cloud and in its derivative forms, especially the cirrocumulus. It is said to be often a precursor of windy weather.

(104.) The *Cirro-cumulus*, most characteristically known as a " mackarel sky," consists often of small roundish masses disposed with more or less regularity and connection. They usually float at great elevations, and often appear as a loftier stratum through the intervals of lower clouds, contrasting strongly by their slow (and sometimes contrary) movement, with the scud and drift of the inferior masses. They are frequent in summer, and attendant on dry and warm weather.

(105.) *Cirro-stratus* " appears to result from the subsidence of the fibres of *cirrus* to a horizontal position, at the same time approaching laterally. The form and relative position when seen in the distance frequently give the idea of shoals of fish." It often precedes wind and rain, and often forms the ground on which halos and parhelia are projected.

(106.) *Cumulo-stratus* would seem to be the modification of *cumulus*, when the columns of rising vapour which go to form it arrive in an upper atmosphere not sufficiently dry to round off its summits by rapid evaporation, allowing them to spread horizontally and form flat-topped, mushroom-shaped masses, the upper parts of which are often curled by the wind of an upper current into cirrous wisps, or cleanly cut off by a horizontal plane, forming an " anvil-shaped cloud" with a lateral projection, generally considered as a precursor of wind below. Its tendency is to spread, overcast the sky, and settle down into the *Nimbus*, and finally to fall in rain. When two strata of clouds on different levels tend to unite, it is evident that the intermediate region must be nearly or quite in a state of hygrometric saturation. The cloud then forms confusedly and in irregular masses through the whole region, and finally resolves itself into heavy rain.

(107.) When cloud is present, the sun's rays are of course prevented from reaching the earth directly, and their heat is diffused through the general atmosphere—thus softening and mitigating their ardour. When the sun shines on a cloud, which absorbs its heat, the cloud itself is necessarily partially evaporated, and the vapour by its levity tends to produce an upward current, and thus to counteract the effect of gravity on the globules of which it consists. A globule of water 1-4600ths in. in diameter, in air of five-sixths of the density on the surface, or at the height of about 5000 feet, would have its gravity counteracted by resistance, with a velocity of descent of one foot per second (supposing no friction and no drag); and even if the terminal velocity were reduced to half that quantity by these causes, would still require some such upward action to enable it to maintain its level—a circumstance which sufficiently accounts for the lower level generally observed of cloud during the night. It is more than probable, however, that, when not actually raining, a cloud is always in process of generation from below, and dissolution from above, and that the moment this process ceases, rain, in the form of " mizzle," commences. In a word, a cloud in general would seem to be merely the visible form of an aerial space in which certain processes are at the moment in equilibrio, and all the particles in a state of upward movement.

(108.) IV. *Rain.* In whatever part of a cloud the original ascensional movement of the vapour ceases, the elementary globules of which it consists being abandoned to the action of gravity begin to fall. By the theory of the resistance of fluids, the velocity of descent in air of a given density is as the square root of the diameter of the globule. The larger globules, therefore, fall fastest, and if (as must happen) they overtake the slower ones, they incorporate, and the diameter being thereby increased, the descent grows more rapid, and the encounters more frequent, till at length the globule emerges from the lower surface of the cloud, at the " vapour plane," as a drop of rain; the size of the drops depending on the thickness of the cloud stratum, and its density. Rain indeed has been observed to fall (at least apparently) from a cloudless sky, but the occurrence is one of extreme rarity, and it seems hardly possible to be certain that it has not been brought by wind at a high level from very great distances. A very minute rain from a clear sky is known in France by the name of *serein*, and seems to be not uncommon.

(109.) The quantity of rain which falls on any given place may be measured by the very simple contrivance called a " rain-guage," which is an open vessel of a definite aperture (suppose a square foot), and of a funnel shape below, to conduct the rain fallen into a graduated vessel where it can be measured to a nicety, a very minute superficial depth of rain being thus read off on a magnified scale, even though hardly more than enough to wet the surface. It is usually recorded in inches of actual depth, and the wetness of a year or of a season is expressed by the number of inches and parts to which the earth's surface would be covered, if it could neither run off, sink into the soil, or evaporate. Some very extraordinary and unexpected facts respecting the fall of rain have been disclosed by the use of this instrument, which would appear to indicate that its formation is by no means limited to the region of visible cloud. At one and the same place a series of rain-guages, placed at different elevations above the soil, indicate very different quantities of rain, the amount being *greater* at the *lower* level. Thus Dr Heberden found in twelve months, from July 7, 1766, to July 7, 1767, the amount of rain at the top of Westminster Abbey to be only 12·099 in., while on the top of a house close by, but much inferior in altitude, it was 18.139 in., and on the ground 22·608 in. Thus also Mr Phillips found the fall of rain at York for twelve months, in the years 1833-34, at the height of 213 feet from the ground, to be 14·963 in.; at 44 feet, 19·852 in.; and on the ground, 25·706 in. Again, at the Observatory of Paris the ratio of the rain collected during the nine years (1818-1826) on the terrace of the Observatory, and 3 metres from the ground (or 27 metres = $88\frac{1}{2}$ feet lower in level) was that of 1 : 1·116, the difference being much less proportionally than in England, where the ratio from Mr Phillips's observations is that of 1 : 1·719 at 213 feet, and 1 : 1·296 at 44 feet. The usual account given of this phenomenon (Kämtz, i. 419) is that rain falling from a high level, and therefore colder than the temperature of the air at the surface of the ground, arriving in an atmosphere nearly or quite saturated with moisture, condenses on itself, or causes the condensation, in the chilled air, of an additional quantity of vapour. But it is evident that this cause, though not uninfluential, is totally inadequate to account for so great a difference. Admitting a given weight of rain to arrive at 213 feet from the ground, with the temperature of the region at which it was formed unaltered, and supposing it to acquire in the remaining 213 feet the full temperature of the air (both of them extreme and indeed extravagant suppositions), admitting too (though hardly less extravagant) the mean height of formation of the rain to be 12000 feet, it would bring down with it a cold of 40° Fahr., which would condense (whether on the drops or in saturated air if diffused through it) only 40-960ths, or 1-24th = 0·042 of its weight, = one-seventeenth of the quantity to be accounted for. Still less can the effect be due to a greater *obliquity* of fall at a higher than at a lower level, since the same quantity of rain must fall on the same horizontal surface after changing its obliquity as before. Dr Heberden, in the spirit of that meteorology which refers everything not clearly understood to electricity, ascribes an electrical origin to the phenomenon. The real cause is yet to seek, and there is no more interesting problem which can fix the attention of the meteorologist. Visible cloud rests on the soil at low altitudes above the sea-level but rarely: and from such cloud only, would it seem possible that so large an accession of rain could arise.

(110.) The amount of rain which falls habitually per annum in any locality depends on a great variety of circumstances, the most influential being its proximity to large bodies of heated water, such a prevalent direction of wind as shall not drift the vapour away from it, and the absence of any lofty mountains in the direction of the moist wind, to act as a barrier by causing its depositions on them. As we recede from the sea into the interior of great continents rain becomes rare, especially if the soil be sandy. Thus in the Great Sahara of Africa rain is unknown, as also in Arabia and part of Persia, in the great desert of Gobi, in the table-land of Thibet, &c. The greater part of the enormous evaporation of the equatorial seas is at once condensed and discharged again in rain from the cumuli which mark its up-rush into the higher and colder regions of the air, the rain being most continuous in those latitudes between the tropics, over which for the time the sun is vertical, or in the region of the calms. In this zone the nights are for the most part clear, but as the day advances the clouds thicken and pour down torrents of rain, clearing again at sunset.

(111.) Rain is of unfrequent occurrence, however, in the zones on either side of the calms, where the trade-winds blow steadily and regularly. These winds themselves, coming from higher latitudes, are *acquiring temperature and taking up moisture* from the sea. The returning counter-currents having discharged their first overload of moisture, pursue their course aloft, free from cloud and relatively dry; and in the neutral interval between them and the opposite lower current, cloud is not generated, or rain produced, by the intermixture of the two—the upper portions of the trades not being saturated, for the reason just adduced. The clouds which do occur in these winds belong not to their higher strata but to a much inferior level, not exceeding five or six thousand feet in altitude, while the medial line between the winds has nearly double that elevation. Such at least are the phenomena on Teneriffe, as exhibited during the late residence of Mr C. P. Smyth on the summit of that mountain for a fortnight in the month of August, during the whole of which time the sea horizon was never once visible, a stratum of these low clouds lying uninterrupted in every direction, the *upper half* of the peak being free from cloud, and *its summit*, at 12500 feet, just surpassing the medial line, and coming within the upper or SW. current.

(112.) Between the tropics there is, properly speaking, no winter or summer. The year is divided into a dry and wet season—the dry, when the sun is in the opposite hemisphere, and the trade wind blows strong; the wet, when in the same, and approaching the zenith. In the neighbourhood of the equator, where the sun passes the zenith twice at several months' interval, there are two dry and two wet seasons, or rather two unequal maxima and minima of rain. Where monsoons prevail, however, the law of rain is different. Thus, on the eastern coast of the peninsula of India, the rains occur during the north-east monsoon, and on the western during the south-east or trade.

(113.) Beyond the tropics, where the *anti-trade* or returning current descends to the level of the earth's surface, and by degrees takes up the temperature of our milder latitudes, its vapour, held so far in abeyance, becomes available for the production of rain, unless intercepted, as above indicated, by some lofty mountain barrier tossing up the stream and prematurely precipitating its vapour. Where this obstacle does not exist, however, the rains are distributed in the extra-tropical regions with considerable indifference as to season; in some, indeed, a certain approach to a wet and dry division of the year prevails, as, for instance, along the coast of Portugal, as well as in Italy and the south of France, where scarcely any rain falls in summer, while at Pekin the contrary rule prevails. Since, however, the deposit of water from the air, as it travels, must of necessity bear some rude proportion to the actual quantity *in transitu*, the amount of rain or snow which falls on any country must, on a general average, diminish as the latitude increases, a conclusion confirmed by observation.

(114.) The west coasts of England and Ireland form a rather remarkable exception to this law. They receive with the west and south-west winds which generally prevail, the vapour of the Gulf Stream. In consequence the annual fall of rain is not only much greater than on the eastern and southern coasts, but in one district, that of the Lakes of Cumberland, is quite enormous. The annual fall at Seathwaite, in Borrowdale (Lake district) amounted, according to the careful observations of Mr Miller, to no less than 141·54 inches on an average of three years; while that in London is only $23\frac{1}{2}$. To bring this result into comparison with what obtains elsewhere, we subjoin a table (see next page) of the mean annual amount of rain in some of the more remarkable localities.

(115.) Rain, except in the tropical regions, is perhaps the most irregular of all meteorological phenomena, both in respect of the frequency of its occurrence and in the quantity which falls in a given time. The quantities recorded are, in some instances, truly astonishing. It is considered, in the greater part of England, a heavy rain if an inch fall in the course of twenty-four hours; yet at Seathwaite, above mentioned, 6·62 inches are recorded by Mr Miller to have fallen on November 27, 1845, in that time. At Joyeuse (Ardeche), in France, 31·173 inches fell in twenty-two hours; at Genoa, 30 inches in twenty-four hours; at Gibraltar, 33 inches in twenty-six hours. "On the mountain tops overhanging Bombay, 24 inches of rain have been recorded in a single night."—(*Perry, Bird's Eye View of India*, p. 17). These are, however, only sudden, unsustained falls. But in tropical regions we have instances of what may almost be called deluges. Humboldt collected, at Rio Negro, in the rainy season in May, *as an ordinary rain*, $1\frac{3}{4}$ inch in five hours. Admiral Roussin found, for the amount of rain at Cayenne, between the 1st and 24th February 1820, no less than 12 feet 6·96 inches, and on one night, between 8 P.M. and 9 A.M., he collected $10\frac{1}{4}$ inches. At Cherra Ponjee, in the Khasyah mountains, east of Calcutta, nearly 600 inches per annum are stated to have fallen.

(116.) V. *Hail.*—In a balloon ascent performed by Messrs Green, Rush, and Spencer, on September 4, 1838, after mounting to an altitude of 19185 feet, during which ascent the thermometer, at 12000 feet, marked 46° Fahrenheit, they found, on descending again to the last mentioned level, a temperature of 22° Fahrenheit only, or 24° colder than in their ascent. At the same time, they found there a heavy fall of *snow* in progress. It is evident that this arose from the condensation of vapour *at* that level, and that, from the intrusion of some current, a mass of intensely cold air had been introduced, which, finding vapour near saturation, converted it into snow. It is equally evident that, had the latter condition prevailed not at the level in question, but at a somewhat higher, where the condensation might have been into *rain* very near the freezing point, the drops, in descending, would have been frozen solid and fallen as *hail.* It might have been so equally, had the precipitation been so copious as to allow the coalescence of a great number of minute particles in a nascent state into drops frozen together instanter, since there is good reason to believe that the solid form is never assumed without transition through the liquid, however momentary.

(117.) The generation of hail seems always to depend on some such very sudden introduction of an extremely cold current of air into the bosom of a quiescent, nearly saturated mass. Hailstorms are always purely local phenomena, and never last long. They often mark their course by linear tracks of devastation, of great length and very small breadth. In the hailstorm of July 13, 1788, which passed across France from south to north, two such tracks were marked, of 175 and 200 leagues in length respectively, parallel to each other, the one four leagues broad, the other two, and separated by a tract five leagues in breadth, in which only rain fell. A similar character is very common, though not to such an extent. Such linear hailstorms are always attended with violent wind, sudden depression of the barometer, indicating a great commotion in the air, and probable mingling of saturated masses of very different temperature. To attribute to hail, as is often done, an electrical origin, because hail is often accompanied with thunder and lightning ("hailstones and coals of fire"), seems to us to be putting the effect for the cause.

(118.) Hail may be very properly distinguished into single hailstones and aggregated masses. Single stones have generally a crystalline structure, radiating from a centre if large, forming spherical, oval, or rounded masses, often marked out (on making a section) into concentric layers, like the rings in the section of a branch. They fall from the size of small peas to that of an egg, an orange, or a man's head, and weighing from a few grains up to fourteen pounds and upwards. Dr Thomson, in his *Introduction to Meteorology*, a work in which the reader will find assembled a most extraordinary collection of the recorded marvels of meteorology, gives many instances of the fall of large hail-stones. One, described by Captain Delerosse, as having fallen at

Baconniere, July 4, 1819, fifteen inches in circumference, had a beautiful radiated structure (fig. 6), marking it as a single stone, formed in passing through two distinct regions of condensation. Dr Buist stated to the Bombay Geographical Society, that in India the hail-stones are from five to twenty times larger than those in England, often weighing from six ounces to a pound, seldom less than walnuts, often that of oranges and pumpkins! These storms are almost always accompanied by violent wind and rain, thunder and lightning, and are frequent in the delta of the Ganges, especially in the low country within fifty miles of the Bay of Bengal.

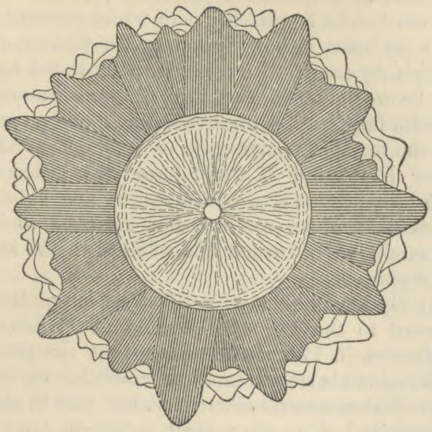

Fig. 6.

(119.) Great hail-storms are often preceded by a loud clattering and clashing sound, indicating the hurtling together of masses of ice in the air. The recent experiments of Professor Tyndall on the reuniting of broken ice by "regelation," or a sort of welding, fully explains the formation, under such circumstances, of large masses of ice of irregular forms in this aerial conflict. Such are recorded to have fallen of almost fabulous magnitude. In Candeish, in 1826, in a hail-storm which perforated the roofs of houses like small cannon shot, a mass fell which took some days to melt, and must have weighed more than a hundred-weight.—(*Malet.*) On May 8, 1832, a mass fell in Hungary a yard in length and nearly two feet in thickness.—(*Thomson.*) And if it be true, as stated in the *Ross-shire Advertiser* in 1849, that a block "of irregular shape, nearly twenty feet in circumference," fell in August of that year on the estate of Mr. Moffat of Ord, immediately after an extraordinarily loud peal of thunder, Heyne's relation of a hail-stone as large as an elephant, at Seringapatam, in the reign of Tippoo Sultan, may perhaps find believers. The Ross-shire mass is stated to have been composed of lozenge-shaped pieces, one to three inches in size, firmly congealed together.

(120.) VI. *Snow.*—When time is allowed, and the process of precipitation and congelation takes place in a less tumultuous manner, so as to allow the deposited particles to accrete according to regular arrangements, small spiculæ form, crossing one another at angles of 60°, the primitive crystal of ice being a rhomboid of 60° and 120°, producing as one of its secondary forms the regular hexagonal prism, having (as all such crystals) one axis of double refraction parallel to the axis, as is easily seen in a sheet of ice formed in still water on exposure to polarized light. When deposited as hoar-frost in the condensation of dew, the crystallization is confused by contact with and adhesion to the radiant body, but when supported only by air and receiving accretion on all sides, a high degree of regularity is attained, and the most perfect and symmetrical six-rayed star-like forms arise, of which (drawn from actual observation of the falling spangles, in very cold weather) Dr Scoresby has given several figures, and Mr Lowe and Mr Glaisher have more recently published series of engravings. The variety of forms affected by these delicate mechanisms is infinite; the beauty of their patterns incomparable. By Mr Glaisher's permission we have transferred a few of his figures to our pages (Pl. XIX., figs. 2-15). Mr Lowe has been fortunate enough to observe them in the act of forming, and to witness the whole process of construction of some of their most elegant and complex varieties.

(121.) It can hardly be doubted that clouds at great elevations consist of frozen particles. The phenomena of parhelia and some species of halos are explicable only by the refraction and reflexion of light in prisms, with angles of 120° and 60°, as M. Bravais has shown (following up the theoretical views of Mariotte and Young) by a neat and elegant mechanism. Now these are the angles of the primitive rhomboid actually measured by Dr Clark. In *such* clouds, at all events, vesicles cannot exist, and in the gradual melting of the snow spangles, the laws of capillary attraction, by filling up all re-entering corners, would effectually preclude the inclusion of the smallest air-bubble, though a compound snow-flake hurriedly melted might now and then entangle one.

(122.) Fallen snow of even a very moderate depth, is a powerful agent in mitigating the extreme effects of frost on the soil. Owing to its loose texture and its inclusion of eight or ten times its bulk of air, it is a very bad conductor; and although its upper surface may be cooled by radiation or otherwise to a very low point, its interposition cuts off the communication between the chilled surface and the soil beneath it. The farmer looks to a fall of snow as his best security for the preservation of his autumn-sown and sprouting crops through the winter.

(123.) *Level of Perpetual Snow.*—Since by ascending into the atmosphere a temperature inferior to congelation is everywhere met with, it is evident that a mountain of some certain elevation will have the mean temperature of its summit at or below the freezing point; and although it does not follow that where the mean temperature is precisely 32°, snow will necessarily be found all the year round (since this will depend on the greater or less accumulation of it in the cold seasons, and on the greater or less evaporation in the warmer ones), yet, somewhere about this limit, and at all events at no great elevation above it, we must expect to encounter the phenomenon of perpetual snow. If we take 1° Fahr. for the average depression of the thermometer for 100 yards of increased altitude in mountain ascents, as a rough approximation, and assume 84° for the mean equatorial temperature, this would give $(84-32) \times 300$ ft. $=15600$ ft. for the height above the sea level, at which, under favourable circumstances, the perpetual snow line may occur under the equator; we say under favourable circumstances, for it is evident that if the mean temperature of the year be ever so little above the freezing point, we cannot expect snow to lie all the year round, especially on the summit of a mountain where all the water produced by melting immediately runs off, and therefore ceases from that moment to act as a reservoir of cold. Now the mean of Humboldt's determinations of this element for the mountains of equatorial America from 4°.46 N. lat. to 1°.30 S. (*Asie Centrale*, p. 461, tab.) gives 4774 metres $=15670$ feet.

(124.) This, however, must be considered as a *minimum* reckoning. In the celebrated work just cited, Baron Humboldt has given a table of the most authentic determinations of the snow-level for 34 mountains *trigonometrically* measured from 71° N. lat. to 54 S. Of these the mean annual temperatures *at the sea-level* are correspondingly stated for 18 stations — calculating on which it would appear that about 2100 feet on an average ought to be added to the height calculated on the decrement of temperature assumed in the last article, to give that of the snow line.

(125.) In fact, however, no general rule or principle of calculation can be laid down, and though attempts are not wanting to construct formulæ which shall afford a close approximation to the height in any geographical position, it is impossible to place any reliance on them. This will be the more evident when we come to consider the causes which must of necessity influence the result. Of these the principal are—1st, The situation of the slope on which the snow lies on the mountain chain, with respect to the incidence of the sun's rays. Thus, on the southern declivity of the Maladetta in the Pyrenees, the level in question is nearly 1200 feet higher than on the northern; 2d, and more especially its situation with respect to the direction of the wind, which brings the chief supply of moisture to be deposited in snow, and which will naturally be heaped on that side of the mountain which acts as an obstacle to its progress. To these causes must be added, 3dly, the greater or less steepness of the slope; and above all, 4thly, the greater or less degree of habitual *dryness* of the region in which the mountain is situated, by which the snow itself is evaporated and carried off. So great is the influence of these causes, that in the Himalayas, where some of the mountain peaks attain the enormous altitude of 28000 feet, the snow line on the southern side of the great chain occurs at 13000 feet, and on the northern at 16600, or even (according to Mr Lond) 18300, the moist winds of the SW. monsoon depositing their snow almost wholly on the southern side, while the northern is exposed to the evaporation of one of the driest regions of the globe. On the other hand, on the eastern slope of the Cordillera, in Chili, the snow-level occurs at 15900, while on the western it rises to 18500 (Humboldt's *Asie Centrale*, iii. 360), the difference again being attributable to the direction of the wind (the SE. trade), to which the chain of the Andes forms a barrier, and of which, to a certain extent, it diverts the course, and the excessive aridity of the region between the chain and the Pacific, in which rain is a thing almost unknown. Apart from the illustration it affords of the distribution of temperature in different strata of the atmosphere, the subjects of the level of perpetual snow, the inferior prolongation into glaciers, and the occasional instances where ice occurs in caves far below the snow-line, preserved throughout the summer (or even in open pits, as in the quarries of the Niedermennig on the Rhine), belong rather to physical geography than to meteorology proper.

(126.) VII. *Atmospheric Electricity, Lightning, Thunder, &c.*—The community of nature between lightning and electricity was suspected from the very earliest discovery of the electric spark, by Wall, in 1708, but it was not till 1752 that Franklin suggested the idea of obtaining evidences of their identity by erecting pointed metallic conductors properly insulated. The experiment was tried in France with success, but Franklin, tired of waiting for the erection of a pointed rod on a spire in Philadelphia, had the happy idea of flying a kite and exploring the string for electricity. The experiment succeeded, meriting by its success that sublime image which forms the inscription on one of his medals,

> "Eripuit fulmen cœlo, sceptrumque tyrannis."

Franklin's kite was flown with ordinary pack-thread, held by a few feet of silk line, and the electric effects obtained by him were feeble, though sparks were produced. But Romas, using in place of a string, a fine wire, obtained, during a thunder-storm (1757), flashes of fire nine or ten feet in length, thirty of which succeeded each other in an hour, besides innumerable flashes of seven feet, which, by means of a conductor, insulated by a glass handle, he was enabled to direct at pleasure—not altogether with impunity, being struck down on one occasion; though the terrible catastrophe of July 26, 1753 (when Professor Riehmann of Petersburg was killed on the spot while explaining to a companion the construction and movements of an electrometer attached to his conductor) might have warned him of the dangers attending such experiments.

(127.) By means of a wire 370 feet long, attached by a silk cord to the top of a steeple at Maintenon, the Abbé Mazeas, in 1753, ascertained that the presence of a thunder-cloud is not an essential condition for the manifestation of atmospheric electricity, but that in clear, dry, and especially hot weather, electric effects are produced at all hours between sunrise and sunset. He even noticed a certain regularity of diurnal increase and decrease. From that time the exploration of atmospheric electricity has formed a part of meteorological enquiry. It is performed by erecting in a clear exposure, at a considerable height, a pole, carrying at the top an insulated and pointed metallic rod, connected with an insulated wire to convey the electricity into a fitting place for examination. There it communicates with an electrometer, a Leyden jar, a condenser, or an apparatus for measuring the length of the spark (if any), by which the kind of electricity (vitreous or resinous) may be tested, and its intensity measured and registered. When violent, a bell is made to ring by the alternate attraction and repulsion of a metal ball, suspended by a silk thread. The best collector of electricity, which is often used when a rod like a fishing rod, with an insulating handle, is thrust out from an upper window, is a bit of amadou, held in a metallic forceps, the smouldering smoke of which being an excellent conductor, as it were searches the air into which it ascends, and conveys its electricity down to the wire attached. A sponge moistened with alcohol, and set on fire, is also an excellent collector.

(128.) Read, to whom we owe a very elaborate series of researches, continued almost hourly, without intermission (except for sleep), for two years (1791-2). Coulomb, Cavallo, Saussure, Schubler, Colladon, and others, have shown that the normal character of aerial electricity is positive or vitreous. Of 987 trials, Read found that 664 gave positive indications; but as his method of observation improved, he found that the ratio of positive cases increased; and moreover, that a great number of the negative were only apparent, arising from induction, the top and bottom of his rod giving contrary indications. Out of 10500 observations made at the Kew Observatory in 1845-47, 10176 showed positive, and only 364 negative electricity—the latter being almost always accompanied with heavy rain.

(129.) Not only is the normal electricity of the atmosphere positive at all seasons, hours of the day, and places, but the intensity of its manifestation is invariably greater the higher in it a conductor is raised. This would appear to be the case even in the very highest regions. Thus in Gay Lussac's ascent, a wire 150 feet long, hung from the car of the balloon, manifested a *negative* state of induced electric tension at its *upper* extremity (where only it could be tested), thus indicating a higher state of positive electricity in the highest strata; or, in other words, the usual condition of electric observation on the ground being reversed, and the state of the *lower* strata being explored by the wire, it was found to be *relatively* negative. Hence it manifestly follows that, relatively to the air, the earth's surface is habitually negative—the positive electricity being repelled inwards, and the negative drawn to the surface. As moisture is withdrawn from the lower strata of the air, by deposition in dew when evaporation ceases; so electricity, when not in the act of being supplied from below (as presently to be shown), is perpetually, though slowly, drawn off by conduction.

(130.) Fog is, for the most part, strongly electric, and invariably positive, even during the deposition of dew. Read found the vapour near the ground, in the act of condensing into dew, always highly electric. The importance of this remark will presently appear.

(131.) From the observations of Saussure, Arago, Schubler, and others, it appears that the electric tension of the atmosphere is subject to a diurnal periodicity with a double maximum and minimum. The maxima occur about 10 A. M. and 10 P. M., and the minima from noon to 4 P. M., according to the season (summer or winter), and a little before sunrise. The nocturnal minimum is much more strongly marked than the diurnal. The electric tension is also stronger in winter than in summer. On the open sea, except during storms, there is but little indication of atmospheric electricity, but the masts and rigging of ships interfere greatly with the requisite arrangements for observing it.

(132.) The origin of aerial electricity has been traced with every appearance of probability to evaporation. Saussure and Beccaria proved by many experiments that the rapid evaporation of water from heated bodies gives rise to a separation of the vitreous and resinous electricities (see ELECTRICITY), the one being carried off by the vapour, the other remaining in the residue or being conducted away by its support, but nothing uniform or consistent either as to the positive or negative character of the electricity thus conveyed into the air, or its amount under given circumstances was obtained, until the subject engaged the attention of M. Pouillet, who, in a remarkable memoir read to the Academy of Sciences in 1825, announced the following results:—1*st*, Simple change of state from the solid or liquid to the vaporous form of any body, is unaccompanied by any electrical excitement. The evaporation of pure water or of any substance not decomposed, or at least partly decomposed in the act, produces none whatever. 2*d*, When evaporation is accompanied with chemical change, electricity is developed. Water evaporated from alkaline solutions carries off resinous and leaves behind vitreous electricity. The reverse happens when it evaporates from an acid, or from neutro-saline solutions, including that of sea salt, or from heated iron which it oxidizes. 3*d*, The processes of vegetation in which water is abundantly separated from the other constituents of plants, and perhaps also their disengagement of oxygen under the influence of light, or carbonic acid under contrary circumstances, are also sources of electricity.

(133.) Thus we are led to look to the immense evaporation both from sea and land, and to the vital processes going on in the latter, as furnishing at least the chief supply of electricity to the air. Volcanic eruptions and conflagrations contribute their quota. Thus in the great eruption of Vesuvius in 1794, described by Sir William Hamilton, the dense cloud of mixed vapour, smoke, and ashes, which overhung the mountain, was overcharged with lightning, which darted around in continual flashes (*ferille*) upon Somma and the slopes of the crater. Wind, too, by its friction, or by that of the dust, &c., which it carries with it, may also contribute somewhat to the general stock.

(134.) In what state free electricity exists in gaseous matter is at present a mystery. The simplest conception we can form, is that of its investing the ultimate molecules of vapour as an electric coating of infinitesimal tension, far too feeble to discharge itself from one to the other, and so to escape by what is called "*conduction through a moist atmosphere.*" If this be granted, we can conceive the co-existence at a distance from each other of masses of air oppositely electrified, and equally capable of giving out a portion of their contents by *contact discharge*, to a rod, wire, flame, &c., and thus explain the collection of electricity by these means from the air, and its diversity of character as to *plus* and *minus*.

(135.) But whatever may be the state of the ultimate molecules of vapour, it seems impossible but that when a great multitude of them lose their vaporous state by cold, and coalesce into a drop or snow-spangle, however minute, that drop will have collected and retained on its surface (according to the laws of electric equilibrium), the whole electricity of its constituent molecules, which will therefore have some finite, though very feeble tension. Now, suppose any number (1000 for instance) of such globules to coalesce, or that by successive deposition one should gradually grow to 1000 times its original *volume*. The diameter will be only 10, and the surface 100 times increased. But the electric contents being the sum of those of the elementary globules, will be increased one thousandfold, and being spread entirely over the surface, will have a tenfold density (*i. e.* tension). This simple view of the subject, put forward in the most distinct form, at the very origin of the discussion of the nature of lighting by Eeles (*Phil. Tr.* 1752, p. 527), needs only to be carried a very little farther than the then state of electric knowledge enabled its author to do, to render a complete explanation of all the ordinary electric phenomena. And, first: the comparatively high electric state of fog (and cloud is nothing else), is an obvious consequence of it. Every minute globule of water, of which fog consists, carries about with it an electric coating, which it is ready to part with by constant discharge to the surface of any conductor, and the denser the fog, and the larger its globules, the greater the amount of electricity given out. Again, the electricity of the superficial air occasioned by the deposition of dew, is in perfect accordance with this view, and is a corollary from the general proposition too obvious to need insisting on. Again, as regards the diurnal fluctuation, when the air is exhausted of its vapour by night deposition in dew, and by upward diffusion without a new supply, the electricity is at its minimum. It increases as new vapour rises under the influence of the ascending sun, decreases again (though not much) as the increasing warmth of the air renders it more capable of holding the still larger amount of vapour uncondensed, and as the vapour itself rises rapidly to form cloud, increases again as night comes on, dew begins to form at sunset, and vapour to settle into globules by atmospheric radiation, and once more decreases as the quantity of these electrified globules diminishes by deposition and diffusion. There is no doubt a certain amount of slow conduction back into the soil, the intimate nature of which it is very difficult to conceive rightly, but of which the phenomena of electricity of weak tension furnish abundant examples by which a considerable portion of the electricity near the surface is returned to the earth, and which is more effective, the more "relatively moist" is the air, and by which the march of the diurnal fluctuation, and its epochs of maxima and minima, are materially influenced.

(136.) When condensation of vapour takes place aloft, as when a cloud is formed, the tension on the surface of its globules may increase by the process explained, till a portion of the electricity is enabled to work its way to the surface of the cloud, regarded as a conductor, though a bad one, by the general law of electric equilibrium, which tends to throw out the fluid to the surface, and universally, no doubt, the exterior of a cloud is in a higher state of tension than the interior, and its under surface, as opposite the earth, than its upper. When the almost infinite dimensions of a cloud, in comparison with one of its constituent globules, is considered, it must be evident that, were the whole electricity of each globule thus at once determined to the surface, a tension so enormous would arise as would discharge the whole in a single flash, at whatever height the cloud might be. But this is assuredly not the case. Probably but a very minute fraction of the interior electricity is at once conveyed to the surface, the further communication being delayed until the exterior tension is relieved, either by slow dissipation or by self-discharge. When this happens, the accumulation commences anew by the same kind of percolation (if we may use the term to express the outward struggle of the electricity of the globules), till another and another discharge at length exhaust the supply.

(137.) It will easily be seen, that when thousands of these electriferous globules again further coalesce into rain drops, a great and sudden increase of tension at their surface must take place. Their electricity, then, is enabled to spring from drop to drop, and rushing in an instant of time from all parts of the cloud to the surface, a flash is produced. Accordingly, in thunder-storms, it is the commonest of all phenomena to find each great flash succeeded by a sudden rush of rain at such an interval of time as may be supposed to have been occupied in its descent. The sudden precipitation of large quantities of rain, and especially of hail, which is formed in a cold region where the insulating power of the air is great, is almost sure to be accompanied with lightning, which the usual perversity of meteorologists, where electricity is in question, long persisted, and even yet persists, with few exceptions, in regarding as the cause, and not the consequence of the precipitation. The theories of the electrical formation of hail which have been advanced, indeed appear to us too absurd to need a moment's consideration. The utmost amount of electrical agency which we can conceive influential in determining precipitation, is the sudden relief of tension on the discharge of a flash, which may permit, and perhaps by the vibration of the air in the thunderclap cause, the coalescence of *globules* into *drops*, which would otherwise have been kept asunder by their mutual repulsion. As a cause of winds, or any atmospheric movements not merely molecular, we attribute to it no importance whatever. As a chemical, and still more as a magnetic agent, however, there is every reason to believe atmospheric electricity to play a very important part in the economy of nature, as we cannot but admit the possibility at least of a connection between the diurnal variations in the electric state of the general atmosphere and the diurnal inequalities of terrestrial magnetism; and the transformation of oxygen into ozone (the most powerful of all known disinfectants) by the electric spark (and therefore on a larger scale by lightning), is not a matter of conjecture but of experiment.

(138.) There is one phenomenon which at first sight seems opposed to the view we have taken of the production of lightning—the negative electricity frequently observed during the descent of rain. But the researches of Faraday (*Phil. Trans.*, 1843) have shown that the friction of water-drops (when pure) against all substances (and therefore probably against air) develops negative electricity most powerfully in the substance rubbed. And the probability is converted into certainty by the fact that the spray of a descending waterfall fills the air around with negative electricity, sensible even at several hundred feet distance. It is probably to this cause that we must attribute the rapid alternations of positive and negative indications in the atmosphere which always attend thunder-storms.

(139.) It is certain that the flashes of lightning are often some miles in length. The prolonged roar, interrupted by explosions, of the thunder, which, excited at the same instant along the whole course of the flash, reaches the ear in succession by the transmission of sound at a uniform rate from every point, sufficiently proves this. Nothing is more common than to see flashes of lightning subtending at the eye an angle of 30°, the nearest point of which, estimated by the commencement of the thunder, cannot be less than two or three miles distant, and which its prolongation proves to be very oblique to the line of sight. We have been assured by a celebrated Abyssinian traveller, that he has seen flashes in that country extending from horizon to horizon, and which he could not estimate as under 50 or 100 miles in length. It is evident, then, that the electricity in lightning does not merely spring across a nonconducting interval to the nearest object (which in most cases would be the earth), but finds a path of ease, and is led on from interval to interval (as its zigzags denote) along a line of least resistance, and is not improbably reinforced in its course by other electricity not of itself intense enough to break the obstacle opposed to its escape.[1] By far the greater number of discharges are made into air or into less electrified cloud, and only a very small percentage into the earth.

(140.) Of those which do so, the destructive effects are well known, and volumes might be filled with instances of their amazing power, and capricious and unaccountable forms of its manifestation (Arago, *Bureau des Long.* 1838.) We shall mention only one or two as specimens. In a storm at Ludgvan, in Cornwall, as related by Borlase, *Phil. Trans.*, 1753, a flash of lightning striking a chimney-stack of hewn stone four feet square, carried it bodily away, and threw it into a pond twenty feet distant. In another, described by Arago, a wall containing twenty-six tons of brick-work was carried *en masse*, retaining its vertical position, nine feet from its place. We have seen a large oak tree, near Alton, Hants, which was rent into ribands, and every limb of which had been struck off as if by an axe, and had fallen around the tree, as by mere privation of support, without lateral projection. In producing these effects, the electricity would seem to act immediately by the expansion of vapour generated by its violent heat. When it strikes into deep sand, it produces those extraordinary hollow tubes *of fused quartz!* known as "fulgurites," of which the British Museum possesses a magnificent specimen, dug out near Dresden by Prof. Fiedler. Other effects of lightning are recorded in the Athenæum, No. MDXXXV., March 28, 1857, too marvellous to be recounted here, but which, should they be verified, would open quite a new field of inquiry in electrical research.

---

[1] This is not a mere hypothesis. In an experiment suggested by the author to the late Professor Daniell, and performed as soon as suggested, the striking distance of a voltaic battery was greatly increased by passing a common electric spark from the positive to the negative pole. The vastly increased striking distance of a magneto-electric combination in the neighbourhood of flame, in which its detours may be observed, affords a perfect illustration of the process described in the text.

(141.) Thunder-storms occur with very unequal frequency in different geographical situations. In Jamaica, according to Mr Graham Hutchinson, a thunder-storm bursts over the mountains near Port Royal every day from the beginning of November to the middle of April, at about 1 h. P.M., continuing about an hour and a half. In the neighbourhood of Cape Town, thunder-storms are few and feeble, while on the eastern coast of South Africa they are frequent and violent. The one region is arid, the other well watered.

(142.) The quantity of electricity discharged during some storms must be enormous. In the storm of Aug. 23-4, 1855, the blaze of lightning was almost uninterrupted for many hours, from a series of clouds passing from west to east, in two lines, over the south of England. The commencement of the SW. monsoon in India, in May 1848, was marked by "a thunder-storm extending over 600 miles from N. to S., and measuring 50 miles in breadth." The thunder-storm of September 3, 1841, "visited at the same time London, Paris, Rouen, Magney, Lille, and Evereux."—(*Thomson*). The mere evaporation of water would seem at first sight inadequate for the supply of so vast an expenditure, were it not that we learn from Dr Faraday that the chemical action of a "grain of water on four grains of zinc can evolve a quantity of electricity equal to that of a powerful flash of lightning!"—(*Phil. Trans.*, 1834, p. 117.)

Systematic View of Meteorological Periodicities — General Principles of Climatology.

(143.) The climatology of the globe is the summary of our knowledge of the climates of all the places on its surface, so presented to our minds as to convey the notion of law, and give it an ideal unity. To do this it is necessary to study *seriatim* the elements which enter into our estimate of climate, and follow out the course of the variations of each,—1*st*, independently of the others, and then in connection with them, or, in other words, to determine for each of these elements, 1*st*, its mean or average amount, as measured in its appropriate units; 2*dly*, the extent and laws of its deviations from that amount; and, 3*dly*, their mutual interdependence, or the reaction of each element on the rest. Such features as are not susceptible of definite measurement, as have no appropriate units, or as we have no instruments competent to measure, must of course be excluded. Looked upon in this general point of view, the science in question can hardly be considered as advanced beyond its infancy.

(144.) It is a dynamical law absolutely universal, and one which extends even beyond the domain of mere dynamics, that all periodicity in the action of a cause propagates itself into every, even the remotest, effect of that cause, through whatever chain of intermediate arrangements the action is carried out. When the effect is indirect, and especially when it is the result of one and the same law of periodicity in the same cause operating circuitously through several systems of intermediate connection, the numerical valuation of the effect (which, in the simplest case of direct action, depends on the calculation of an expression of the form $A + B . \sin. (nt + C)$, where A is the mean or average value of the result, B, C constant quantities, and nt an arc proportional to the time directly, and the length of the period inversely) resolves itself into that of a series of similar terms, containing not merely nt, but its multiples $2\,nt$, $3\,nt$, &c., each with its own appropriate constants, and which therefore run through their periods respectively in half, one-third, &c., of the period from which they originate. Thus, if the original period be a diurnal one, and θ be the time converted into arc at 15° per hour, the ultimate expression of the effect will always put on the form

$$E = A + B \sin. (\theta + C) + B' \sin. (2\,\theta + C') + \&c.,$$

in which A is the mean or average value of the effect in question, and B, C, B′, C′, &c. constants determined *a priori*, if such determination be possible; if not, by observation from the comparison of as extensive a series as possible of registered values corresponding to determinate instants of time. The term containing θ, which runs through its period in a day, expresses the leading feature of the effect—that which gives it its character of a *diurnal* fluctuation; the others, which run through theirs respectively in 12h., 8h., 6h., &c., express subordinate fluctuations, more or less materially modifying the law of its increase and diminution, and the epochs of its maximum and minimum, and in certain cases giving rise to double maxima and minima in the twenty-four hours. In meteorology, it has hitherto been seldom found necessary to carry such series out beyond their third terms.

(145.) When the acting cause is subject to two or more distinct periodical fluctuations, these make their appearance in the numerical expression of the effect under the form of periodical combinations, such as may arise from multiplying together terms of a similar form containing nt, and another arc $n't$ similarly derived from the other period. In astronomical researches these are usually resolved into sines and cosines of the sums or differences of nt, $n't$, and of their multiples. But in meteorology this would be inconvenient, and a different mode of regarding such combinations is found preferable for the following reason:—

(146.) The sun's action being the ultimate efficient cause of all meteorological change, every meteorological fluctuation of a regular character will arrange itself, on the principle above laid down, into diurnal and annual periodicities, including under this expression semi-diurnal and semi-annual ones, &c., and such as may result from their superposition (leaving out of question the period of 11·11 years, depending on the constitution of the sun itself, see art. 7). But the year being a very great multiple of the day, we may regard the solar agency as practically invariable during a single day, or such a small number of successive days as may suffice to bring out the full diurnal effect, which comes to the same thing as adopting in general the diurnal form of expression,

$$E = A + B . \sin. (\theta + C) + B' . \sin. (2\,\theta + C') + \&c.$$

for the fluctuating effect, and regarding the co-efficients A, B, C, &c., as constant for any single day, but each subject to an annual periodicity, and as being, each of them, expressible under the same general form, substituting for θ the corresponding annual arc—for which, if we choose, we may use the sun's mean longitude. Thus each of the co-efficients of the diurnal formulæ,

$$A + B . \sin. (\theta + C) + B' . \sin. (2\,\theta + C') + \&c.$$

comes to be regarded as itself a periodical function of the form,

$$a + b . \sin. (\Theta + c) + b' . \sin. (2\,\Theta + c') + \&c.,$$

Θ being the sun's mean longitude.

(147.) Every one of these co-efficients, whether diurnal or annual, generally considered, is dependent on the geographical position of the place of observation; in other words, is a function of the latitude, longitude, and elevation above the sea-level of that place, which, being arbitrary and of unknown form, may be considered as embodying all the local peculiarities of whatever nature; and it is not until all these co-efficients are determined, or at least all which have an appreciable magnitude, for each meteorological element—in temperature, barometric pressure, tension of vapour, rain, &c., wind, and electricity—that the climate of the place can be said to be fully known.

(148.) Any one of these functions, though its analytical form may be quite beyond the reach of our enquiry, yet, by a sufficiently extensive and continuous combination of observation and calculation, carried on upon a system presently to be explained, may become known numerically, and tabulated for every accessible part of the globe; and being so tabulated, the points at which it has equal values may be laid down on a globe or chart, and being connected by a continuous line, and this done for a succession of values, progressing by convenient and regular intervals in its scale of magnitude, from the maximum which it has in any part of the globe down to the minimum which occurs anywhere; a series of level lines, or isometeoric lines (if we may coin a word to convey the general notion) will arise, which will present to the eye the progression and connection of this particular co-efficient over the world. Exactly as if wishing to convey, for instance, an idea of the exterior form of the solid surface of the globe, we should commence by delineating the coast-lines of the continents and islands, which are the level-lines for 0 ft. from the sea-level, and similarly laying down points wherever the height of 100 ft. above, or depth of 100 ft. below, the sea occurred, and connecting them, should get the level lines of + 100 ft. or — 100 ft., *i.e.*, what would be the coast-lines were the sea to rise or sink 100 ft.; and so on, to the tops of the mountains and extreme depths of the ocean.

(149.) This mode of exhibiting to the eye by a picture (a picture which might become a model by executing it in relief) the law of variation of a function known only by observation, over the surface of the globe, or any particular district of it, was first devised by Halley to express the law of the variation of the magnetic compass, but first introduced into meteorology by Humboldt, to exhibit the law of distribution of temperature, by laying down a system of *Isothermic lines*, or those in which the *mean annual temperature* is alike throughout; that is to say, in which the co-efficient, a, in the expression for the mean temperature of the whole year, viz., $a + b \,.\, \sin.\,(\Theta + c) + \&c.$, is constant; and which, therefore, serve to connect in idea, as places having at least one very eminent meteorological feature in common, all those points in the globe which receive (from whatever cause) the same annual total of heat. To these lines we shall recur hereafter. Climatology as a science (or rather as a branch of physical geography, to which, rather than to meteorology, it properly belongs), would be complete, or nearly so, if we possessed a complete atlas of such charts, each containing the isometeoric lines for all the really influential co-efficients, both annual and diurnal (which are not very numerous), exhibiting the mean values of each of the annual co-efficients from the observations of many years, and the mean values and annual maxima and minima of each of the diurnal ones. Hitherto only a few of such lines have been traced, and that imperfectly, viz., the lines suggested by Humboldt, or the *Isothermal*, *Isotheral*, and *Isocheimal* lines, or those in which the *general* mean temperature, the mean *summer* temperature, and the mean *winter* temperature are respectively constant; the *Isogeothermal* lines of Kupffer, in which the *mean temperature of the soil* is constant (and which are not always identical with the Isothermals), the Isobarometric lines of Kämtz, in which the limits of fluctuations of barometric pressure are equal (a series of which it is not easy to see the use), and a few others. We shall now proceed to consider by what means such knowledge can most readily and effectually be attained.

(150.) *Determination of Meteorological Averages and Co-efficients.*—The general form into which, as we have seen, every meteorological *quantitative* expression can be thrown, clearly indicates the system of observation which ought to be followed, so as to lead most directly to a knowledge of their mean values. It is a well-known property of the sine or cosine of an arc, that if the circumference be divided into any number, n, of equal parts, θ, we shall have,

$$\sin.\,(\theta + c) + \sin.\,(2\,\theta + c) + \ldots\ldots \sin.\,(n\,\theta + c) = 0$$

Suppose, then, we would ascertain the diurnal mean, A, of any element, E, supposed to be expressible as in art. 144. Were we sure that E contained only one periodical term, $B \,.\, \sin.\,(\theta + C)$, it would suffice to make a series of observations at intervals of 12 hours, on summing up which, as the + and — values of this term would destroy each other, the sum divided by the number would afford the value of A. If an eight-hourly interval be substituted for a twelve, a like summation will eliminate the terms depending both on θ and $2\,\theta$; if a six-hourly one, those depending on θ, $2\,\theta$, and $3\,\theta$, and so on. So far as meteorological computation has hitherto been carried, this would appear to be in most cases sufficient, the co-efficients of the successive terms diminishing rapidly. From a simple observation *per diem*, no average can be concluded, except it be made at such an hour as experience shows to be that on which the quantity observed has usually its mean value. This differs for each element and for each locality, and is itself a desirable item of meteorological inquiry.

(151.) Annual means may be obtained by summing diurnal ones. If the series be incomplete, two courses may be followed, viz., 1*st*, By subdividing the year into monthly groups, calculating the means for each month from the observations recorded, and taking a mean of the twelve results; or, 2*dly*, By striking out days corresponding to those deficient at 3- or 4- monthly intervals from each.

(152.) The *law of fluctuation* requires us to know the values of the several constants which enter into the periodical terms. To do this effectually from a series of recorded observations, requires the application of the "method of least squares." If the observations be numerous, and made at irregular hours, this is attended with a frightful amount of calculation; but if they form a regular series made at definite hours of the day, and either complete, for many days, or *capable of being completed by the insertion of the deficient observations according to any observed law of progression, or in the absence of such law, by a mean of the adjacent day's observations at homologous hours*, nothing can be simpler or more expeditious than the treatment of such a series by least squares, so as to give the most probable values of the constants. The following practical rule, the investigation of which is, we believe, originally due to Bessel, will give them:—

(153.) Suppose we have such a series of observations at epochs $\theta, 2\,\theta, 3\,\theta, \ldots\ldots n\,\theta =$ dividing any entire period into equal intervals, reckoning from and up to the end of the period, or any other convenient epoch. Let $S_1, S_2, \ldots. S_n$ be the sums of the observed values, at homonymous epochs, throughout the series. Look out, in a table of sines and cosines, for the sines and cosines of $\theta, 2\,\theta, \ldots.\, n\,\theta$ converted into degrees at the rate of 15° per hour for the diurnal, or 30° per month for the annual fluctuation (or their logarithms, if we proceed logarithmically), and call the sines in succession s_1, s_2,

.... s_n, and the cosines $c_1, c_2, \ldots c_n$, observing that $s_n = 0$ and $c_n = 1$. This done, compute the quantities a_0, a_1, ... a_n, b_1, ... b_n, by the following formulæ, in which N is the total number of observations at all the epochs.

$$a_0 = \frac{1}{N}(S_1 + S_2 + \ldots . S_n)$$

$$a_1 = \frac{2}{N}(c_1 S_1 + c_2 S_2 + \ldots . c_n S_n)$$

$$a_2 = \frac{2}{N}(c_2 S_1 + c_4 S_2 \pm \ldots . c_{2n} S_n)$$

$$a_3 = \frac{2}{N}(c_3 S_1 + c_6 S_2 + \ldots . c_{3n} S_n) \text{ \&c.}$$

$$b_1 = \frac{2}{N}(s_1 S_1 + s^2 S_2 + \ldots . s_n S_n)$$

and so on. These will be the *most probable values*, respectively, of the co-efficients in the general expression of E under the periodical form,

$$E = a_0 + a_1 . \cos. \theta + b_1 . \sin. \theta + a_2 . \cos. 2\theta + b_2 . \sin. 2\theta + \text{\&c.}$$

which may then be transformed into

$$E = a_0 + B_1 . \sin. (\theta + C_1) + B_2 . \sin. (2\theta + C_2) + \text{\&c.}$$

by taking $B = \sqrt{a_2 + b^2}$; $\tan. C = \frac{a}{b}$.

(154.) In the practical application of this formula, it is not necessary that the number of the terms of which the final result E is to consist, should be pushed farther than necessity or convenience may require, and it is a peculiarly valuable property of these expressions, that if the approximation be stopped at any one term, as, for instance, at the term $B^1 . \sin. (\theta + C_1)$, and the co-efficients B_1 and C_1 be determined accordingly, then should it be considered afterwards desirable to carry it a term farther, so as to include the next sub-period expressed by the term $B_2 . \sin. (2\theta + C_2)$, it is not necessary to recompute the former co-efficients, their values remaining unaltered, so that the several sub-periodic terms are separately and independently calculable from any *complete* series of observations, just as if the others had no existence. And moreover, the constitution of the formulæ is such that any number of complete cycles of observation may be treated as a single cycle, by taking the means of the recorded observations at homonymous epochs, and thus forming from them a single cycle.

(155.) For example, supposing we have a series of *mean monthly* results, obtained during a series of years, for any meteorological element, such as temperature, and we wish to deduce from them the law of the annual fluctuation. In the first place, we take the mean of all the results for January as a new January mean, of February for February, and so on, and denoting their means so obtained in their order, by $S_1, S_2, S_3, \ldots . S_{12}$. If we wish merely to obtain the most probable mean annual temperature, we use the expression,

$$A = \frac{1}{12}\left\{ S_1 + S_2 + \ldots . S_{12} \right\}$$

If we would now carry the inquiry one step farther, and determine the amount of fluctuation regarding the curve of temperature as one of a single undulation, neglecting subordinate flexures and sub-periods, we retain the same value of A, and calculate B_1 and C_1 by the formulæ,

$$\begin{aligned} 6\, a_1 &= (S_1 - S_5 - S_7 + S_{11}) \;.\; \cos. 30° \\ &\quad + (S_2 - S_4 - S_8 + S_{10}) \;.\; \cos. 60° \\ &\quad - S_6 + S_{12} \end{aligned}$$

$$\begin{aligned} 6\, b_1 &= (S_1 + S_5 - S_7 - S_{12}) \;.\; \sin. 30° \\ &\quad + S_2 + S_4 - S_8 - S_{10}) \;.\; \sin. 60° \\ &\quad + S_3 - S_9 \end{aligned}$$

$$B_1 = \sqrt{a_1^2 + b_1^2}; \quad \tan. C_1 = \frac{a_1}{b}$$

And if we would now go on farther to investigate the semi-annual sub-period, or that depending on $2\,\theta$, we retain the means of A, B_1, C_1, already computed, and still using the same sums S_1, S_2, &c., go on to find a_2, b_2, and from them B_2 and C_2 by the formulæ,

$$\begin{aligned} 6\, a_2 &= (S_1 - S_2 - S_4 + S_5 + S_7 - S_8 - S_{10} + S_{11}) \\ &\qquad \times \cos. 60° \\ &\quad - S^3 + S^6 - S_9 + S_{12} \\ 6\, b_2 &= (S_1 + S_2 - S_4 - S_5 + S_7 + S_8 - S_{10} - S_{11}) \\ &\qquad \times \sin. 60° \end{aligned}$$

$$B_2 = \sqrt{a_2^2 + b_2^2}; \quad \tan. C_2 = \frac{a^2}{b_2}.$$

In applying which it will be remembered, of course, that as the means S_1, S_2, &c., belong to the middle of the months, the values of θ corresponding to *them* are 30°, 60°, &c., so that the commencement of the year from which θ reckons, is, in effect, placed in the middle of December. If we reckon the time, then, from the beginning of January, this amounts to putting $\theta' + 15°$ for θ; or, retaining the same values of the co-efficients A, B_1, B_2, &c., increasing C_1 by 15°, C_2 by 30°, &c. For the third term, the co-efficients are still more simple in their expression, viz.,

$$\begin{aligned} 6\, a_3 &= - S_2 + S_4 - S_6 + S_8 - S_{10} + S_{12} \\ 6\, b_3 &= + S_1 - S_3 + S_5 - S_7 + S_9 - S_{11} \end{aligned}$$

(156.) The application of the formulæ is equally simple and easy in every other case; and, in fact, such is its facility, that it leaves no excuse to meteorologists for not reducing their observations, and should act as a powerful recommendation to induce them, in all cases, to conform to its requisitions in arranging the times of their observations.

(157.) All that depends on regular periodic action may be represented in this manner by periodic functions, the co-efficients of which, as determined by observations for any place, embody the resultant of the mode in which the action is propagated to the place. Each of them is therefore, no doubt, inherently a function of the latitude and longitude of the place, but one complicated with and dependent on the whole geographical system of the globe as one of its data — the configuration of its land, the height and arrangement of its mountain chains, nay, even the depths of its seas and the form of their beds; since all these elements enter into the list of causes which determine the arrival of heat, wind, and moisture at the place.

(158.) It is the task of the practical meteorologist, each at his own station, to furnish his quota of recorded observation towards carrying out this great work—a task tedious, perhaps, and requiring, like all scientific operations, care in observing and precision of statement, but easy in itself, and full of interest at least to such as are able and willing to execute the reduction of their own observations, and thereby to furnish (so to speak) not merely a lump of material rude from the quarry, but a stone hewn and squared on the spot, and ready to take its fitting place in the general edifice. Having fixed on the range and scope of his observations, the instruments whose indications he proposes to record, and the hours at which his personal convenience, and the dependable means at his command will enable him to record them, all he has to do is to pay scrupulous attention to obviate everything which may tend to derange the adjustment of his instruments, or affect the fairness of their exposure—to read them off accurately, and register the readings faithfully, and to adhere precisely to system in their reduction. It should be remembered, however, that no series of observations can be considered of any value for the determination of the *diurnal* co-efficients in which the twenty-four hours are not *equally* divided by the epochs of observation, and of comparatively little if they be fewer than four in number; the most advantageous hours for which, generally speaking, will be found to be 3 h. and 9 h. A.M. and P.M., or 4 h. and 10 h. A.M. and P.M., should the habits of the observer render the 3 h. A.M. observation very irksome.

(159.) To those observers, however, whose means will allow them to avail themselves of the resources which modern art affords, the principles of photographic and mechanical self-registry, which have of late been applied to all the most important instruments, affords an alleviation of all the tedium of personal attendance, and supplies what personal observation never can do — an unbroken record of the march of each instrument during the night as well as the day. On the occasion of a reward of £500, offered in 1846 by the Lords Commissioners of the Admiralty, for the discovery of an available application of photography for such purposes, two systems of procedure were devised and carried into effect by Mr Brooke and Mr Ronalds, the one at the Royal Observatory at Greenwich, the other at the observatory of the British Association at Kew, both of which have been found perfectly adequate to the object, not only of meteorological, but of magnetic self-registry. Without going into minutiæ (which the reader will find stated for the former system in the Introduction to the Greenwich Observations for 1847, and for the other in three papers published in the Transactions of the Royal Society for 1847. We may state the general principle of Mr Brooke's method in few words as follows: — Paper being prepared sufficiently sensitive to receive an impression from the light of an argand or camphine lamp by night, and the reflected light of the sky by day, is stretched between two rollers, so as to be wound on one and unwound from the other uniformly by clock-work, receiving, as it travels, punctures or marks made on it by an appropriate mechanism, at equal intervals of time, suppose hourly, and which, therefore, convert the space travelled over into a scale of time capable of being read off by a scale of equal parts, if necessary. The direction of the motion of the paper is perpendicular to that in which the indicating point of the instrument to be registered moves, whether that be the end of a column of mercury rising and falling (as in the stem of a thermometer, or in the tube of a barometer), on an index arm capable of carrying a screen pierced with a hole to transmit a small pencil of light. If the former, the light is so arranged that *only the vacant part* of the stem or tube above the mercury shall allow a free passage for it to reach the paper, the shadow of the mercury cutting off all below. If the latter, the whole paper is shaded except that point which happens at each instant to be behind the hole. In the one case, the boundary of light and shadow is marked by a curve terminating the continuous photographic impression formed by the unrolling of the paper; in the other, the impression itself takes the form of a curve line, of which the ordinate indicates the reading of the instrument at the moment of time indicated by the abscissa. To facilitate the subsequent reading off of these curves, the graduation of the scale (in the case of the thermometer), is marked on the paper by the shadows of wires carried across the stem at each degree. In Mr Ronalds' second or improved method, described in the third of the papers above cited, an image of the index point terminal line of mercury, or other object which defines the reading of the instrument, is formed by an achromatic lens on the moving paper. One or other of these systems of self-registry, or some equivalent one, is, or ought to be, adopted wherever meteorological observation is carried on as a part of the regular business of a public establishment. Taken in conjunction with the mechanical self-registry of the anemometer, and with that by which the rain-gauge is made to empty itself whenever a definite quantity of rain is collected, and to record the number of such emptyings, and the weight of water it contains at each hour, the system of self-registry may be regarded as complete.

(160.) For the special reductions which each kind of instrument requires, the nature of its adjustments, and the precautions to be observed in its use, we must refer the reader to the descriptions of the several instruments in other parts of this work under their proper heads; to the Admiralty Manual of Scientific Inquiry already referred to, and the Report of the Royal Society on the occasion of Captain Ross' Antarctic Expedition in 1840; and to the former of these works for a detail of the particulars which a complete meteorological register ought to embrace, and the most convenient and advantageous form of statement it admits.

(161.) *Of the distribution of barometric pressure, and its periodical fluctuations.*—The mean barometric pressure on any place is of course dependent on its height above the sea level, so that each locality has corresponding to it a certain individual correction or reduction to the sea level, which affects equally all its barometric observations, When the level of the place is trigonometrically ascertained, the mean temperature of the station being known, this reduction may be exactly computed; and were it a fact that the mean barometric pressure at the sea level were everywhere the same, the height of every place might be determined from the mean height of the barometer as given by observation. This, however, is not the case. We have already seen (art. 54) that in the open ocean the pressure diminishes on approaching the equator from either side, as well as the reason for this diminution. But this is not all. The atmosphere is not in a state of statical equilibrium, nor are the forms of its strata of equal density identical (as they would be in that case) with the ellipsoids of equal level, for the very obvious reason, that the surface of a fluid in motion (even when unagitated by waves), is not that of the same fluid at rest. The surface of a river, though smooth, is not a horizontal, but an inclined plane. That of a swift stream with an unequal bottom is not a plane at all, but a surface of ridges and depressions, fixed in place and permanent in form, as is seen in the familiar case of the ripple caused by a smooth round stone at some depth below the surface; hence we might be prepared to expect great differences between the surfaces of equal level and of equal density in the interior of extensive continents, where the atmosphere, swept *en masse* from the sea, up the gradual slope of the land surface, is lifted with all its strata preserving their relative bearings on each other, the extent of elevated country on all sides tending to prevent lateral overflow. Under such circumstances there may, or rather must, exist great discordances between the trigonometric and barometric determinations of altitudes (the only form in which the cause in question can make its appearance), and which, it may be remarked generally, go to render all barometric determinations uncertain in windy weather.

(162.) What may not, however, be so obvious, or rather what, when first proposed, appears quite paradoxical, is that, even in the open ocean, there exist extensive tracts in which a permanent *depression* of the barometer to the enormous extent of an inch and upwards (equivalent to an elevation of 800 feet above the sea level), is found to prevail. Such a tract is the whole extent of the Antarctic Ocean, from 63° to 74° S. lat., and 8° to 7° W. long. as ascertained by Sir James C. Ross (*Voyage of the Erebus and Terror*, ii. 376, 385); and a corresponding depression, though not to so great an extent, appears, by the observations of Ermann, to exist in the region nearly diametrically opposite, about the Sea of Ochotzk, and in the interior of the Asiatic continent of that neighbourhood.

(163.) It is impossible not to perceive, in these singular phenomena, the evidence of the existence of what must be regarded as a fixed system of ripples in the general atmosphere, caused by the great system of circulation in both hemispheres, of the trades and anti-trades reacting on the general mass of the continents as obstacles in their path, and dependent for their depths and limiting forms on the configuration of the surface of the land. The progressive change of mean atmospheric pressure at sea, in proceeding from the equator southwards, is stated by Sir J. Ross as follows:—

Lat. South.	Mean Pressure.	Lat. South.	Mean Pressure.
0° 0′	29.974	51°33′	29.497
13 0	30.016	54 26	29.347
22 17	30.085	55 52	29.360
34 48	30.023	60 0	29.114
42 53	29.950	66 0	29.078
45 0	29.664	74 0	28.928
49 8	29.469		

(164.) For northern latitudes, the results hitherto collected run very irregularly. Meteorologically, however, this is not a cause which would appear to be productive of any marked train of consequences. And in relation to the matter at present in hand, it goes only to show, that the first term of the periodic function expressing the barometric pressure, is not an absolute constant, even for the ocean, but that it has to be tabulated and worked out by local observation into a system of isobarometric lines, carried indifferently over both sea and land, and, as regards the latter, distinct from the level lines. We are far, indeed, from any approach to the construction of such a system.

(165.) The periodic fluctuations of the barometer are annual and diurnal. The consideration of the former will enable us to form a neater conception of the mode in which the latter arise. When it is summer in one hemisphere it is winter in the other. Hence (See art. 78), the air generally incumbent on the heated hemisphere is dilated, and expands both upwards and laterally, as well by its own increased elasticity as by the increased production of vapour. It therefore not only encroaches on the other hemisphere by lateral extension, but what is far more influential, flows over upon it. In order to perceive clearly the nature of the process, we must separate in idea the aqueous and aerial constituents of the portion of atmosphere so transferred. The generation of the former goes on in the heated hemisphere, and replaces, in part at least, the loss of pressure arising from the transfer of air, while in the other the excess of vapour so introduced is constantly undergoing precipitation, and is thus continually being withdrawn from the total mass, leaving behind it, however, to accumulate, the dry air which accompanied it. Thus, if we regard the total barometric pressure as subdivided into that of the dry air and of the aqueous vapour, and denote the former by P, the latter by p, we see that the dry pressure P is diminished in the hot, and increased in the cold hemisphere, without any countervailing action, while p is in process of increase from below by evaporation, and of diminution from above by overflow, in the former: and *vice versâ* in the latter. If, then, the observed barometric pressure at every point in either hemisphere be analysed by calculation into its two constituents, by taking account of the hygrometric state of the atmosphere, and subtracting from the total pressure $P+p$ the portion p due to the amount of vapour present, the remainders ought to exhibit, as a general result, an excess of dry pressure P in the winter hemisphere over that in the summer.

(166.) So far as observation has hitherto gone, this result is perfectly corroborated, though unfortunately there are not yet accumulated sufficiently numerous and extensive series of observations in which the effects of the aqueous pressure can be duly separated from the dry. As examples, we shall select the series for the Indian stations, Calcutta, Benares, Seringapatam, and Poonah, calculated by Dove from the observations of Prinsep Sparmann and Colonel Sykes, as compared with that at Apenrade from those of Neuber, and with the results obtained at the Meteorological Observatories of Prague, Toronto, and Hobart Town, V.D.L.

Stations.	P, PRESSURE OF DRY AIR.			*p*, PRESSURE OF VAPOUR.		
	Max. in	Min. in	Differ.	Max. in	Min. in	Differ.
			inches.			inches.
Calcutta,	Jan.	July	1.019	Aug.	Jan.	0.551
Benares,	Dec.	July	1.244	July	Dec.	0.645
Seringapatam,	Jan.	June	0.455	May	Jan.	0.217
Poonah,	Dec.	June	0.760	July	Dec.	0.435
Apenrade,	Feb.	July	0.450	July	Jan.	0.346
Prague,	Dec.	July	0.383	July	Jan.	0.285
Toronto,	Dec.	July	0.271	Aug.	Feb.	0.380
Hobart Town,	July	Nov.	0.218	Feb.	July	0.125

These are large quantities; but we see that as the maxima of P correspond in point of time with the minima of p, it is only their differences which constitute the total or observed annual fluctuation of barometric pressure.

(167.) Since, as observed (art. 165), the annual fluctuation of p is the result of an excess of supply over expense in one hemisphere, and of expense over supply in the other, it may very well happen that the annual fluctuation of p in certain localities may exceed that of P, and being in a contrary direction, may either neutralize the fluctuation of the gross pressure $P+p$, or convert it into one of an opposite character. This, however, is but rarely the case, and where instances of it do occur, as at Sta. Fé de Bogota, and Bangalore (*Kämtz*, ii. 299), they are for the most part readily enough accounted for by the influence of local peculiarities.

(168.) If we consider that in general the values of P and p, regarded independently, fluctuate in opposite directions, and hence the maximum of the one corresponds, or nearly so, in epoch with the minimum of the other, we shall easily see that, representing P by

$$P = A + B \,.\, \sin.\,(\Theta + C) + B' \,.\, \sin.\,(2\,\Theta + C') + \&c.,$$

we shall have, at least approximately, for p an expression such as,

$$p = a + b \,.\, \sin.\,(\Theta + C + 180^\circ) + b' \,.\, \sin.\,(2\,\Theta + c') + \&c.$$

the value of C in the term Θ differing by 180°, while those in the other terms (C', c', C'', c'', &c.) may or may not stand to each other in a similar relation—the only condition being, that they shall be such as to render the co-efficients B, B', &c., b, b', &c., all positive. The gross pressure $P + p$, then, will come to be expressed by the form,

$$P + p = (A + a) + (B - b) . \sin. (\Theta + C) + \beta . \sin. (2 \Theta + \gamma) + \beta'' . \sin. (3 \Theta + \gamma'') + \&c.,$$

Since $B' . \sin. (2 \Theta + C') + b' . \sin. (2 \Theta + c')$ may always be reduced to the form,

$$\beta . \sin. (2 \Theta + \gamma), \&c.$$

(169.) Thus we see that the tendency of the cotemporary action of the two elements composing the gross pressure is, 1*st*, to produce a mean annual pressure $(A + a)$ equal to the sum of the separate pressures; 2*dly*, to subdue the influence of the term depending on Θ, by reason of the opposition of signs affecting B and b in the joint co-efficient $B - b$; and thus, 3*dly*, to give a greater *comparative* influence to the terms depending on 2Θ, 3Θ, &c. Now it will be observed that a series thus constituted, of sines of Θ, 2Θ, &c., when made to run through its whole period by varying Θ from 0 to 360°, will have only a single maximum and minimum when the co-efficient of $\sin. (\Theta + C)$ is large in comparison with those of the other sines, but when the contrary is the case, a double, or even triple or multiple maximum and minimum may result from such mutual relations among the co-efficients as may very easily occur. The principal terms nearly neutralizing each other by their mutual opposition, leave the general character of the law of periodicity of the compound effect to be decided by the relations *inter se* of the subordinate ones, and thus is explained, without prejudice to the general reasoning in art. 77, 78 (which remains true as regards the *form* of the atmosphere as disturbed by the sun's action) the fact, which appears on first sight in opposition to that conclusion, that the annual oscillation of the gross barometric pressure presents in a great many localities the phenomenon of a double maximum, or even a still more complex character. Thus, in Paris, to take a single instance from a mean of eleven years' observations (1816–1826), the total pressure exhibits two maxima in January and in July, the former being highest, and two minima in April and October, the latter being the lowest. (*Kämtz*, ii. 295.)

(170.) The great length of time in which the efficient causes are acting in one direction, to produce the annual oscillation in question, admits of a very considerable fraction of the atmosphere to be transferred from hemisphere to hemisphere, and to allow a range in the values of P, for instance, to the large extent (as we have seen in the case of Benares) of nearly an inch and a quarter of mercury, partially neutralized by a fluctuation of more than half an inch of aqueous vapour. Thus the effects are brought out into prominence, in both elements, by the long-continued action of the causes; and thus, by the study in the first instance of the annual oscillation, we are led to an easy understanding of the perfectly analogous phenomena in the diurnal oscillations (or, as they have sometimes though very improperly been called, "atmospheric tides") which have a good deal perplexed meteorologists, but whose analysis, into what we have for convenience called wet and dry pressure, has happily been suggested by M. Dove as affording a rational explanation.

(171.) To simplify our conception of the diurnal oscillation, we will suppose the sun to have no declination, but to remain constantly vertical over the equator. The surface of the globe will then be divided into a day and a night hemisphere, separated by a great circle passing through the poles, coincident with the momentary horizon, and revolving with the sun from east to west in twenty-four hours. The contrast of the two hemispheres, both in respect of heat and evaporation, in this case will evidently be much greater than in that of art. 165, and therefore the dynamical cause, the motive force, transferring both air and vapour from the one to the other will be much greater. But on the other hand, much less time is afforded for this power to work out its full effect, and long before this can be accomplished for any locality, the circumstances are reversed, and a contrary action commences. The causes, then, and the mode of their agency, are perfectly analogous, in the production, whether of the annual or diurnal oscillation; but in the former, the feebler acting cause is aided by the very much greater length of the period; in the latter, its superior intensity is in great measure neutralized by the frequency of its reversal. There is another consideration, moreover, which cannot be without its effect in establishing a distinction between the two cases. By far the larger portion of the land is distributed over the northern hemisphere, and of the water over the southern. The former is more uniformly terrene, the latter more uniformly aquatic; and as, under the circumstances now considered, the transfer of air does not take place in the direction of meridians, but at right angles (mainly) to their direction, we should be led to expect that the amount of counteraction in the diurnal fluctuations of the dry pressure P by those of the wet p, would be, generally speaking, very different in the two hemispheres, and that therefore the extent of fluctuation in the gross pressure $P + p$ would, generally speaking, present a corresponding difference. A sufficient amount of observation has not yet been accumulated to bring this conclusion to the test of experience; but we cannot help remarking that the very same cause (the excess of water in the southern hemisphere), acting according to the difference of conditions in the case of the annual oscillation, ought to result in an average uncompensated action on the dry air, urging it towards the northern hemisphere, and to its replacement, bulk for bulk, by vapour, which being lighter than air, *may* be one of the causes of the generally lower atmospheric pressure over the Southern Ocean —a certain percentage of the due proportion of dry air being permanently driven out and prevented from returning by the constant outflow of vapour.

(172.) It ought to be observed, that the oscillations in question are only in appearance analogous to those of the oceanic tides. In the latter, the tide wave is merely a circulating form without any lateral transfer. The sun's heating action on the atmosphere is not one which, destroying a portion of its gravity, tends to alter its form of equilibrium, but one which, leaving its gravity unaltered, tends to throw its strata by their dilatation, and by the introduction of vapour from below, into forms incompatible with equilibrium, and therefore necessarily productive of lateral movements. When anemometry is further perfected, we may expect to trace the influence of this chain of causation into a morning and evening tendency of the wind (on a long average of observation), to draw towards the points of sunrise and sunset, to compensate the overflow from off the heated hemisphere, which takes place aloft in the contrary direction.

(173.) *The diurnal oscillation of the barometer* is a phenomenon which invariably makes its appearance in every part of the world *where the alternation of day and night exists*, on reducing any considerable series of hourly observations, though in extra-tropical latitudes it is for the most part so overlaid by casual variations as not to be remarked in a single day. On the other hand, between the tropics, and especially in the equatorial regions, its regularity of progress is most striking. Thus Col. Sykes remarks (*Phil. Trans.* 1850) that, among many thousand observations taken personally by himself on the plateau of the Deccan (1825-30), there *was not a solitary instance* in which the barometer was not higher at 9-10 A.M. than at sunrise, and lower at 4-5 P.M. than at 9-10 A.M., whatever the state of the weather, &c., might be. Humboldt also observes (tom. i. p. 308) :—"This regularity is such that, in the daytime especially, we may infer the hour from the height of the column of mercury without being in error on an average more than 15 or 17 min. In the torrid zone of the New Continent I have found the regularity of this ebb and flow of the aerial ocean undisturbed either by storm, tempest, rain, or earthquake, both on the coasts and at elevations of nearly 13000 English feet above the level of the sea. The amount of horary oscillation decreases from the equator to 70° N. lat., where we have very accurate observations made by Bravais at Bosekop, from 0·117 in. to 0·016 in." Within the Arctic Circle, however, the diurnal, for very obvious reasons, dies out, or rather merges in the annual oscillation.

(174.) Generally speaking, the diurnal oscillation presents the phenomenon of a double maximum. The epochs of the maxima are about 9 h. or $9\frac{1}{4}$ h. A.M., and $10\frac{1}{2}$ h. or $10\frac{3}{4}$ h. P.M., and the minima at 4 h. or $4\frac{1}{4}$ h. P.M. and 4 h. A.M. The fact that the barometer frequently, "both in summer and in winter, stands higher in the cold mornings and evenings than in the warmer midday," seems to have been first made matter of remark by Dr Beale in 1666. In 1682, Messrs Des Hayes and De Glos observed, that at Goree the barometer was usually lowest when the thermometer was highest, that it stood higher by night than by day, and that the daily depression (between the morning and evening maxima) exceeded the nightly. At Surinam the same phenomenon was noticed by an anonymous observer, and distinctly described in 1722. Towards the middle of the last century (1735-61), its existence at Quito, in the Antilles, in India, and at Sta. Fé de Bagota, was severally established by Godin. The observations of Humboldt as to the extreme regularity of its progression in equatorial America are corroborated by those of Colonel Wright in Ceylon. That the double maximum and minimum of its march really originates in almost all cases in the manner above explained, by the approximate destruction of the second term in the series

$$(A + a) + (B - b) . \sin. (\theta + C) + \beta . \sin. (2\,\theta + \gamma) + \&c.$$

owing to the opposite march of the dry and wet elements of the total pressure, has been put out of doubt by the calculations of Dove. Yet there are localities, as for instance at Bombay, in which even, in the expression of P, the co-efficient of the second term is so small in comparison with the others, as to give rise to the appearance of a double maximum in the dry pressure itself, and the mode in which this is accomplished is evidently referable to the more complicated local relations which arise from the juxta-position of land and sea under exaggerated circumstances of temperature and radiation, giving rise to alternating sea and land breezes—one minimum of the dry pressure being found to coincide with the greatest strength of the sea breeze, the other with that of the land breeze, and the maxima with the minima of force of the wind.

(175.) If we regard only the gross pressure $P + p$, the following table will exhibit the amount of its daily fluctuations above and below the mean value, as deduced from the calculations of Kämtz (ii. 254, &c.)—

PLACE.	Latitude.	Morning Min.	Forenoon Max.	Afternoon Min.	Evening Max.
		in.	in.	in.	in.
Atlantic Ocean	0° 0′	—0.056	+0.069	—0.045	+0.045

(176.) As examples of the application of the general form of expression in cosines of the sun's hour angle from noon, we shall subjoin only the values obtained by Kämtz by the method of least squares from the whole series of observations recorded for three of the above localities, viz., Payta, Callao, and Padua.

For Payta.

$$P + p = 29^{\text{in.}}\cdot840 + 0^{\text{in.}}\cdot050\ .\ \sin. (\theta + 203^\circ\ 2') + 0^{\text{in.}}\cdot037\ .\ \sin. (2\,\theta + 153^\circ\ 43').$$

For Callao.

$$P + p = 29^{\text{in.}}\cdot824 + 0^{\text{in.}}\cdot099\ .\ \sin. (\theta + 180^\circ\ 59') + 0^{\text{in.}}\cdot036\ .\ \sin. (2\,\theta + 171^\circ\ 6').$$

For Padua.

$$P + p = 29^{\text{in.}}\cdot797 + 0^{\text{in.}}\cdot005\ .\ \sin. (\theta + 183^\circ\ 46')\ 0^{\text{in.}}\cdot010\ .\ \sin. (2\,\theta + 135^\circ\ 59')$$

(177.) The stations in the foregoing table are (except in the cases of Munich, Halle, and Abo) at the sea level. On mountain stations, or at least on such as rise abruptly from that level, or from an extensive plain, there exists a cause of diurnal oscillation in the barometric pressure of quite a different nature from that above considered. The whole vertical column of air, from the sea level to the top of the atmosphere, being dilated by the increase of diurnal temperature, it is evident that in the hotter portion of the twenty-four hours, a certain portion of the air below the cistern of the barometer must be lifted above it, and *vice versâ* for the colder. The actual weight of air incumbent on the mercury must thus be alternately varied in excess and defect of its mean amount, and the mercurial column balancing it must rise and fall accordingly. The effect of this cause (which runs counter to the law of oscillation of the dry air at the sea level, though forming part and parcel of the mechanism by which that law is determined), is easily calculable for any given elevation and diurnal change of temperature. Supposing that of the whole aerial column between the sea and the station uniform, and equal to the mean of the upper and lower, it is easily shown that the effect in question will attain its maximum value at an altitude where the barometric pressure is one 2·7182818th of that at the sea level, *i. e.* $11^{\text{in.}}\cdot03$, corresponding to about 26100 feet, and at this height the total diurnal fluctuation due to a change of temperature of 30° Fahr. would amount to the very considerable quantity $0^{\text{in.}}\cdot672$. The effect at inferior elevations for 10° of diurnal oscillation of temperature is calculated in the following table:—

Alt. in Feet.	Diurnal Oscillation for 10° F.	Alt. in Feet.	Diurnal Oscillation for 10° F.	Alt. in Feet.	Diurnal Oscillation for 10° F.
	inches.		inches.		inches.
1000	0.022	6000	0.111	11.000	0.168
2000	0.043	7000	0.125	12.000	0.176
3000	0.062	8000	0.137	13.000	0.184
4000	0.080	9000	0.148	14.000	0.191
5000	0.096	10000	0.159	15.000	0.197

These quantities, when increased in the ratio of the actual diurnal changes of temperature, are quite large enough at any considerable elevation to overlay and mask the real diurnal oscillation, and ought therefore to be applied as a reduction to the sea level, whenever local circumstances are such as to render such reduction safe and possible, which is not often the case.

(178.) *Diurnal and annual fluctuations of temperature, and climatological distribution of heat.*—We have seen (arts. 11, 107) that moisture in the form of visible clouds, or even in that *excessively divided, yet unevaporated state* which is sufficient to injure the transparency of the atmosphere, and which must be confessed to belong to the yet unresolved problems of meteorology, produces absorption of the sun's rays, and the conversion of sensible into latent heat. The diurnal march of temperature, then, in the general atmosphere is intimately connected with its hygrometric state, and especially with its degree of *relative* dryness, *i.e.*, its more or less near approximation to a state of saturation; and for the same reason that the heat of the day is mitigated by the evaporation of the diffused moisture, so is also the cold of night by its deposition, and hence arises a phenomenon of very general prevalence, viz., that the difference between the daily and nightly extremes of temperature, or the extent of its diurnal fluctuations, is greater in summer than in the winter, or rather to speak more generally, and in language applicable alike to inter and extra tropical localities, in those seasons where the air is *relatively drier* or *moister*. In fact, it is evident that when the air is relatively dry, evaporation during the day is more active and a larger portion of the incident heat becomes latent; and on the other hand, that as it is necessarily the dew-point which limits (at least approximately) the temperature of the lowest stratum of air at night (see art. 45), since in the act of condensation the vapour gives out its latent heat, and therefore so long as the supply is continued prevents its further depression, the farther removed from saturation the air is, the greater depression can be effected by radiation before that limit is reached. The near coincidence of the dew-point with the lowest nightly temperature, at every season of the year, has been shown by Anderson from observations made at Kinfauns Castle during the year 1815, and the calculations of Kämtz show that the difference between the daily extremes of temperature is universally greatest in those months of the year when the relative dryness of the air is the greatest.

(179.) In India, again, where, properly speaking, there cannot be said to exist a winter, the moist and cloudy season is that in which the least diurnal fluctuation of temperature occurs—a circumstance sufficient of itself to show that it is not to the difference in the lengths of day and night, or to the low altitude of the sun in winter that the phenomenon in higher latitudes must be attributed, since between the tropics these causes can have but little influence. The east and west coasts of Ceylon exhibit in this respect a pointed contrast. At Colombo, on the western side of the island, the least diurnal change of temperature takes place in July, and the greatest in January, the rainy season being that of the SW. monsoon, when the sun is north of the equator; while at Trincomalee, on the eastern side, the reversed conditions as to moisture obtain, accompanied with a corresponding reversal in the extremes of temperature.

(180.) The uniformity of temperature which prevails at sea, and the greater general uniformity of an insular as contrasted with a continental climate, has already been noticed (art. 40), and is at least partly referable to the same cause, viz., the alternate conversion of sensible into latent heat, and *vice versa*, by the evaporation and condensation of moisture disseminated through the atmosphere during day and night, in addition to the causes there enumerated. In consequence, in the neighbourhood of the sea, on an average of the whole year, the twenty-four hours are unequally divided into the hotter and the colder portions; that is to say, those in which the temperature is above, and in which below the mean—the comparative shortness of the hotter portion being compensated by a greater absolute elevation of temperature, and the length of the colder by a less absolute depression.

(181.) The foregoing considerations sufficiently show how vain would be any attempt to conclude even an average of the progression of daily temperature, *a priori* setting out with a knowledge of the declination of the sun and the latitude of the place, and thence calculating the amount of heat received even in a calm atmosphere. Observation only can lead to any just conclusion, and the general process indicated in art. 150 must be resorted to, leaving to subsequent theoretical enquiry the difficult (indeed at present impracticable) task of assigning to direct solar and terrestrial radiation, moisture, and wind, their share in producing the final result. As instances, however, of the kind of results which are attainable in this direction, we shall here set down the formulæ for the mean diurnal temperature, calculated by Kämtz from the hourly observations of Chiminello at Padua, and those instituted by Sir David Brewster, at Fort Leith, near Edinburgh, viz., for Padua—

$$T = 56^\circ.75 + 4^\circ.79 \sin. (\theta + 51^\circ.47') + 1^\circ.00 \sin. (2\,\theta + 66^\circ.33') + 0^\circ.22 \sin. (3\,\theta + 233^\circ)$$

and for Fort Leith—

$$T = 48^\circ.24 + 3^\circ.03 \sin. (\theta + 44^\circ.43') + 0^\circ.43 \sin. (2\,\theta + 44^\circ.43') + 0^\circ.14 \,. \sin. (3\,\theta + 175^\circ.11').$$

(182.) It is a matter of much importance, in cases where a complete and continued series of meteorological observations cannot be obtained, and in sea voyages, where no lengthened stay is made at any one place, to ascertain the mean temperature approximately from the least possible number of observations. This may be accomplished in different ways, viz.—1*st*, By taking care to observe at those hours, or one of them in which the temperature is habitually, exactly, or very near its mean through the twenty-four hours, or at such hours as shall have the mean of their temperatures very nearly coincident with that of the day. Such hours are 4 A.M. and 4 P.M., or more conveniently 10 A.M. and 10 P.M. If four observations *per diem* can be made, these four epochs should be chosen in preference. 2*dly*, By taking the mean of the maximum and minimum for the mean temperature. This, however, is a coarse and rude approximation, as is obvious on considering what has been above stated, art. 180, as to the greater length of time during which, at stations near the sea, and still more at sea, the temperature ranges below the mean than above it. Kämtz recommends (from a discussion of the observations at

Padua and Fort Leith above mentioned) to employ the formula $m+\frac{\mathrm{M}-m}{36}(5{\cdot}076+x)$ where x is a variable co-efficient, fluctuating from 0·366 in December to 0.560 in August; and which may, for the purpose in question, be taken quite near enough at 0.44 . sin (Θ + 120°), Θ being sun's mean longitude. The mean temperature of the day may also be very approximately obtained from three temperatures t, t', t'', observed at 7 A.M., 2 P.M., and 9 P.M., by the formula

$$\frac{t+t'+2\,t''}{4}$$

or if observed at 8 A. M., 3 P. M., and 10 P. M., from the expression

$$\frac{7\,t+7\,t'+10\,t''}{24}$$

(183.) The annual fluctuation of temperature is derived from the consideration of the consecutive values of the mean temperatures of each day, or of the constant co-efficient A in the expression of the diurnal temperatures, considered as a periodical function of Θ, the sun's mean longitude; or, if we please, of θ, the arc proportional to the time commencing from any given date. For simplicity we shall suppose, however, that the value $\theta=0$ commences on the 1st of January, so that $\theta=15°$ corresponds to the middle of January, 45° to that of February, &c., or rather to the exact days nearest the middle of each month, which divide the year into 12 equal parts. The monthly mean of temperature being obtained by taking the arithmetical means of the daily ones for each month, the annual formula

$$\mathrm{T}=a+b_1\,.\,\sin.\,(\theta+c_1)+b_2\,.\,\sin.\,(2\,\theta+c_2)+\&c.,$$

will be obtained, as in art. 155. The following values for a series of stations in order of latitude calculated by Kämtz, will serve as examples for extra-tropical latitudes :—

Place of Observation.	Latitude.	Value of A deg. Fahr.	Value of B.	Value of C.	Value of B′	Value of C′	Hottest Day.	Coldest Day.
Enontekies . .	68°40′ N.	26°.85 F.	23.93	266°59′	1.92	404°21′	July 26.	Jan. 20.
Upsal, . . .	59 48 N.	41 .70	19.77	266 23	1.07	420 15	July 21:	Jan. 16.
Christiania, . .	59 54 N.	41 .60	19.15	264 26	2.13	434 29	July 20.	Jan. 17.
Manchester, . .	53 29 N.	47 .66	12.09	264 46	0.98	372 32	July 27.	Jan. 12.
Paris, . . .	48 50 N.	51 .44	14.48	266 13	1.39	344 31	July 28.	Jan. 15.
Padua, . . .	45 25 N.	54 .21	21.03	260 52	1.15	381 17	July 26.	Jan. 15.
Turin, . . .	45 5 N.	53 .00	20.08	267 41	1.81	343 41	July 27.	Jan. 5.
Fort Sullivan, . .	44 0 N.	41 .81	20.59	258 31	0.49	361 3	July 29.	Jan. 24.
Rome, . . .	41 54 N.	59 .87	14.64	260 21	1.23	386 14	Aug. 1.	Jan. 16.
Fort Johnston, . .	34 0 N.	66 .60	15.19	265 31	0.49	408 20	July 21.	Jan. 18.
Cape Town, . .	33 52 S.	66 .49	8.72	$\left\{\begin{matrix}264\ 38\\-180\end{matrix}\right\}$	1.28	357 43	Jan. 6.	Aug. 4.
Abusheher, . .	28 15 N.	77 .06	16.89	262 47	1.57	352 20	July 18.	Jan. 12.

To which, as a further example, we shall add the expression of the annual variation of temperature at St. Petersburg, from the *Correspondance Meteorologique* of M. Kupffer, 1848, where the terms beyond the 3d order, though given in the original, are suppressed as insignificant, viz.—

$$\begin{aligned}\mathrm{T}=38°{\cdot}73+23°{\cdot}32\,.\,\sin.\ &(\theta+263°\ 42')\\+\ 0°{\cdot}89\,.\,\sin.\ &(2\theta+115°\ 27')\\+\ 0°{\cdot}39\,.\,\sin.\ &(3\theta+234°\ 31')\end{aligned}$$

(184.) The general *coup-d'œil* of the annual progression of temperature afforded by these results is not a little remarkable. The values of C, upon which the epochs of the maximum and minimum and mean temperature mainly depend, are very nearly alike, and have but little reference to the latitude of the place, and as we see the epochs set down (those for Cape Town, whose latitude is south being reversed), all agree in placing the extreme of heat and cold nearly about the 26th July and the 14th January. The epochs of the mean computed from the formulæ offer a similar agreement; all fall within a very few days of the 24th April and 21st October. A general mean of the whole, which may be taken as a very near approximation to the law of annual temperature over at least the whole of the extra-tropical northern hemisphere, and probably also of the southern, may be expressed thus :—

$$\begin{aligned}\mathrm{T}=\mathrm{A}+\tfrac{1}{2}\,(\mathrm{M}-m)\,.\,\sin.\,(\theta+263°\ 54')\\+\tfrac{1}{30}\,\mathrm{M}-m)\,.\,\sin.\,(2\,\theta+23°\ 46')\end{aligned}$$

Where M and m are the maximum and minimum respectively of the mean diurnal temperatures (*Kämtz*, i. 126). As the co-efficient of the second term is 1-15th that of the first, which is the precise fraction by which the intensity of solar radiation fluctuates by reason of the change of the sun's distance—this might almost lead to a surmise, that the semi-annual term has its origin in this cause (since it is obvious that it cannot have a purely local origin.) In effect, if we consider the simple expression, $\mathrm{T}=\mathrm{A}+\mathrm{B}\,.\,\sin.\ (\theta+\mathrm{C})$, as varied by regarding A and B (which are evidently proportional, *cæteris paribus*, to the force of direct solar radiation) each to be variable by reason of the varying proximity of the sun, and to be represented respectively in general by $\mathrm{A}+a\,.\,\sin.\ (\theta+\alpha)$ and $\mathrm{B}+b\ .\ \sin.\ (\theta+\beta)$; A and β being still the *mean* values of these co-efficients in a whole revolution, the expression for T will become

$$\mathrm{A}+a\,.\sin.(\theta+\alpha)+\mathrm{B}\,.\sin.(\theta+\mathrm{C})+b\,.\sin.(\theta+\beta).\sin.(\theta+\mathrm{C})$$

which is reducible to the form

$$\mathrm{M}+\mathrm{N}\,.\,\sin.\,(\theta+n)+\frac{b}{2}\,.\,\sin.\,(2\,\theta+p),$$

M, N, P, n, p, being constants. This cause, then, would in fact introduce a term depending on $2\,\theta$, or having a semi-annual period, into the ultimate effect of the sun, and proportional to the eccentricity of the earth's orbit. We are quite ready to admit that this reasoning is not very strict, but the coincidence is a remarkable one, and it is rather thrown out as a surmise than as a demonstration.

(185.) Between the tropics, however, other and powerful causes, having obvious reference to geographical situation, tend to increase the semi-annual term, depending on $2\,\theta$, and by rendering it more nearly comparable to that depending on θ, disturb the regular increase and decrease in a very marked manner. Not only does the sun between the tropics pass twice a year through the zenith of each station, but the interception of his beams by cloud during the afternoon at least of almost every day in the wet season, the descent of a large quantity of cold rain from the upper regions of the air, and its evaporation from a heated soil, all go to disturb the simple law of increase and diminution of heat with the sun's meridian altitude and the length of the days, which moreover vary but little in these regions. Owing to these causes, then, the heat in those regions near the tropics where a rainy monsoon prevails, instead of continuing to increase as the sun becomes more nearly vertical, so as to produce a burning summer, remains nearly stationary, and even in some localities undergoes a slight depression, thus producing a double minimum with the progress of the rains, while in others, where this cause does not act, no such duplication takes place.

(186.) To determine with precision the mean annual temperature of a place requires the accumulation of many years' observation. This is abundantly shown by comparing the results obtained in successive years for a long period, wherever records exist of a dependable character, which can hardly be said to be the case, however, earlier than the year 1770, owing not only to absence of due care in ascertaining the zero points, and verifying the scales of thermometers, but also to the want of sufficient attention to circumstances of exposure, &c. Where, however, such records do exist, it is found that differences to the extent of two or three degrees of Fahrenheit in the means for individual years from a general mean of the whole occur. Thus in a series of annual temperatures deduced by Mr Glaisher from the records kept at the Royal Observatory at Greenwich, during the 85 years elapsed from 1771 to 1855 (both included), we find the extremes of cold and hot years to be respectively 51°.3 and 45°.1, differing by 6°.2 *inter se*, and 3°.1 each from the general average. So also in the series of mean temperatures for Manchester for 25 years from 1794 to 1818, derived by Dalton, we find a variation of 5° F. in hot and cold years; and in a similar series for Paris, as deduced by Bouvard from the records of the Observatory of that city for 21 years, nearly as much. Such differences might be expected when we consider the exceedingly variable influence of winds and cloudy and rainy seasons; and the differences, moreover, from year to year, succeed each other with great irregularity, so that it becomes exceedingly difficult to form any judgment as to the existence of a law of periodicity in this respect. The observations of Mr Luke Howard, indeed, in the neighbourhood of London, have led him to suspect a decennial period of fluctuation; and the records of the Greenwich Observatory above mentioned show a marked tendency to a regular increase and diminution, with a period of 14 years from minimum to minimum; but these two results partly contradict each other, and, so far as other similar records have been examined, no distinct conclusion on the subject would appear to have been arrived at. We shall not long, however, remain in ignorance on this point. Multiplication of stations, in which normally accurate observations are made, will furnish data in 15 or 20 years fully competent to decide the question; since any cause of a general or astronomical nature (such as that alluded to in art. 7) must of necessity make its appearance on the comparison of a great many stations, in the lapse of a single period, quite as evidently, indeed more so, than at one and the same station in the lapse of many.

(187.) As the mean annual temperature at any place is a very important element in its climatological relations, it is desirable to point out means by which it may be obtained with the least possible amount of observation and registry by residents whose avocations will not allow them to perform a complete series of meteorological observation. From what has been said (art. 184), it will easily be collected that from observations of the daily temperature from a week before to a week after the 24th April and the 21st October, in any part of the world beyond the tropics, will afford a certain approximation to the temperature in question; so will also a mean between the extreme temperatures (similarly observed at about epochs of maximum and minimum, January 14 and July 26.) Another method consists in deadening and weakening the effect of casual diurnal fluctuation by recording twice in the 24 hours, at 12 hours' interval, the readings of a thermometer with a long stem, having the bulb and lower part of the stem packed in a tin box of dry sand or saw-dust, but otherwise fairly exposed. A few days' attention to such a thermometer will show at what interval beyond the hottest and coldest times of the day its indications attain their maxima and minima, the means of which will give very nearly indeed the mean diurnal temperatures. The enclosure of a maximum and a minimum self-registering thermometer in a large cask of dry sand, which might be opened and read off twice a year, would also probably afford a very accurate mean result.

(188.) From what is said in art. 39, it is evident that the temperature of the soil at some considerable depth below the surface will never vary greatly from the mean annual temperature of the air, and that therefore the temperature of the last-drawn portions of large quantities of water, freshly drawn from deep, closed wells, or that of copious perennial springs which there is reason to believe do not rise from any very great depths (and so bring up the higher temperature of the interior of the earth), or descend from much higher land in the neighbourhood, will also afford a considerable approximation. At four feet deep, the mean temperature of the soil in extra-tropical regions may be considered as attained about the 10th of June and the 6th of December, at which times, therefore, its observation will give nearly the yearly mean temperature. Boussingault states that under the equator it is sufficient to observe the temperature of the soil at that or even a less depth, at any time, to obtain a very near approximation to this element.

(189.) As this element of all other meteorological data is that which it is desirable to obtain with the greatest precision, it is necessary to be on our guard against receiving, as final, results so obtained. The temperature of the soil is necessarily influenced by that of copious rain, which brings with it the temperature of the upper strata of the atmosphere, and carries it rapidly down below the surface, in a very different manner from that of sunshine, nocturnal radiation, or aerial conduction. Where the rains are distributed with tolerable equality over the year, the aberration of the mean temperature of the soil from that of the air from this cause is not likely to be material. But it is otherwise where the reverse of this condition prevails. Thus Smith found, in Congo, the temperature of a well 100 feet deep 73° F., being 5° below the mean temperature of the place of observation. Again, when the earth is long covered with snow, which during its melting preserves a uniform temperature of 32°, and while unmelted, greatly impedes the free communication of heat between the air and the earth, it cannot be that the same law of the downward propagation of temperature should be followed as if the same amount of water had fallen in a liquid form. M. Kupffer has constructed a series of lines analogous to Humboldt's isothermal lines, which he terms isogeothermal lines, and which connect the points at which the mean temperature of the soil is constant, thus forming a series of curves for 0°, 5°, 10°, ... as far as 25° Cent. These are by no means coincident with the isothermal lines of the same temperatures. Thus, for instance, the two curves for 10° C., which coincide over the southern part of England, begin to diverge where they enter on the continent of Europe,

—the isogeothermal curve deviating northwards in its eastern progress, until at a point in Asia, about half way between the Baikal Lake and the Caspian Sea (see the chart, Pl. CLXXIII.) (or in lat. 50°, long. 80° E.) it meets the isotherm of 5° C., thus indicating a difference of 5° C = 9° F. between the air and soil; and again, at a point north-east of Petersburg, in lat. about 63°, long. 40° E., a similar encounter between the isotherm of 0° (32° F.) and the isogeotherm of 5° (41° F.) takes place.[1] It is probable, however, that in most places where the soil is porous or gravelly, and where well-water is not found but at some considerable depth, the temperature of the soil at three or four feet deep under an area extensively roofed over and well drained around, and where no artificial temperature is kept up (and in cities many such may be found), a very exact annual temperature might be obtained.

(190.) But it is rather to careful observations of the temperature of the equatorial seas (according to a suggestion of Arago) at a few feet below the surface that we should look for normal results, capable of being compared from year to year with a view to bring into view any secular or periodic change of mean annual temperature. There are vast regions of the Pacific where, "over thousands of square miles, a wonderful uniformity of temperature prevails," and where both the diurnal and annual fluctuations are reduced within exceedingly narrow limits. In these, therefore, the accumulation of observations during voyages made with instruments *really* dependable, and executed with *really* scientific precautions, would very soon put us in possession of some decisive conclusion on this most interesting point.

(191.) The influence of the alternate annual approach and recess of the sun, consequent on the eccentricity of the earth's orbit, to produce an annual fluctuation of the *mean temperature of the whole earth*, has been shown in art. 12 to be *nil*. But Prof. Dove has shown, by taking at all seasons the mean of the temperatures of points on its surface diametrically opposite to each other, that the *average temperature of the whole earth's surface* in June considerably exceeds that in December. This is owing to the great excess of land in the northern and of water in the southern hemisphere, which gives to the general climate of the former more the character of a continental, to the latter more that of an insular or oceanic one (art. 40). Suppose A and a to be the summer and winter average temperatures in the former, and B and b in the latter. Then the summer falling in June in the northern, and in December in the southern, the June temperatures in both will be A, b, and their mean, or the average June temperature of the whole earth, $\frac{A+b}{2}$. Similarly the average December temperature will be $\frac{a+B}{2}$, and the difference, or (June—December) will be $\frac{A+b}{2}-\frac{a+B}{2}=\frac{A-a}{2}-\frac{B-b}{2}$, which is a positive quantity, because the fluctuation $A-a$ is (for the reason assigned) greater than $B-b$.

(192.) The best general idea of the distribution of heat over the globe is to be gathered from a chart of the isothermal lines; and as the limits of this article forbid our entering into any detailed account of a subject which properly belongs rather to the department of physical geography, we shall content ourselves with referring to that given in Plate CLXXIII., in which we find these lines already laid down on Mercator's projection, and to that given with less precision and in less detail, but conveying a clearer notion of their forms in high latitudes in the polar projection, Plate CLXXIV., and to the description of them under the head of CLIMATE, observing only that in the latter, one point only of maximum cold ($3\frac{1}{2}$° F.), that namely in the neighbourhood of Melville Island, is laid down, whereas the existence of a second point of even lower mean temperature (2° F.) appears to be sufficiently well established somewhere about the 79th degree of north lat., long. 120° east (which is accordingly duly projected on the other chart). The curves, accordingly, about the north pole bear no inapt resemblance (as remarked by Sir David Brewster) to the isochromatic lines, or coloured sphæro-lemniscates exhibited by polarized lights in a biaxal crystal, whose optic axes are inclined to each other about 30°, having the pole itself almost centrally situated between them, and their line of junction nearly coincident with that diameter of the polar basin which bisects it and passes through its two great outlets into the Pacific and Atlantic Oceans—a most remarkable feature, strongly indicative of the absence of land, and of the prevalence of a materially milder temperature (possibly not averaging below 15° F.) at the actual pole. Of the point or points of maximum cold in the southern hemisphere we know nothing.

(193.) The general equation of the optical curves in question is,

$$\sin.\theta.\sin.\theta'=T.$$

T being a number expressing what is called in optical language the *order* of the tint exhibited (and which varies in arithmetical progression, on passing from one curve to another in succession of the same colour) and θ, θ' the distances of any point in one and the same curve from the two poles respectively. Thus in fig. 7, S and S′ being the poles, P the middle point between them, A B C D the *optic equator* of the polarizing crystal, A P C, D P B meridians, the one passing through S S′, the other at right angles to it, and M N any one of the isochromatic curves of the order T, we shall have $SM=\theta$, $S'M=\theta'$. There can be no doubt then, from the general resemblance of the two sets of curves, that supposing a mean temperature thermometrically indicated by T to prevail at any point, M, in north latitude, a curve K L M N O traced by calculation from the equation $a.\sin.\theta.\sin.\theta'=T-\tau$ (a being some certain numerical constant independent of t), would approximate at least in some rude and general way to the isothermal line corresponding to T. Suppose this done for temperatures varying by *equal thermometric intervals* and a series of curves so drawn. It is obvious, then, that these curves, in respect of their magnitudes, distances from their foci and the pole P, as well as

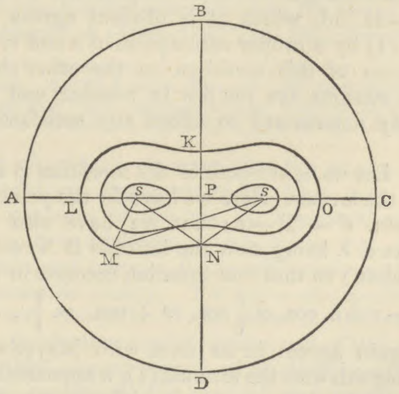

Fig. 7.

---

[1] We are bound to state what we find recorded, but we must confess that such results appear to us incredible.

in their general gradations of flexure, will coincide, or nearly so, with a series of isochromatic curves *equidistant in their orders of tint*. Now, this latter series will divide the meridians B P D and A P C, in a succession of points distributed over them, not at equal differences of distance from the pole P, nor alike in the two meridians, but following a certain law of progression in each. Let us enquire what this law is; and to begin with the meridian P D, passing through the poles:—Take $\lambda = \mathrm{A\,L}$, the latitude of L, then, for the values of θ, θ' corresponding to the point L, we have $\theta = 90^\circ - (c + \lambda)$ and $\theta' = 90^\circ - (c - \lambda)$, and therefore

$$\mathrm{T} - \tau = \sin.\,\theta\,.\,\sin.\,\theta' = \cos.\,(c + \lambda).\,\cos.\,(c - \lambda)$$
$$= \frac{a}{2}\left\{\cos.\,2\,c + \cos.\,2\,\lambda\right\}$$

or, which comes to the same thing, putting $\gamma = 90 - c$ ($= 75^\circ$, since $c = 15^\circ$ or thereabouts.)

$$\mathrm{T} - \tau = a(\cos.\,\lambda - \cos.\,\gamma^2)\ .\ .\ .\ (1)$$

Now it is remarkable that this is precisely the form in which Mayer endeavoured to express empirically the decrement of temperature in proceeding from the equator towards the pole, from such observations as could be obtained about the middle of the last century, and which has been adopted by Kirwan and most other meteorologists since his time with various more or less successful attempts to assign values to the constants a and $a\,.\cos.\,\gamma$ (regarded as a single co-efficient). M. Kämtz, who has taken vast pains to combine by the method of least squares, the mean temperatures on different meridians, so as to afford the most probable value of the co-efficient of Mayer's formula $a\,.\cos.\,\lambda^2 + \beta$, assigns for the meridian now under discussion, running from Melville Island through the interior of the American continent, as the centigrade reading of the mean temperature $\mathrm{T} = 56^\circ{\cdot}77 \times \cos.\,\lambda^2 - 21^\circ.56$, which it is obvious agrees with our equation (1) by a proper assumption of a and τ. On the prolongation of this meridian on the other side of the pole, the stations are too few in number and probably too loosely determined to afford any satisfactory comparison.

(194.) Let us next consider the meridian B D at right angles to the former. Here we have for the point N, $\theta = \theta'$, and $a\,.\sin.\,\theta^2 = \mathrm{T} - t$; but we have also $\cos.\,\theta = \sin.\,\lambda\,.\,\cos.\,c$, λ being now the latitude B N reckoned on this meridian; so that our equation becomes in this case,

$$\mathrm{T} - \tau = a.\cos.\,c^2\left\{\cos.\,\lambda^2 + \tan.\,c^2.\right\}\ .\ .\ (2)$$

which again agrees in its form with Mayer's formula. Comparing this with the formula (1), it appears that the coefficients of $\cos.\,\lambda^2$ in the two meridians are to each other in the proportion of $1 : \cos.\,c^2$, or about 100:93. The mean of the results obtained by Kämtz *in the northern portions* of the Atlantic and Pacific Oceans, compared with that similarly derived for the opposite meridian, gives 100 : 69 for the same ratio, which at least is so far satisfactory in the way of agreement, that the difference lies in the right direction. It will, of course, be understood that we have not the smallest intention of tracing any *physical* analogy between the two sets of curves, our only object being to point out the coincidence between them (which we do not remember to have seen before noticed), in respect of the arithmetical progression of temperature in the one series corresponding to that of chromatic sequence in the other, as something different from and additional to a mere general resemblance of form.

(195.) Another consequence of the general causes pointed out in arts. 37, 38 of the different habitudes of land and water as regards their reception and retention of heat, is the general law which appears to prevail in respect of the comparative severity of the winters and heat of the summers in the interior of the great continents of the northern hemisphere and on their coasts, and of the general mildness of climate on west coasts as compared with east, in the extra-tropical latitudes. The former is a very obvious result, and is strongly exemplified in the interior of Russian Asia. Thus Tobolsk, Barnaoul, and Irkutsk, with summers in which the thermometer for weeks together attains 86° or 88° F., have winters in which the *mean* temperatures are from —0° to + 4° F. Thus, too, at Astrachan, the mean summer temperature averages 70° F., allowing the production of the most magnificent grapes in the open air, with a mean annual temperature of only 48°, that of London. At Kislar, at the mouth of the Terek, in 44° N. latitude, that of the south of France, the thermometer sometimes falls in winter to—22° F. It is to Leopold Van Buch that we owe the first notice of this remarkable contrast of climates, the subject of which has been extensively pursued by Humboldt, Schouw, and others. The other consequence is not so obvious. Where the prevalent winds (the anti-trades) blow from the south-west, they carry with them an oceanic temperature and an abundant supply of vapour (which, as we have seen, tends to equalize the extremes of temperature) to coasts having a westerly exposure, while, on the other hand, the same winds arriving on eastern coasts after passing over extensive continents, propagate forwards in that direction the extreme climates of their interior. Again, those winds which are incident on eastern coasts from the seaward side, having mainly a north-eastern character, bring with them the cold of a higher latitude. This latter effect is strongly felt on the east coast of our island, while the extreme mildness of the west coast of Ireland and the north-west coast of Scotland equally testifies to the powerful influence of the there prevalent south-westerly winds.

(196.) Before quitting the subject of temperature and its variations, we must notice a conclusion which has been supposed to be obtained by dividing the year into penthemers or portions of five days each (with one of six in leap years), and calculating from extensive series of observations the mean temperature of each penthemer. This task has been executed by Ofverbom for a series of fifty years' observations taken at the Observatory of the Academy of Sciences at Stockholm, and by Brandes for a great many other European stations from Petersburg to Rome. The results go to indicate two rather remarkable *hesitations*, or even slight retrogressions in the generally regular increment of temperature from winter to summer, viz., one about the 12th of February, the other between the 4th and 14th of March, the date being later as the station lies more to the south. Both would seem to be attributable rather to northerly or north-easterly winds setting in about those dates than to any general cause, though some speculations would go to assign them a very remote origin, and even to trace them up to a periodical partial obscuration of the sun by flights of meteors (!)

(197.) *Of the periodical fluctuations in the hygrometric state of the atmosphere, and of the distribution of aqueous vapour on a large scale.*—With exception of a few very limited regions in which fogs are habitually prevalent, and certain points here and there occurring in which rain is almost constantly falling, the general state of the atmosphere is one of more or less hygrometric dryness, so that, as a rule, evaporation may be considered as going on continually over the whole surface of the globe, being only interrupted where that surface is during certain hours of the night cooled by radiation below the dew-point. During these, the earth is actually abstracting moisture from the air, at all other times supplying it; but far more copiously during the day than the night. Meanwhile, the very highest regions of the atmosphere being from time to time drained of their moisture by precipitation, there is always a demand for vapour upwards, which (in the view we have taken of cloud, art. 107) is no way intercepted in its ascent by the existence of a region where it assumes for a while a visible form, and which can only be looked upon as a temporary halting place, the upper surface of the cloud evaporating while the cloud itself is renewed by condensation of the ascending vapour at the lower; unless, indeed, the radiation from the cloud itself should for a time so far lower its temperature as to suspend for a while or even reverse the process. (See art. 95.)

(198.) At the epoch of maximum cold, when the surface of the earth is at or near the dew-point, the hygrometric state of the air, to a considerable altitude, is near saturation, and frequently either a stratus cloud rests on the ground or exists at a much lower altitude than in the day, and when this is not the case, still the whole column of air, by reason of the general depression of temperature, is much nearer to its point of saturation than in the day time.

(199.) It is the practice of meteorologists to designate by the expression "humidity of the air," the degree of its approach to complete saturation with vapour, and to give precision to this language by attributing to that degree a numerical value, viz., the ratio of the quantity of vapour actually present per cubic foot, as calculated from the dew-point, or otherwise determined (art. 89), to that which would exist per cubic foot were the air saturated, or were the dew-point identical with the actual temperature. Thus a scale of degrees of humidity is formed, 1·00 being that of complete saturation, and 0 that of absolute dryness. In this sense of the word it will, of course, be readily understood that a low degree of "humidity" is compatible with the presence of a large quantity of aqueous vapour. It is not the vapour as such (which, while it exists as a gas, is, like all other gases, "dry"), but its readiness to be deposited in a "wet" state on a surface but little lower in temperature, that is intended to be expressed. To obviate the discordance between this language and that of common parlance, the terms "relative humidity" and "relative dryness" are sometimes used.

(200.) As a general meteorological fact, however, there is not merely a want of accordance, but an actual opposition between both the diurnal and annual progress of the "degree of humidity," or "relative humidity" of the air and the "tension of vapour," as indicated by hygrometric observation—a seeming paradox, but one very easily explained. To take the case in hand—the diurnal variation—we have seen that at those epochs of the night when the temperature has reached its lowest point, and dew is either actually deposited or nearly so, the humidity is at its maximum. But it is precisely at that moment that the supply of vapour from the earth having been for several hours cut off, or even a reverse process in progress, while yet vapour has been diffusing itself into the non-saturated regions aloft, and is still continuing to do so, the actual amount of moisture per cubic foot is small, and is still in process of diminution. This epoch is usually a little before sunrise. As the day advances, the temperature increases, and becomes more and more in excess of the dew-point. The air, therefore, becomes relatively drier, evaporation goes on more rapidly, the lower strata become fuller of vapour, as measured by its tension, which at length becomes such as to keep pace with the upward diffusion, which now in its turn is stimulated. The cloud-level, or vapour-plane, rises; and if the night has been clear, the air calm, the sun powerful, and the soil wet, the appearance of cumuli soon begins to render visible testimony to the nature of the process in progress. When the heat of the day has reached its maximum, this process is in its greatest activity. The "humidity" has now reached its minimum, and the evaporation, which is in the direct ratio of the temperature and relative dryness, its maximum. From this epoch, however, the supply of vapour from below being most copious, while the temperature no longer increases, it is evident that the humidity must begin to increase, while the tension also, for a longer or shorter time, will do the same, until by the decline of the sun the increase of humidity so far puts a stop to the evaporating process as to render it barely competent to supply the expense of upward diffusion, at which moment the tension becomes a maximum, and from which it also decreases, and continues to do so the humidity increasing, during the remainder of the twenty-four hours until next sunrise, when the same cycle of causes and effects will recur.

(201.) Such at least will be their succession in calm and clear weather, and in a normal state of circumstances; and as regards the generally contrary march of the relative humidity as compared with that of the temperature and the vapour-tension, such is really the course of the phenomena. The epochs, however, and their order of priority, are obviously very liable to be disturbed by a variety of circumstances, among which the most influential are rain, winds (especially such as recur in daily periodicity, as sea and land breezes), and cloud which cuts off the sunbeams from the soil, and puts a stop to the increase of evaporation *before* the temperature has attained its maximum, thereby tending to bring the epoch of maximum tension towards coincidence with that of maximum heat. We find, for example, on comparison of the three elements in question, as derived from six years two-hourly observations at the Royal Observatory at Greenwich (1842-1847), the following results:—

	Maximum.	Minimum.
Temperature,	55°·22 F. at 1h. 20m. P.M.	44°·85 F. at 4h. 10m. A.M.
Vapour-tension,	0·345 in. at 1h. 20m. P.M.	0·303 in. at 3h. 40m. A.M.
Humidity,	0·938 in. at 4h. 30m. A.M.	0·753 in. at 1h. 20m. P.M.

Where it should be observed that the amount of cloud at Greenwich is a maximum at 0 h. 20 m. P.M., at which hour 73 per cent of the sky, on a general average, is covered, and a minimum at 9 h. 44 m. P.M., when 60 per cent of cloud prevails, the general average of the year being two-thirds cloudy. For other exemplifications of the same law, the reader is referred to the table of normal results in fixed observatories at the end of this article.

(202.) The annual march of humidity and vapour-tension as compared with that of temperature depends on the same principles, and is governed by the same laws; the humidity, however (as is also the case with the diurnal cycle), being much more regular in its progress than the vapour-tension, and the limits between which the latter element oscillates being much wider, as might be expected from the greater duration of the cycle, and the consequently longer time given for the causes in action to work out their full effect before removal. Thus in Greenwich the annual maxima and minima, and their approximate epochs, as appears from the series of observations already referred to, are for the

	Annual Maximum.	Annual Minimum.
Temperature,	63°·37 F. in July.	34°·20 Jan.-Feb.
Vapour-tension,	0·466 in. in July.	0·195 in. Jan.
Humidity,	0·930 in. in Jan.	0·783 in. June.

(203.) *Of the general distribution of moisture through the atmosphere.*—Locally and temporarily, nothing can be more capricious than either the humidity or the vapour-tension, as we ascend into the higher regions of the air. Meteorologists, from Saussure and Deluc downwards, have sought in vain for anything like a regular law of decrement like that which at least approximately prevails respecting temperature. Mr Rush relates that in his sixteenth ascent to the height of 19440 feet in the Nassau balloon, June 29, 1850, with Mr Green, they traversed a stratum of air 8600 feet in thickness, in which *absolute hygrometric dryness*, the zero of vapour-tension, existed. This must of course be received with some reserve; but it suffices at least to show that in regions of the globe where cloud is the rule and pure sky the exception, masses of air are occasionally intermingled with the generally moist atmosphere, which would seem to have been all but absolutely drained of their moisture, either by long sojourn in the polar regions, or in the highest and coldest strata of the atmosphere. Meanwhile, at the ordinary levels, we know little at present of the average or *climatic* distribution of vapour. Of some things, however, we may be certain, viz., 1*st*, That on the open ocean, far from land, the dew-point, in the day time, can never be many degrees below the actual temperature of the air, and at night must always be very nearly identical with it. 2*dly*, That the mean vapour-tension in hot climates must necessarily be greater than in cold. 3*dly*, That, *cæteris paribus*, the relative humidity of the air must be a maximum over the sea, and a minimum in the interior of continents, especially where there is much sand, which allows the rain-water to sink, and which speedily dries at the surface; or much bare rock, which, never being more than superficially moistened, affords no supply of vapour to the air. For it is obvious that in such regions there must be less evaporation for an equal incidence of sunbeams; that therefore less of their heat will become latent, and their efficacy in heating the air will be in consequence greater, so that the temperature will rise in the day-time faster than the dew-point, and that in an increasing ratio; and, moreover, that from the very combination of these causes, there will be less tendency to the formation of cloud over such regions, and therefore a greater amount of direct sunshine thrown on the soil. Thus we have a system of mutually reacting causes and consequences (no uncommon arrangement in meteorology), all tending to exaggerate both the heat of the climate and its relative dryness: the only counteracting power being that of radiation, both diurnal and nocturnal, but especially the latter. Where, in addition to all these causes, those winds which blow from warmer regions or from tropical seas, before arriving over the place in question, have to pass over lofty mountain ranges, and have been chilled in so doing, and drained of their moisture, by the precipitation of snow or rain, it may well be imagined that a state of extreme relative aridity will prevail. 4*thly* and *lastly*, We may be very sure that the upper regions of the atmosphere (not only as being colder, and therefore incapable of retaining without deposition a quantity of vapour equal to that of the lower, but for the reasons assigned in art. 88) must be *habitually, and on a general average*, both absolutely and relatively drier than the lower, though the existence of cirrus cloud at very high levels (certainly sometimes exceeding 30000 feet) sufficiently proves that even at such altitudes saturation with moisture occasionally takes place. During the sojourn of Mr P. Smyth on the Peak of Teneriffe, the aridity of the air was found to be always excessive. On one occasion at Guajara (alt. 8843 feet) the depression of the dew-point below the temperature of the air was observed to be no less than 54° F., and on another, at Alta Vista (10707 feet), 40°, the depression at the sea level being habitually about 10° in the middle of the day.

(204.) In actual cloud (although in the earlier history of hygrometry the fact was questioned, owing to the imperfection of the hygrometers used), both common sense and observation go to prove that the extreme point of humidity is attained, since where water is bodily present in every cubic inch of air, and refuses to disappear by evaporation, a state of absolute saturation must exist, just as in brine in which finely powdered salt is suspended without solution we conclude a state of saline saturation. Hence we are led to some singular enough conclusions with respect to the law of decrement of *humidity*, as distinct from vapour-tension.

(205.) In the day time, so long as the sky is cloudless over any spot, it is evident that there is no point in the aerial column above it at which the dew point is surpassed, so that the supply of moisture from below is carried off by diffusion upwards, and it will depend entirely on the copiousness of this supply, and the rapidity with which it ascends into the higher regions, whether, as the day advances, the vapour-tension and humidity shall follow a contrary or similar progression. If the supply be abundant and borne up rapidly to a colder level, a cloud will be formed, and it is obvious that for some time before its actual visible appearance, the air in that region where it is about to be formed must be gradually approaching saturation, and attain it at the moment of deposition of the first molecule of water in a liquid state (and here we cannot help remarking, *obiter*, that it is utterly inconceivable how, under such circumstances, a *vesicle* should be formed). From the ground, then, up to the vapour-plane, wherever such plane exists, whatever be the law of vapour-tension, the humidity (perhaps with some interruptions in respect of regularity) continually increases up to 1·000, its natural limit, which it maintains through the whole thickness of the cloud stratum. This level passed, the upper surface of the cloud *performs, to all intents and purposes, as regards the higher atmosphere, the office of a lake or sea*, being a thoroughly *wet* surface on which that atmosphere reposes. Henceforward, therefore, the law of decrement of moisture will be the same as it would be over the sea itself under the same circumstances of temperature and pressure. Nor does anything prevent (the sun striking on and evaporating it) why a second layer of cloud should not be formed again at a higher level, and so on—a phenomenon, in fact, of no rare occurrence. In such a case, if we take the height for an abscissa, as A B, the curve of humidity will be an undulating one, such as E F G H I, attaining its maximum, 1·000 (= B F or C H) at F or H, and having a minimum between them as at G, while the curve of tension P Q R S T follows a progression totally different—the relation between any pair of their respective ordinates, C H, C S, being that which subsists between the

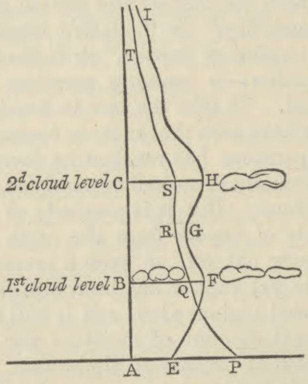

Fig. 8.

temperature, tension, and humidity generally, a relation expressible by the equation,

$$V = H \,.\, \varphi(t)$$

where V is the vapour-tension, H the humidity, and $\varphi(t)$ the function of the temperature t, which expresses the force of saturated vapour at that temperature (art. 92).

(206.) *Dependency of atmospheric pressure, temperature, and moisture on the direction of the wind. Dove's general views of this dependence.*

There can be no doubt that by persevering and long-continued observation, the same laws of diurnal and annual periodicity will be found to be observed in the direction and force of the wind as in the other meteorological elements; but they are so much more masked by what we must at present term casual and accidental causes, that, except in certain great features (such as have already been described, art. 58, *et seq.*) and in certain geographical situations, they cannot emerge from the mass of overlying irregularities except in very long periods. The extreme mobility of the air, the powerful agencies at work to set it in motion, and the extensive propagation and prolonged duration of movements once communicated to an elastic fluid so constituted, all go to mix up, at each particular spot and moment, into one common resultant, motions which have originated at many very remote points, and at very different epochs. Along the coasts of heated continents, or even islands in tropical regions, indeed, the diurnal alternation of sea and land breezes is a result obvious enough of itself and confirmed by observation; and in the temperate zones, the approach of the sun to their respective poles is masked by a bias in the general direction of the wind towards an easterly, and its recess by one towards a westerly direction, the more marked the nearer the point of observation is to the exterior limit of the trade winds. But as regards the wind in general, it is found more advantageous to abandon this point of view, and to regard it, not in its remote connection with the general cause of periodicity, but in its immediate relation to the other meteorological elements with which it stands in more obvious connection.

(207.) The winds, which are originally caused by the equatorial heat and generation of aqueous vapour, or by extensive local agencies of the same kind elsewhere produced, act as their transporters from place to place, and as their distributors over the globe. It is, therefore, very obvious that a wind blowing with any degree of continuance and force from a lower to a higher latitude must bring with it to the latter both the superior temperature and moisture of the region it has left, and *vice versâ.* Thus in our latitude, a south-west wind is warm and moist, a north-east cold and dry. The excess of vapour in the former has a powerful tendency to form cloud in coming into a colder climate, and to be deposited in rain; the latter arriving with a low vapour-tension in a warmer region, absorbs both heat and moisture, clearing the sky of cloud, and, while depressing the temperature, gives that peculiar "bracing" quality which is the effect of a cold, dry air, in contrast with the "relaxing" influence of moist warmth. These effects are familiar to every one, and have been remarked from the earliest times. The general indication thus afforded has been, however, pursued into minute detail by M. Dove in his excellent work entitled *Meteorologische Untersuchungen* (Berlin, 1832), in which he has succeeded in exhibiting in a very distinct manner, by an extensive induction from observations in almost every region of the globe, the close and immediate dependence of all the three great meteorological elements, temperature, moisture, and atmospheric pressure, on the direction of the wind, or the point of the compass from which it blows. In other words, assuming θ to represent the angle which that direction makes with the meridian of the place (reckoned from the north or south according to the denomination of the elevated pole), any one of these elements, E, is found to be expressible, on an average or mean value during a whole year or series of years, by the equation of the form,

$$E = A + B_1 \,.\, \sin.\,(\theta + C_1) + B_2 \,.\, \sin.\,(2\,\theta + C_2) + \&c. \ldots (a)$$

(208.) The mode in which a law of this kind may originate is not difficult to understand. Suppose, 1*st*, the earth without diurnal rotation, and the sun to move round it from east to west, and at any given spot (suppose in the northern hemisphere) let a wind blow direct from the south with a certain force and during a certain time, this will bring over the place of observation the warmth and moisture of a latitude more southerly (suppose) by 10°. But now suppose a wind of the same force to blow for the same time, not from the south, but from the eastward or westward of south, at an angle $\theta°$ with the meridian: the atmosphere of a place 10° remote, measured on a great circle, will be still transferred to the place, but owing to the inclination of its path, only $10° \times \cos.\,\theta$ more south. If, therefore, the former wind brought with it an accession of temperature or moisture, represented by e, this will bring the accession $e \,.\, \cos.\,\theta$ proportional to the difference of latitude travelled over. It may happen, however, from the circumstances of the locality, that the warmest or moistest region in the neighbourhood may lie, not due south of the place, but in a direction making an angle $90° - C$ with the meridian. In this case, then, the extraneous temperature, or moisture so induced, will obviously be represented, not simply by $e \,.\, \cos.\,\theta$, but by $e \,.\, \cos.\,(\theta + C - 90°)$ or $e \,.\, \sin.\,(\theta + C)$.

(209.) The effect of the earth's diurnal rotation is to cause a wind setting in from the southward to veer more and more westerly the longer it has continued to blow, and from the northward more easterly, so that, to use M. Dove's expression, the direction of the wind belies the region from which it has travelled. The wind, therefore, which really reaches the spot in question from the most southern region (and which brings the greatest amount of extraneous heat and moisture) will not be a south wind on its arrival, but one having more or less of a westerly character, according to the latitude of the place and other circumstances of local resistance, and *vice versâ* for the opposite influences. In so far, then, as the great equatorial and polar system of wind-currents is concerned, the general effect will be represented nearly by the formula,

$$e \,.\, \sin.\,(\theta + C')$$

on a mean of every season and of every direction of the wind; and if to this be added the subordinate influences which may be propagated to the locality in question from regions nearer at hand than the equator, and which may each and all of them give rise to similar effects, represented by $e' .\, \sin.\,(\theta + c')$, $e'' .\, \sin.\,(\theta + c'')$, the total effect, being the sum of all these, will, as is easily seen, be reducible to a single term of the general form, $E \,.\, \sin.\,(\theta + C)$.

(210.) The effect of any wind in heating a place will evidently be proportional not merely to its excess of temperature, but to the quantity of air having that excess which passes over the place, and which has changed its latitude, that is to say, in the absence of any information as to its velocity, to the degree of frequency and duration of that particular wind. The co-efficient

e, then, in the expression $e \,.\, \sin.\,(\theta + C)$ is dependent on this degree, which itself, in any given locality, is dependent on θ, the north-east and south-west winds being most frequent, and the other winds rarer, in some definite relation to their duration. In other words, e is a function of θ, having two maxima, viz., for $\theta = 45°$ and 225°, and two intermediate minima, not necessarily at right angles to these. e, then, may be conceived as generally capable of expression in some such form as $(e) + f \,.\, \sin.\,(\theta + g) + h \,.\, \sin.\,(2\,\theta + i)$, the combination of which with $\sin.\,(\theta + 45°)$, or $\sin.\,(\theta + C)$, will give rise to a set of terms containing the sines and cosines of θ and its multiples, with co-efficients depending on $(e), f, g$, &c., and which are reducible, in their ultimate expression, to the general form in art. 146.

(211.) The dependence of the barometric pressure on θ in a similar form of expression is not so evident on these principles. But it must be remembered that a warm and moist atmosphere is lighter, bulk for bulk, than a dry and cold one, and that as the effect of a surface wind (at least of one of any continuance) is to transfer bodily the lower strata of the atmosphere of one place to another, so the barometer, apart from all other causes of periodical fluctuation, will vary in inverse correspondence with the temperature and moisture.

(212.) M. Dove, and after him Kämtz and others, following out in greater detail this train of inquiry, have come to very positive and distinct practical conclusions on all these several heads. In fact, it appears, as a general law, that in the "wind-rose," or compass-card, there are two points not far from diametrically opposite each other: the one in the neighbourhood of the NE. point, the other in that of the SW., from which when the wind blows, *on the long average*, both the temperature and the vapour-tension have their maxima and minima, the former at the NE., and the latter at the SW. The same, or nearly the same, points or poles of the compass-card indicate, reversely, the minimum and maximum of barometric pressure. Particular localities show deviations from each other and from the general and normal form of expression, both in respect of the precise situation of these "weather-poles" on the compass-card, and in their exact diametral opposition, as also in the situation of the intermediate mean position. On the whole, however, for each locality, and for each of the three elements in question, it is found practicable to represent its variation, in terms of the azimuth θ of the direction of the wind, by the expression,

$$E = A + B_1 \,.\, \sin.\,(\theta + C_1) + B_2 \,.\, \sin.\,(2\,\theta + C_2)$$

in which C_1 is very nearly the same angle for all of them, and in which B_2, the co-efficient of the term of the second order, is found to be small in comparison of B_1, that of the first. And it is evident that the total barometric pressure $P + p$, and the vapour-pressure p, having both this form of expression, their difference P, or the pressure of dry air, will admit of a similar one by a proper determination of its co-efficients, which are easily deduced from those of its component elements by putting

$$\begin{aligned} &P_0 + P_1 \,.\, \sin.\,(\theta + C_1) + P_2 \,.\, \sin.\,(2\,\theta + C_2) \\ &+ p_0 + p_1 \,.\, \sin.\,(\theta + c_1) + p_2 \,.\, \sin.\,(2\,\theta + c_2) \\ &= P'_0 + P'_1 \,.\, \sin.\,(\theta + C'_1) + P'_2 \,.\, \sin.\,(2\theta + C'_2) \end{aligned}$$

where P' represents the mixed pressure, and the several numbered and accented letters the respective co-efficients of the general formula, and which, reduced by the usual trigonometrical transformations, afford equations by which any one set of these values may easily be derived from the other two. It is evident, moreover, without any calculation of this kind (as M. Dove observes), that since the elastic power of the vapour has its maximum at the SW. point, where the *total* barometric pressure has its minimum, the dry pressure P must have its minimum there also; in other words, that c_1 being approximately $= C_1 + 180°$, C'_1 will be nearly identical with C.

(213.) Pursuing the inquiry still further, M. Dove finds, as indeed might be expected, that these co-efficients are severally and separately, like all meteorological local elements, periodical functions of the season of the year, or of the sun's mean longitude; and he has been enabled to assign for several localities their spring, summer, autumn, and winter values, his conclusions having been completely established, in their general expression, by all subsequent observation.

(214.) It is sufficiently obvious, from the principle with which we set out (art. 208), that a similar series of relations ought also to subsist in the southern hemisphere, *mutatis mutandis*; that is to say, that the directions of the maxima and minima, instead of NE. and SW., will be SE. and NW., in conformity with the general law of the winds in the two hemispheres.

(215.) As an example of the results obtained in this branch of meteorological enquiry, we shall here set down the values of the co-efficients in the expression $E = A + B_1 \,.\, \sin.\,(\theta + C_1) + \&c. \;.\;.\;.\;.$ as calculated by Prof. Johnson from the series of meteorological observations made under his superintendence at the Radcliffe Observatory at Oxford. These are (*Radcl. Obs.* 1854, p. xxvi.) for the

	A	B_1	C_1	B_2
Temperature T	48°·60 F.	2°·34	254°35′	0
Dry Pressure P	29·404 inch.	0·108 inch.	75 33	0
Vapour-Press. p	0·307 inch.	0·026 inch.	259 39	0

where it will be noticed, that 180°+75°33′=251° 33′, and therefore, conformably to the theoretical views above delivered, the dry pressure has its minimum very nearly corresponding to the maximum of temperature and of vapour-pressure. Whenever, as in this case, which is the most common, the terms of the second and higher orders, are insensible or nearly so, the co-efficient B_1 determines the maxima and minima, so that the respective values of $2\,B_1$ will express the total amount of fluctuation in temperature, pressure, &c., at the stations which have their origin in changes of wind.

(216.) It is very easy to perceive that with this dependence of the great elements of weather upon the direction of the wind, the other features which stand to them in the relation either of immediate consequences or proximate causes, must go hand in hand—such as cloud, rain, &c. For instance, at Karlsbad, from the calculations of Eisenlohr, it appears that, during the prevalence of SW. wind, 1 day out of 17·29 on an average only is free from cloud, and during that of NE. 1 out of 3·04, the intermediate winds being accompanied with intermediate degrees of frequency. So also for rain: 1 day out of 2·75 during SW., and one out of 11·92 NE.; the minimum of rain, however, here occurring with an E. or ENE. wind; stormy weather 1 out of 17·36 of SW., and 401·50 NE., clearly indicating the influence of the headlong down-rush of the upper equatorial current of the *anti-trades* in the manner indicated (art. 62.)

(217.) Not less distinctly marked is the degree of frequency of each particular direction of wind in connection with the direction itself. Out of 40 places enumerated by Dove in every part of Europe in which sufficiently prolonged series of observations of the direction of the wind had been collected by him, 21 have a very large and decided predominance of days of west wind, 16 of SW., 2 only of NW., and only one (Kasan) SE. We have already seen (art. 83) that the prevalent wind in Europe generally is WSW. or thereabouts. After these, the other or inferior maximum occurs at E. in 18 places, NE. in 11, N. in 5, and SE. in 6, the average direction of this maximum being about ENE. so that the position advanced in art. 216 is fully borne out by observation.

(218.) At the end of this essay the reader will find a table containing the mean, the maximum, and the minimum values (with their epochs diurnal and annual) of the principal meteorological elements obtained from the data afforded by the best and most systematically conducted series of observations, being for the most part those which have been carried on since 1840, in the magnetic and meteorological observations established by the British, Russian, American, Belgian, and other governments, and national and local institutions, on a concerted system of hourly or bi-hourly observation. They afford numerous and striking exemplifications of the laws explained above, and clearly show their general applicability, especially as regards the contrary march, both annual and diurnal, of the humidity and vapour-tension; the greater range of the annual as compared with the diurnal fluctuations, and the dependence of the average amount of vapour present in the air, and the extent of both kinds of fluctuation on the latitude. It would have been easy to have covered our pages, indeed to fill volumes with climatological records and statements, such as the reader will find in Humboldt (*Asie Centrale*, vol. iii.), amassed by the diligence of Mahlman; in the more extensive collections of the latter and Prof. Dove, in the 4th vol. of the *Repertorium der Physik;* and in the Reports of the Senate of the University of New York to Congress; the *Correspondence Meteorologique* of the Russian observatories, &c. Not only, however, do the limits allowed us forbid the adoption of such a course, but we consider it more instructive to concentrate attention upon a few carefully determined and selected cases than to diffuse it over a larger field of bewildering particulars.

Optical Phenomena of Meteorology—1. *The Rainbow.*

(219.) The explanation of the rainbow, suggested by Roger Bacon, but only first clearly made out by Newton, is so familiar an illustration of the laws of coloured refraction in every treatise on optics, that we should not have thought of introducing it into this essay but for the vagueness of idea and misconception which are generally prevalent respecting the origin of the "supernumerary bows," *i.e.*, those coloured fringes which are often seen in the interior of the primary rainbow, and more rarely (on account of the comparative faintness of the whole phenomenon) at the exterior of the secondary rainbow. They have been explained by Dr Young on his fertile principle of interferences, but his explanation (*Phil. Trans.* 1804) is so obscurely expressed, or rather indicated, as to be hardly intelligible, which is perhaps the reason why Kämtz, the most exact and industrious of reporters in matters of meteorological theory, while assembling all the other explanations which from time to time had been put forth by Pemberton, Venturi, Brandes, and others (some of them very absurd, and with none of which he appears to feel satisfied), passes this, the only correct one, in silence. Neither is it noticed by M. Pouillet in his recent elaborate *Elémens de Physique*, who in place of it, offers a surmise as to their origin which cannot be the true one, and which is refuted by an experiment of M. Babinet, which he cites in illustration. Mr Coddington, in his treatise on reflexion and refraction, explains only the Newtonian Bows, his subject not extending to the phenomena of interferences, while Dr Lloyd, in his treatise on light and vision, contents himself with mentioning the fact of their having been explained by Dr Young, without giving the steps of the explanation. We shall not, therefore, scruple to devote some small portion of our allotted space to rescuing this very beautiful illustration of the law of interference from unmerited neglect.

(220). Let θ be the angle of incidence of a solar ray on the surface of a spherical drop of water (θ being 0° when the ray enters at the vertex next the sun, and passes diametrically through the drop, and 90° where it just grazes its circumference), φ the corresponding angle of refraction, and μ the refractive index for a ray of any given colour, μ being greatest for violet and least for red rays. Then shall we have $\sin. \theta = \mu . \sin. \varphi$, and the deviation of the ray by refraction will be $\theta - \varphi$. If the ray be reflected internally after entering the drop, it is easy to see, by tracing its course within the sphere, that at each reflexion an additional deviation in the same direction of $180° - 2\varphi$ will take place, and at its final emergence a further deviation (still in the same direction) equal to that at entering or $= \theta - \varphi$, so that the total deviation after n reflections will amount to $n . 180° + 2\theta - 2(n+1)\varphi$, which is a function of θ in virtue of the relation $\sin. \theta = \mu . \sin. \varphi$; ($a$) Now this function, which is $n . 180°$ when $\theta = 0$, diminishes as θ increases (since μ being nearly $\frac{3}{2}$, $2(n+1)\mu$ is necessarily greater than 2), and continues to diminish until it attains a minimum, when its differential vanishes, or when $d\theta = (n+1)\, d\varphi$, which, by eliminating $d\varphi$ by combining this with the differential of equation (a), gives

$$\sin. \theta = \sqrt{\frac{(n+1)^2 - \mu^2}{(n+1)^2 - 1}}$$

and for the case of the primary bow, where $n = 1$, $\sin. \theta = \sqrt{\frac{4 - \mu^2}{3}}$ in which substituting for μ the exact refractive indices of the extreme red and violet rays for water, we find for the red rays $\theta = 59° 32'$, $\varphi = 40° 22'$, and Δ (the deviation) $= 137° 36'$, and for the violet the corresponding values 58° 46′, 39° 30′, 139° 32′. When the deviation is a minimum, the rays incident more and more remotely from the vertex of the drop, and which, up to that point, were dispersed at their emergence by their change of deviation, cease to be so, and emerge parallel. An eye, then, properly situated with respect to the drop will receive a parallel red pencil of rays in a direction 137° 36′ remote from that of the sun, and one of violet in a direction 139° 32′ remote from it; or, in other words, at the angular distances 42° 24′ and 40° 28′ respectively, from the point of the heavens opposite to the sun, which are therefore the angular radii of the elementary red and violet rainbows.

(221.) So far the Newtonian explanation of the bow. As regards the fringes, if we put $D = 180° - \Delta$, it is evident that D will represent the deviation of the emergent ray, not from the direction in which the sun's rays *proceed*, but from that in which the sun is *seen*, and will therefore express the *dispersion outwards* of the emergent ray from the latter direction, and will be a maximum when Δ is a minimum. The parallel *pencil of rays*, therefore, by which the rainbow is seen, has the maximum angle of dispersion outwards from the sun, and all other rays at their emergence will have a less, whether their points of emergence be nearer to or farther from the vertex of the drop. For every such point, then, *more* remote from the vertex, it will be possible to find a corresponding point less remote, such that individual rays (*not pencils*) emerging from both shall have the same angle of dispersion; and which, of course, shall pursue parallel directions, and when incident on the eye shall be collected on the same precise point of the retina, and shall therefore be in a condition to interfere with, and destroy or reinforce each other, according to the difference of their total paths traversed both within and without the drop, before reaching the eye.

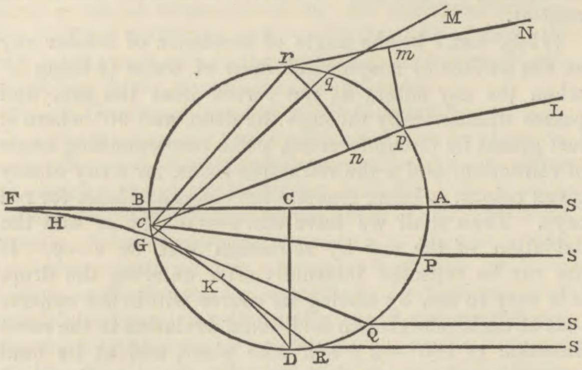

Fig. 9.

(222.) Let A B D be a section of the drop through the sun (in the direction C S from the centre C). Draw D E perpendicular to C S; and taking the principal focus for rays refracted at the convex surface E A D, let D G F be the caustic of the quadrant D A. Let S Q G *q*, be the course of the pencil of rays which emerges parallel along *q* M (as the drop's contribution to the rainbow), and taking any point P between A and Q, draw P *c* H, touching the caustic in H, and cutting the surface in *c*. Then will P *c* be the course of the refracted ray before, and *cp* after reflexion, and *p* L its ultimate diversion on emergence. From *c* draw *c* K R touching the caustic in R. This will be the direction of another ray S R after refraction, and supposing *c r* to be its reflected course, the incidences of the rays *cp*, *c r*, on the one side of the sphere will be symmetrical to those of *c* P, *c* R, on the other, and therefore P S and R S (regarded as rays from *c* refracted outwards) being parallel to each other, *r* N and *p* L, the courses of *c r* and *c p* after emergence, will also be so; and P, R will lie on opposite sides of Q, and *p*, *r* of *q*, because as *c* approaches to G the point where the caustic meets the sphere, H and K both do so also. P and R approach and ultimately coincide at Q, and *p r* at *q*, the latter being the point at which *contiguous* rays emerge parallel. Thus, for every point of emergence *p* nearer the vertex than *q*, another *r* more remote has been found, under the condition appropriate to the interference of the emergent rays.

(223.) Thus we see that every ray emerging between A and *q* will have a fellow ray emerging parallel to it between *q* and E, and interfering with it by a difference of undulations, determined by drawing *p m* perpendicular to *r* N, and *r n* a circle, having *c* for its centre; for the difference in question (δ) will be expressed by $\frac{r\,m}{v} - \frac{n\,p}{v'}$ where v, v' are the velocities of light in air and in water, that is, since $v' : v :: 1 : \mu$, by $r\,m - \mu \,.\, n\,p$. It is not necessary to go into any calculation of the value of this; it is sufficient that it increases regularly from 0 (when *r* and *p* coincide with *q*) *not merely because both r m and n p vanish there*, but because at *q* and its neighbourhood $r\,m : n\,p :: \mu : 1$, so that the parallel rays which form the rainbow have no difference of phase, while as the inclination of the emergent rays *r* N, *p l*, to the visual ray of the rainbow *q* M increases, so does also their difference of phases.

(224.) The larger the drop the greater are the linear magnitudes of all the elements composing its form, and therefore of *r m* and *n p*, and consequently δ. Hence, to the same difference of angular directions between the rainbow and any pair of interfering rays will correspond a larger value of δ the larger the drop, and therefore a greater difference of phase and number of fringes; or, in other words, the angular breadths of the successive fringes are inversely as the diameters of the drops. If, then, the drops differ much in diameter, and there be no greatly prevalent average diameter, the fringes formed by one drop will confuse those by another. It is only, then, when owing to some existing condition in the formation of the rain, there is a large preponderance of drops having very nearly the same diameter that these fringes will be visible. They are especially well seen, and the whole phenomenon of the primary bow is exhibited with peculiar distinctness, when on a sunny morning the eye is held close to a gossamer covered with dew (in perfectly distinct microscopic globules of nearly equal magnitude), the back being turned to the sun and the head so placed as to allow his light to fall laterally on the net-work on which the globules are strung like beads. Four or five internal fringes may be distinctly traced within the bow formed by an even undisturbed gossamer.

(225.) The angle of dispersion D being a maximum for rays forming the rainbow, it is obvious that no drop outside of the bow can send to the eye any ray once internally reflected from the sun. Hence the greater apparent illumination of the ground of the sky inside of the bow. The rainbow ray is, in fact, the asymptote of the exterior caustic for rays twice refracted and once reflected.

(226.) In reference to the formation of a rainbow on cloud or fog in the entire absence of rain (art. 93), Colonel Sykes, in his paper on the Meteorology of the Deccan (*Phil. Trans.* 1835), relates a remarkable instance of one seen by him from the top of a precipice from 2000 to 3000 feet in perpendicular height, forming the north-west scarp of the hill fort of Hurrachandarghur, among the Ghauts, overlooking the plains of the Concan (Konkhun), densely covered with fog-cloud, rising somewhat above the level of the precipice, but not covering it. Under these circumstances, having the sun at a low elevation at his back, he says, "A circular rainbow appeared, quite perfect, of the most vivid colours, one half above the level on which I stood, the other below it. Shadows in distinct outline of myself, my horse, and people, appeared in the centre of the circle, as in a picture to which the bow formed a resplendent frame." "From our proximity to the fog, I believe the diameter of the circle at no time exceeded 50 or 60 feet. The brilliant circle was accompanied with the usual outer bow in fainter colours." In the same paper, he also records his observation of a white rainbow in a fog-bank near Poonah, within which he was riding. "Suddenly I found myself emerge from the fog, which terminated abruptly in a wall some hundred feet high. Shortly after sunrise, I turned my horse's head homewards, and was surprised to discover in the mural termination of the fog-bank a perfect rainbow, defined in its outline, but destitute of prismatic colours." "Niehbuhr, in his Voyage to Africa, describes a white rainbow, and Mr St John, in his Lives of Celebrated Travellers (iii. 121), mentions having seen one, on the 21st May 1830, in Normandy, on 'the morning mist.'" On the other hand, it should be mentioned that Mr Smyth, in his recent sojourn on the Peak of Teneriffe, with a cloudless sky and perpetual sunshine above, and with a boundless sea of cloud continually extended in all directions below him, makes no mention of a rainbow being at any time formed upon it.

(227.) *Halos.*—These are of two kinds: the first, large circles of definite and constant diameters, one of 45°, the other of 92°, and which are seldom both seen together. The colours are very feeble, especially of the larger, which is usually almost or quite white. The formation of the lesser of these, as explained by Mariotte, is due to the existence of minute prisms of ice floating in the air, having refracting angles of 60°, and their axes turned in all possible directions. If we take a triangular prism of glass, and turn it about in a sunbeam, it will refract out from one of its angles a coloured beam, whose deviation from the direction of the incident light varies as the prism is turned, being at first very great, but diminishing until at one point of the rotation the deviated beam becomes for a while stationary, and then (the rotation continuing in the same direction) begins again to increase. There exists, then, for every refracting angle of the prism a minimum angle of deviation, dependent on the refractive density and the angle of the prism. In ice, with a refracting angle of 60°, this deviation is about 23° for red light, and therefore, among an infinite multitude of such prisms scattered through the air, a far greater number will throw out a refracted beam 23° inclined to the direct ray of the luminary than in any other direction, since about the position of the maximum a considerable amount of rotation of the prism causes but a very trifling change in the direction of the refracted ray. At the angular distance of 23°, then, from the apparent place of the luminary, there will be a much larger percentage of prisms in the visual line capable of sending a refracted beam to the eye than at any other, and a dim circle faintly coloured with red internally, and better defined within than without, will be seen.

(228.) The halo of 92° diameter is accounted for in a similar manner by refraction through the angle of 90°, at which the sides of hexagonal or triangular prisms intersect their basis, and which in ice gives a minimum deviation for red rays of about 46°. Besides the agreement of these angles assigned by theory with the measured semidiameters of the halos, we have a direct proof, in the fact observed by Arago, that their light is partially polarized in a plane tangent to the circumference of their circles, that they consist of refracted light. The light of the rainbow, similarly examined, indicates reflexion as its principal origin, being polarized in a plane at right angles to the arc, or passing through the sun.

(229.) Besides these principal halos there are smaller ones which are frequently seen encircling the moon, often two, very rarely three, and which are sometimes called *coronas*, a very proper distinction, their origin being quite different from that of the large ones as well as their colours, which are much more lively and inverse as to their order, the red being outward and the violet inward. When two or more are seen at once, the diameter of the second is double that of the first—of the third triple. But the diameter of the interior corona (the unit of the scale) is not always the same, varying from 2° to 4°. The succession of colours is approximately that of the reflected series of thin plates, and they are obviously interference fringes, and as such have been very satisfactorily explained by Dr Young, who considers them to arise from the interference of rays passing on either side of minute globules, all (or a preponderant average) of which have at the time very nearly the same size, assimilating them to the colours of fine even-stapled wool or to lycoperdon dusted over glass, and held between a candle and the eye. Dewed glass so held often exhibits similar rings, and occasionally the cornea of the eye itself becomes filmy by the diffusion over it of minute particles which (such at least is our personal experience) exhibit round a candle two or three beautiful coronas, the second of 17° 57′ in diameter, of vivid colours and most perfect definition. The reason why coronas are seldom seen round the sun is the dazzling brightness of that luminary. If its light be enfeebled by reflection in water, or by a coloured glass, they are often visible. Newton observed three such on one occasion by this means.

(230.) Interference colours are frequently seen irregularly distributed over cloud masses. We had the satisfaction of witnessing a fine display of them from the Col du Mont Cervin on the occasion of an ascent of the Breithorn (Kleine Monte Rosa) in 1821, and since, in cirro-stratus covering the sun, on Sept. 17, 1852, when the pink, blue, and green colours of a mackarel's skin were visible in irregular patches. But the beautiful phenomenon, which it was our good fortune to observe on the 14th July 1841, at 4h. 50m. P.M., being, so far as our reading extends, unique in meteorology, appears to merit a particular description. While riding on that occasion near Hawkhurst, in Kent, with a companion, the attention of both was attracted by the pale well-defined silvery disc of the sun as seen through a very high cloud, of a character between cirro-stratus and cirro-cumulus—like a high "mackarel sky" blotted by a remarkably uniform fog. After a few moments we perceived the edges of the cloud to be beautifully tinged with bands of colour, not disposed in a circular form round the sun as a centre, but following all the sinuosities of the outline of the cloud. The colours, commencing from the white area forming its interior and proceeding outward to the edge, were—1*st*, white; 2*d*, very pale pink; 3*d*, blue-green, a stronger colour; 4*th* (at the edge), purplish pink, considerably intense; beyond which pure blue sky. At one place a 5th band of colour, blue-green (very different from the blue of the sky) formed the edge; the line of demarcation between this and No. 4 distinctly running out at the edge so as to *cut* the outline of the cloud. What, however was especially remarkable, was that *the same fringes were observed bordering detached portions of neighbouring clouds of similar character*, the colours having obviously no reference to more or less proximity to the sun, but *depending on the thickness of the cloud* or the length of the path within it traversed by the visible ray. After watching this phenomenon for a quarter of an hour, the coloured bands grew broader and the tints very strong, and a tendency to form a corona about the sun was perceived. Probably with a darkening glass, one or more might have been well made out. It seems impossible to regard these colours otherwise than as the resultants of the super-position of a series of interference fringes following a regular progression of breadth (due to a progressively increasing size of the drops) from the exterior to the interior of the cloud.

(231.) *Parhelia and bands of light passing through the sun.*—A horizontal band of light is occasionally seen to pass through the sun when at a low altitude, and to be prolonged into a circle parallel to the horizon. This is evidently what would result from reflection on, or refraction through, the faces of innumerable ice prisms floating in *perfectly calm* air with their axes vertical, but having their lateral faces disposed equally in all azimuths. Minute crystals, when formed by precipitation in a liquid at rest, always arrange themselves with their axes parallel as they sink, which may often be rendered sensible by a silky appearance in the liquid produced by agitation (of which iodide of lead precipitated from a dilute solution containing ether affords a beautiful example). Under this condition, then, the dispersed light, which in the halos is scattered in all planes equally, is here confined to a horizontal one, resulting in a bright horizontal circle, the parhelia being the intensified effects of a greater condensation of the dispersed rays at the angles of minimum dispersion, corresponding to the halo itself as the circle does to the diffused illumination of the cloud on which the halo is depicted.

(232.) Any one who considers the complicated forms of snow crystals (art. 120), and the various ways in which refractions and reflections, both external and internal, may take place among them, bearing in mind also that ice is *doubly refractive*, and that at the planes of junction of macled crystals, phenomena of coloration of an intricate nature are presented, will not be surprised to find a great variety and complication of luminous arcs, more or less coloured, and intersecting one another in such a way as to form singular interlaced patterns, occasionally developed under the influence of a bright sun, intense frost, and generally clear sky, on the principles above explained; such, for instance, as the superb exhibition witnessed by Scheiner at Rome in 1629, and repeated in higher perfection, and with fuller detail, for several days in succession, at Moscow, when occupied by the French army in 1812. This most striking phenomenon, which is very seldom more than partially visible, consists of two brilliant halos about the sun, cut diametrically across by a horizontal circle continued all round the heavens, with well-developed parhelia at their intersections, and a third at a very large angular distance, more feeble, the intersections also marked with parhelia. At the summits of the two inner halos, and touching them externally, other circles, as it were their reflected images, pass upwards and include the zenith, that which touches the inner halo having a parhelion at the point of contact. Circles of this description are clearly not phenomena of interference, and can only admit of explanation by the intervention of ice crystals.

(233.) *Polarization of Sky Light.*—This is a very mysterious and a very beautiful phenomenon, when explored by the aid of a polariscope, consisting of a tourmaline plate, with a slice of Iceland crystal or nitre, cut at right angles to its optic axis, and applied on the side of the tourmaline farthest from the eye. In a cloudless day, if the sky be explored in all parts by looking through this compound plate, the polarized rings will be seen developed with more or less intensity in every region but that nearest the sun and that most distant from it—the maximum of polarization taking place on a zone of the sky 90° from the sun, or in a great circle having the sun for one of its poles. The plane of polarization, whatever the direction of the visual ray, passes through the sun, so that the cause of polarization is evidently a reflexion of the sun's light *on something*. The question is, on what? Were the angle of maximum polarization 76°, we should look to water or ice for the reflecting body, however inconceivable the existence in a cloudless atmosphere and a hot summer day of unevaporated molecules of water. But though we were once of this opinion (art. LIGHT, *Encycl. Metropol.* § 1143), careful observation has satisfied us that 90°, or thereabouts, is the correct angle, and that therefore, whatever be the body on which the light has been reflected, *if polarized by a single reflexion*, the "polarizing angle" must be 45°, and the index of refraction, which is the tangent of that angle, unity; in other words, the reflection would require to be made *in* air *upon* air! The only imaginable way in which this could happen would be at the plane of contact of two portions of air differently heated, such as *might* be supposed to occur at almost every point of the atmosphere in a bright sunny day; but against this there seems to be an insuperable objection. The polarization is most regular and complete, as we have lately been able to satisfy ourselves under the most favourable possible atmospheric conditions, after sunset, in the bright twilight of a summer night, with the sun some degrees below the horizon, and long after all the tremors and turmoil of the air, due to irregular heating, must have completely subsided. Even at midnight, the moonlit sky[1] exhibits the same phenomenon, bearing the same reference to the moon's position as to that of the sun by day, the black cross of the polariscope being distinctly perceptible. The difficulty, therefore, of conceiving the polarization as operated by a single reflexion is very great. On the other hand, if effected by several successive reflexions, what is to secure a large majority of them being in one plane (in which case only their polarizing effect would accumulate); and of those which become ultimately effective, what is there to determine an ultimate deviation of 90° as that of the maximum? The more the subject is considered, the more it will be found beset with difficulties; and its explanation, when arrived at, will probably be found to carry with it that of the blue colour of the sky itself, and of the great quantity of light which (whether reflected, refracted, or fluorescent) it actually does send down to us, and of which we confess our inability to render any account less unsatisfactory than that of Newton, who refers it to reflexion on thin transparent particles. These cannot be air, because there can be no reflexion upon air in contact with air of the same density. And they cannot be water, it being impossible to realize even in imagination the existence of globules or bubbles of the requisite dimensions maintaining themselves unevaporated for an instant, when disseminated through the atmosphere of a clear, dry, and sultry day, when through its whole extent there is no doubt of the dew-point being far below the actual temperature, that is to say, under conditions where a sheet of wet paper would become dry in a few minutes—over a sandy desert, for instance, where rain never falls, and cloud is a rarity. We may observe, too, that it is only where the purity of the blue sky is most absolute that the polarization is developed in its highest degree, and that where there is the slightest perceptible tendency to cirrus it is materially impaired. Neither is it in the upper regions only that it is effected. The polarized rings are formed, though much more feebly, and under the same conditions of reference to the sun's position below the limit of the visible horizon as above it, provided only the visual ray have a mile or two of air to traverse in full sunshine.

(234.) *Colours of Clouds.*—Whether or no pure air be an absorptive coloured medium, transmitting the blue rays and absorbing the yellow, we may be very sure that the terrestrial matter which, in the form of smoke, dust, and general undefinable impurity, defiles its lower regions, does exercise an absorptive action of a contrary nature, absorbing the violet end of the spectrum and letting pass the red. This is quite sufficient to account for the red and golden hues of sunset, and of those clouds which are high enough to catch the last rays of the declining sun after its disappearance from the horizon of the spectator on the earth. The red, and sometimes greenish, light thrown on the moon by the earth's atmosphere acting as a lens, and concentrating on it light which has undergone its absorptive effect, sufficiently indicates the nature of that absorption on a general average of the whole atmosphere, which, however, is sometimes singularly suspended, and even changed into one of an opposite character, as in the instance of the blue sun seen at Bermuda from 6 A.M. to 5½ P.M. August 13, two days after the great hurricane of August 10, 1831, a phenomenon which Arago has regarded as merely an effect of contrast, but which, described as we happen to have it very circumstantially in a letter from an eye-witness, we must consider to have been an objective reality.

---

[1] It did so on the night of the evening referred to. This was after a very hot day, and a series of very dry weather. Repeating the observation the next lunation, after copious rains, no trace of the cross or polarized rings could be anywhere discerned, and the skylight, examined by a doubly refracting prism, showed only a feeble partial polarization in the most favourable position. Perhaps there was unperceived cirrus.

(235.) Professor Forbes, in a very curious paper published in the *Edinburgh Phil. Trans.*, vol. xiv., has shown that high pressure steam, in the act of expansion and while still transparent, is highly absorptive of the violet, blue, and a portion of the green rays of the spectrum; and in a second memoir in the same volume, suggests that without supposing absorptive coloration in the air itself, it may exist in a mixture of air and vapour, the latter being in that peculiar intermediate absorptive state which his experiments have clearly shown under certain circumstances (certainly very remote from atmospheric ones) to exist. Whether the ruddy hues above alluded to in the lower atmosphere be really owing to the presence of absorptive steam, is doubtless a question which may be entertained and more fully discussed; but if the sky be blue by reason of absorption, that absorption must be of a directly opposite character (*i. e.*, most energetic on the red rays of the spectrum).

(236.) *Mirage.*—When the surface of the soil is greatly heated, the air in contact with it is dilated, and while yet supporting the incumbent atmospheric pressure, its elasticity being increased, does so with diminished density. In such a case, rays of light coming from a distant object at great obliquities, before they can reach the ground, are bent upwards by refraction, and pursue their further course as if reflected from the surface of water. Thus, to a spectator receiving both these reflected rays and those which, diverging from the same object, reach his eye directly, having never passed into the heated stratum, both the object and its reflected image will be seen, the one direct, the other inverted, and joined by their bases, as if rising out of a lake of still water, which in arid deserts such a stratum of hot air exactly resembles. Under certain circumstances, on sea coasts, such a layer of hot air (drifted probably from a shore of heated sand) occupies a higher level, and in it, as if in a mirror suspended in the air, the inverted images of ships, mast-head to mast-head with the direct, are seen; and even in some rarer cases, again, another repetition of the image upright above both. Singular instances of this kind are described by Professor Vince as seen at Ramsgate (*Phil. Trans.* vol. lxxxix.) M. Biot has given an elaborate explanation of the theory of such phenomena, in a paper in the *Memoirs of the French Academy*. The accounts of arctic voyages are full of extraordinary exemplifications of the same general principle, where the powerful radiation of an arctic summer sun acts on a surface loaded with ice, and produces great contrasts of local temperature.

(237.) When a current of heated air passes through a body of air generally colder, a lateral mirage is sometimes, though rarely, produced. Thus, on the Lake of Geneva, the image of a boat sailing on it has been seen reflected on such a vertical plane of demarcation. A similar effect is sometimes produced by the sun striking on a wall. We remember when walking on a hot sunny day under the south wall of Kensington Gardens, the sun shining full upon it, to have observed the distinct reflection of persons walking on the same footway. A single soldier for instance appeared as two; the shape and colours of the uniform being visible in the reflected image on the wall, which appeared invested with a glassy, mirror-like coating.

(238.) *Aurora Borealis.*—As a meteorological agent, electro-magnetism, to which department of physics this phenomenon refers itself, has no claim to be regarded. So far as has hitherto been proved, there is no meteorological effect either as regards temperature, moisture, barometric pressure, or wind, which is in the smallest perceptible degree influenced by its most vivid displays. They appear to be developed for the most part in a region of the atmosphere too high, and of too great rarity to affect either our instruments or (except on these occasions) our senses, and the only interest they offer to the meteorologist otherwise than as brilliant spectacles, consists in the evidence which they afford of the existence of *some* matter of inconceivable tenuity no doubt, in those elevated regions capable of being thrown into a luminous state by the passage through it of the electric discharge. Whether electricity passing through an absolute vacuum be luminous, we have no means of determining by experiment, since such a vacuum is beyond our power to produce, though the experiments of Davy would appear to indicate that beyond a certain degree of tenuity (already very extreme) in the gaseous or vaporous medium filling glass vessels admitting of inspection of what passes, the electrical discharge between the poles of a battery not only begins to be less luminous, but the conduction itself is impaired. But in certain phases of an auroral display, indications of a very unequivocal character are afforded of a distribution of material substance in forms which, could they be seen under ordinary circumstances, would be called clouds. We allude to those luminous bands extending across the horizon, and patches of auroral light which are either stationary or nearly so in the sky, but which, when attentively watched, are usually perceived to be slowly drifting southwards, and are generally the precursors of a more active phase of the aurora when it bursts into streamers. These perhaps belong to comparatively less elevated regions, and possibly in some cases to be identifiable with the very highest perceptible cirrous cloud. But besides these, there are others probably at a much greater elevation, and which become perceptible only when traversed by those undulating pulsations of light, converging to the magnetic zenith, which constitute a marked feature of certain auroras. As a flash of what is called sheet-lighting (*i.e.* the reflection of an unseen flash on a distant back-ground of cloud) will often disclose the outlines of intermediate cloud otherwise unsuspected, so these pulsations when carefully watched, will be seen to consist of waves of light traversing regions of space, bounded by more or less definite outlines, within which light is momentarily developed by the passage of each pulse, and whose existence as occupying place and having form, whatever else their nature, is only revealed to us in those moments, not as in the case just alluded to by their projection as intercepting masses on a luminous ground, but as giving off light out of their own substance.

(239.) The height of the auroral arch in that form in which it stretches across the sky as a luminous band at right angles to the magnetic meridian has been estimated on several occasions from its apparent zenith distance as seen from different stations, variously at from 50 to 300 miles above the earth. The most unexceptionable determination seems to have been that of an arch observed simultaneously at Gosport, Keswick, and Newtown-Stewart in Scotland, on Oct. 17, 1819, which, by the calculations of Dalton, *Phil. Trans.* 1828, from the zenith distances observed, was 100 or 102, miles above the earth. It has been suggested that such measurements are inconclusive, on the ground that (as in the case of the rainbow) each observer sees his own arch, and that no one spectator sees the same arch as another. But it is obvious that this applies only to an optical image reflected or refracted from some original source of light elsewhere situated, whereas no one can doubt that the light of the aurora originates nowhere but in the place where it is seen. A planet or comet might with equal justice be considered as the image (formed on some unknown reflector) of some other planet or comet not seen. But the want of absolute fixity in the apparent place of the arc itself is a great obstacle to exactness of determination, as such observations are rarely made at precisely noted and astronomically corrected moments of time. There is very positive evidence, however, that auroral light has been seen below the clouds (as in the Polar Seas by Parry, Sherer, and Ross, on Jan. 27, 1825; near the chain of the Rocky Mountains in North America on December 2, 1850, by Hardisty; and at Alford in Scotland on Feb. 24, 1842, by Farquharson), nay, even habitually seen as if hovering over the Coreen Hills in the last mentioned neighbourhood, at a height from 4000 to 6000 feet (Farquharson, *Phil. Trans.* 1839).

(240.) *Meteors, Shooting Stars,* &c.—The fall of a stone or a shower of stones from the sky would seem at first sight to be quite as fairly entitled to be regarded as a meteorological phenomenon as that of a shower of hail; nay, hailstones are *said* to have fallen, each containing a nucleus of iron pyrites. At all events, falls of stony masses accompanied with aerial detonations and luminous appearances are too numerous and well authenticated to admit of doubt. But there is not the smallest reason to believe that such can be formed in, or anyhow collected from, disseminated particles scattered through the air, and on the contrary, so great a mass of facts go to connect "shooting stars" with astronomical phenomena, that we cannot hesitate in assigning them to that department of physics. This, however, does not apply to a class of meteors of which the great one of August 18, 1783, was an eminent example—great fiery globes, of many hundreds, nay thousands of feet in diameter, evidently not of solid materials, being of fluctuating and continually varying form, and giving out most intense light, many of them being compared not merely to the moon in illuminating power, but to the full light of day. The name Bolis or Bolide has been applied to this class of phenomena. That above mentioned traversed the whole of Europe from the North Sea to Rome, at an altitude tolerably well ascertained of about 50 miles, and with a velocity of from 20 to 40 miles *per second.* Its diameter could not have been less than 4000 feet, having been seen under an angle equal to one-third of the moon's apparent diameter when vertically over the eastern counties of England, from Edgeworthstown in Ireland, at a distance of at least 300 miles. That it must have been a body of extremely small density is evident from the fact of its having made a sudden flexure in its course at a certain point of its progress. There is so much that is enigmatical about these bodies—the trains they leave behind them, and which often remain long visible, and change their aspect and form like luminous clouds; the immense velocity of some, approaching to planetary (yet far short of that of the electric spark), and the complete apparent fixity of others; and their tendency (alleged) to affect the direction of the magnetic meridian (which that of 1783 certainly did)—as to take them out of the domain of exact science. In fact, no theory of their origin, making the smallest approach to plausibility, has hitherto been advanced, though the records of the observations of such meteors would fill volumes, and may be found by consulting the indices of almost every collection of scientific memoirs or notices, and every philosophical magazine and journal. See especially the reports of luminous meteors, from A.D. 338-1293, by Chasles (*Comptes Rendus,* March 15, 1841); the great collection of Chladni; four reports by Prof. Powell to the British Association, 1848-51; two by M. Quetelet to the Royal Academy of Brussels, 1839 and 1842; and Schmidt's *Resultate aus 10-jährigen Beobachtungen über Sternschüppen.*

(241.) *Whirlwinds, Waterspouts, Dust-storms.*—Whenever two currents of air running in opposite directions approach and graze one another, eddies will arise, the air of which, forced into rotation, compressed by its own impulse, and finding no escape downwards or laterally, is driven upwards, and ascends with a vorticose motion, which, as a necessary consequence of the dynamical principle of the "conservation of areas," becomes swifter the nearer the indraughted air approaches the axis of the eddy. Whirlwinds so generated differ widely from cyclones, inasmuch as the ascensional movement is not the cause, but the consequence of the indraught of air; they are whirlwinds of compression, whereas cyclones are whirlwinds of rarefaction. The greater part of those violent and sudden whirlwinds which are confined to limited and linear tracts of land, which carry up into the air haystacks, unroof houses and scatter the materials around, tear off branches of trees, upset boats, and commit other local havoc, are probably of this kind. In such whirlwinds, the law of the direction of rotation which the true cyclone obeys (art. 72) is not necessarily observed, and their rotation may be indifferently direct or retrograde according to the relative situation and direction of the currents from which they originate. They are often terminated by heavy falls of rain, a very obvious consequence of the sudden transfer of a great mass of air nearly saturated with vapour at the surface of the earth to a much higher level (art. 110); for the same reason, that is, that a fall of rain has been not unfrequently observed to follow great natural conflagrations, as in the burning of forests or prairies in North America, or in volcanic eruptions, nay, is even said to have been brought on by fires kindled for that express purpose.

(242.) Whirlwinds of this kind taking place at sea give rise to waterspouts (*trombes de mer*), which are very singular and sometimes dangerous phenomena. Tall columns, apparently of cloud, and reaching from the sea to the clouds, are seen moving majestically along, often several at once, sometimes straight and vertical, at others inclined and tortuous, but always when approached perceived to be in rapid rotation. At their bases the sea is violently agitated, and heaped up with a leaping or boiling motion. Indeed water would seem, at least in some cases, to be actually carried up in considerable quantity, and scattered round from a great height, as solid bodies are on land. Hence they have been supposed by some to draw water from the sea by *suction,* a thing obviously impossible. A notion is prevalent among seamen that they may be cut asunder and dispersed by firing a cannon-shot through them, an effect for which no good reason can be rendered, and which certainly savours of the marvellous. Appendages evidently in the nature of imperfectly formed waterspouts are often seen descending from the under surface of rainy clouds on land (we have such a one before our eyes—August 5, 1857), like long loose tapering tails floating in the air, but not meeting the earth. Viewed through a telescope, they are evidently seen to be hollow vaporous cylinders or conoids—a light medial line or axis being clearly traceable through their whole length, and the rotation perceptible on attending to the slight irregularities in their outline (which is very definite.)

(243.) During the hot season, in parched and sandy tracts of flat country, whirlwinds of an opposite character arise from the ascent of the violently heated air in sheets or streams, determined by accidents of local exposure or by any slight elevation of the soil, up which gliding on all sides, the superficial air becomes concentered for the moment, as we see flames arise and divide themselves. When this takes place on a large scale, a true cyclone may be thus generated; but if the ascensional movement be broken up into numerous partial ascending columns, the wind-flaws which sweep along the surface to feed them, wherever they encounter one another, will from that circumstance alone take on an eddying motion and generate whirlwinds, carrying up with them clouds of dust. These, in the African deserts, often appear as tall columns of sand, revolving and advancing, suffocating and actually overwhelming men and horses, and even armies (as in the memorable expedition of Cambyses into the Lybian desert). That the heat of a wind thus loaded with sand may be insupportable, or even deadly, will be easily conceived when it is remembered that a sandy soil, down to several inches in depth, when undisturbed, may under a tropical sun attain a temperature perhaps exceeding 200° F. (see art. 38), and when suddenly swept up and mingled with air, itself already greatly heated, will communicate its accumulated heat to the general atmosphere, and impart to it, at the same time, a drying power proportioned to its elevation of temperature and absence of vapour. The destructive effects attributed to the Simoom are readily explicable on this view of the causes of its heat, without attributing to it any poisonous quality; and the Simoom itself is not improbably in the nature of a cyclone so originating.

(244.) The "dust whirlwinds" of India, which are very frequent in the district about Lahore and in the Punjab, are sometimes stationary for a long time, sometimes advance with great rapidity. "The sky is clear, and not a breath moving; presently a low bank of clouds is seen in the horizon, which you are surprised you did not observe before; a few seconds have passed and the cloud has half filled the hemisphere, and now there is no time to lose—it is a dust storm, and helter-skelter every one rushes to get into the house in order to escape being caught in it." "A broad wall of dust is observed advancing rapidly, apparently composed of a number of large vertical columns, each preserving its respective position in the moving mass, and each column having a whirling motion of its own." "Precisely the same phenomena in kind are observable in all cases of dust storms, from one of a few feet in diameter to those that extend for fifty miles and upwards." "Their rotatory action seems to be continuous above as far as the eye can reach, and the cloud of dust carried up by them, even at the height of some thousand feet, to possess a gyratory motion." "Towards the close of a storm of this kind a fall of rain suddenly takes place."—*Baddeley on the Dust Storms and Whirlwinds of India.* As might be expected from the powerful friction of the dust on the earth when dragged along and in the act of leaving it, the air in these columns is highly electrical. Mr Baddeley states that during the passage of dust storms, he obtained vivid sparks, and in some cases streams of electricity, from a wire suspended from an insulated bamboo, which would instantly cease on the fall of the terminating shower.

(245.) A vast quantity of solid matter is thus carried up into the higher regions of the air, and no doubt conveyed to great distances, where it sometimes falls, intermingled with rain. Along the west coast of Africa the air is frequently loaded with drifted dust, which covers the decks of ships far out of sight of land. Nay, even on the Peak of Teneriffe, up to the height of 10700 feet, Mr P. Smyth relates that the air during his sojourn on the mountain was very frequently rendered hazy by floating dust, of which there were often several strata, separated by perfectly clear intervals which could be distinctly traced as projected on the distant mountain heights of Palma, far above the uniform cloud-level (described in art. 111) and of such density as totally to obscure the sun previous to his descent below the cloud-level. Showers of fish, frogs, flannel (matted confervæ), bread (edible fungus), infusoria, and other unaccountable substances, are among the more palpable evidences on record of the elevating and transporting power of whirlwinds.

(246.) In conclusion of this essay, which has already extended beyond the limits assigned us, we subjoin a table of the mean values and annual and diurnal average maxima and minima, at a few select stations, of the chief meteorological elements of temperature, pressure, vapour-tension, humidity, and cloud, not as embodying any general climatological results, but in illustration of the main features of meteorological action laid down in the foregoing pages. In the table, to save room, the letters B, P, V, T, H, C, R, are used to denote respectively the total barometric pressure, that of dry air, and that of aqueous vapour or the vapour-tension, the temperature of the air, the degree of relative humidity, the amount of cloud estimated in tenths of the hemisphere covered, and the rain or other aqueous precipitation. Capital letters are used to indicate the annual and monthly means, corresponding to the months of annual maxima and minima, whether simple or multiple, the means for the whole year being entered in the column marked α, and those for the maxima and minima in their order of succession and their epochs, in the subsequent columns β, γ, δ, &c. Similarly for the diurnal march of the same quantities, these are represented by small letters: their means (being identical with the annual means) are not repeated in col. α, but their daily maxima and minima, with their epochs and hours of their occurrence, *reckoned from noon*, occupy the subsequent columns. In the monthly epochs, (1), (2), (3), &c., represent January, February, &c. Where ½ occurs, whether in the indication of the month or the hour, the average moment of the maximum or minimum falls on or about the limit between two consecutive months or hours. These epochs are, however, only approximate. The barometric and vaporous pressures are in English inches, the temperatures in degrees of Fahrenheit's scale, and degrees of humidity and cloud in hundredths of their respective units, viz., complete saturation, and a totally clouded sky.

(247.) The student who wishes to obtain a deeper insight into the subject of Meteorology than can be conveyed in the limited space we can devote to it, will find ample information in the following works:—

Æpinus de Distributione Caloris.

Albany Institute. Annual Reports of its Regents to the Senate—Do., Report of the Committee for Term Observations, trans. ii.

Anderson. Description of an Atmometer, Ed. Phil. Jour., ii. 64.

Annales de l'Observatoire Physique Centrale de Russie, publiés par l'ordre de sa Majesté Nicholas I.

Annuaire Magnetique et Meteorol. du Corps des Ingenieurs des Mines de Russie.

Apjohn. Theory of the Moist Bulb Hygrometer, Edin. Phil. Trans. xvii.

Arago. Notices Scientifiques, Annuaire du Bureau des Long. Paris —1824, (various Meteorol. Notices)—1826, Do.—1828, Rayonnement Nocturne—1833, Influence de la Lune—1834, Etat Thermom. du Globe Terrestre—1835, Puits Artesiens—1838, Sur le Tonnerre.

Atkinson. Refraction and Decrement of Temperature, Mem. Ast. Soc. ii.

Bacon. F. de Ventis, 1664.

Baddeley. On Dust Whirlwinds and Cyclones in India.

Beccaria. Dell' Elettricita Atmosferica.

Beechey, Capt. Narrative of the Voyage of the Blossom to the Pacific and Behring's Straits, 1825-6-7-8, vol. ii., Meteorological Journal.

Benzenberg. Die Sternschnuppen.

Biot. On Mirage and unusual Refraction, Mem. de l'Acad., 1809.

Birt. Tabulæ Anemometricæ, Reports to the British Assoc. on Atmospheric Waves.

Blodget. Climatology of the United States, London, 1857, (Trubner and Co.)

Bouvard. Influence de la Lune sur l'Atmosph. Tem.; Corr. Math. et Phys. de l'Obs. de Bruxelles, viii.

Bravais and *Martin.* Comparaisons Barom. faites dans le Nord de l'Europe, Mem. Acad. Brux., xiv.

Brewster, (Sir D.) On the Mean Temperature of the Globe, Edin. Phil. Trans. ix.—On the Distribution of Heat in the Arctic Regions, Do.—Results of Therm. Observations at Leith Fort, Do. x.

Buist. Catalogue of Indian Hailstones and Meteors—Provisional Report on the Met. Obs. at Colaba, Bombay, 1844.

Cacciatore. De Redigendis ad Unicam Seriem Comparabilem Observationibus Met., Palermo, 1832—Lettera sulle Osservazione Meteor., Palermo, 1825.

Carrel. Obs. Met. faites a Aoste. Bibl. U. de Geneve, 1842.

Castellani. Richerche sull' Aumento delle Pioggie, Turin, 1848.

Cavallo. Atmosph. Electricity, Ph. Tr., 1776, 1777.

Chladni. Ueber Feuermeteore—Nouveau Catalogue des Chutes de Pierres, ou de Fer, des Poussieres, &c. &c.—Annuaire du B. des Long. Par., 1825.

Colebrooke. Abstracts of Capt. Webb's Obs. on the Himalayas, Jour. R. I., vi.

Cordier. On Temperature of Interior of the Earth, Mem. Acad. Sci., 1827.—(Transl. Ed. P. J., Nos. 10, 11.)

Correspondence Met. de l'Obs. Centrale Physique de Russie.

Cotte. Meteorologie, Paris, 1774—General Results and Axioms, Jour. de Phys. xliv. xlv.

Crosse. Account of an Apparatus for Ascertaining and Collecting the Electricity of the Atmosphere.

D'Alembert. Sur la Cause Generale des Ventes, Berl. 1747.

Dalton. On Rain and Dew, Manchester Mem. v.—On the Constitution of Mixed Gases, Do.—Met. Obs. and Essays, Lond., 1793—On Constitution of the Atm., Phil. Tr. 1826—On Height of Aurora Borealis, Ph. Tr., 1828.

Daniell. Meteorological Essays—On the Constitution of the Atmosphere.

Darwin. Ph. Tr. 1788—(First suggests the Self-cooling of Air by Ascending to a Higher Level.)

D'Aubuisson. (Variation of Temperature with the Latitude), Jour. de Phys. lxii.

De Luc. Recherches sur les Modifications de l'Atmosph., Geneva, 1772—Idées sur la Meteorologie, Lond. 1786—On Hygrometry, Ph. Tr. 1791—On Evaporation, do., 1792.

Dobson. On the Harmatian, P. T., 1781.

Dove. Tables of Mean Temperature, Rep. of B. Assoc., 1847—Meteorologische Untersuchungen—Introduction to vol. iii. of the Mag. and Met. Obs. at Hobart Town, V. D. L.—Mem. Acad., Berl., 1846—Poggendorff, Annalen, 1829.

Eeles. On Vesicles and Atmospheres of Electricity, Phil. Trans., 1775.

Ermann. Ueber Boden-und-Quellen-Temperatur—Reise um die Erde—Ueber Einige Barom. Beob., Poggendorff, lxxxviii.—Meteorol. Beob. bei Einen-See-Reise, Schumacher's Astron. Jahrb., 1840.

Espy. Philosophy of Storms, Lond., 1841—Report on Meteorol. of U. S.

Foggo. Ed. Ph. Tr., No. 27.

METHODISTS, a numerous religious body both in this country and in America. They are divided into several distinct sects; but from the minute shades by which these are distinguished, and the extreme obscurity of some of their numbers, it is difficult to furnish a perfectly accurate account of them. We shall describe those which are best known.

Wesleyan Methodists.

The first in order of time, as well as in point of numbers, is that of *Wesleyan Methodists*. This body derives its name from its principal founder, the Rev. John Wesley. Whilst a student at Christ Church College, Oxford, and engaged in the pursuit of theology, as preparatory to his entering into deacon's orders, Wesley's mind had become strongly imbued with that peculiar asceticism which colours the writings of Thomas à Kempis, Fénélon, William Law, and occasionally of Jeremy Taylor, of whose works he had been a diligent and admiring student. On his assuming the sacred office this tendency was increased rather than diminished; and when, after officiating as curate to his father, who was a clergyman in Lincolnshire, for about two years, he returned to Oxford to resume his duties as a fellow of Lincoln College, it was apparent that it had acquired the complete ascendancy over his mind. His condition at this time was distressing. He felt himself burdened under a sense of guilt in the sight of God, and ignorant of the only way in which that burden could be relieved. Sympathy of feeling and unity of opinion led him to enter into an association which had been formed during his absence among a few of his former friends, in whom a similar course of discipline had produced similar effects. Of this society he soon became the leader and most active member, employing the resources of his comprehensive mind for the regulation of their meetings, and setting an example of diligence in the discharge of every office, and of patience in the endurance of every penance, which in their misguided zeal they had instituted among them, in the hope of thereby obtaining the Divine favour. The regulations which they had adopted for the guidance of their conduct were unusually severe: they were in the habit of partaking of the sacrament every week; they were abstemious in their diet, and plain in their clothing; they had set hours for reading Thomas à Kempis, with meditation and prayer, and for musing on the Passion; they spent much of their time in visiting the prisons and the hospitals; they observed rigidly all the fasts of the English Church, besides a constant abstinence on Wednesdays and Fridays; and in several other respects they exhibited the hold which a morbid asceticism had acquired over their minds. By such conduct, while they commanded the respect of a few, they became the object of ridicule and derision to the many, and had to run the usual gantlope of jokes and nicknames which is destined for all, especially at a university, who are audacious enough to be guilty of innovation either in politics or religion. Of the various titles which the wits of the university devised for them, the only one that has adhered to them is that by which they are now distinguished, viz., Methodists. The author of this appellative is said to have been a fellow of Merton College, who, observing the regularity with which they divided their time among their different pursuits, exclaimed, "Here is a new sect of Methodists sprung up;" alluding to the ancient Methodici, or College of Physicians, at Rome, of whom an account is given by Celsus in the preface to his work *De Medicina*. At this time their members amounted to fifteen, most of whose names Wesley has preserved in his journal. Among the rest are those of James Hervey, the author of the *Meditations*; and George Whitefield, for some time the most efficient assistant, and subsequently the most powerful rival, of Wesley.

The regular formation of this society took place in the year 1729. During the three following years it maintained its ground under the energetic guidance of its head, and increased to the number of twenty-five. In the course of the year 1733, however, Wesley being frequently absent from Oxford, his associates began to lose heart, and to shrink from the persecution which continued to assail them; so that on his return from a visit he had paid to Manchester and other places in that year, he found the members reduced to five. Grieved, but not disheartened, he immediately set himself to repair the loss, but with what success does not appear. His exertions, however, were so great, that, combined with his abstemiousness, they began seriously to affect his health. It is probable that this, together with other circumstances of a private nature, combined with his religious zeal to induce his acceptance of an offer made to him by the trustees of the new colony of Georgia to go out as one of the chaplains of that settlement. This offer was made about the middle of 1735, and towards the close of that year he left England, accompanied by his brother Charles and two other of his Oxford associates, in order to enter upon the duties of his office. On his voyage out he became acquainted with David Nitschman, a Moravian bishop, who, with a party of his followers, was proceeding in the same vessel to join a colony of their brethren already established in the new settlement. From this individual he derived no small advantage in a religious point of view; nor was the insight which he thus obtained into the Moravian institutions and polity without service to him, when in subsequent years he had to assume the office of arranging and legislating for a party of his own.

But Wesley's connection with the Georgian colony was not of long continuance. It was dissolved in 1737, and in the month of February of the following year he arrived in London, a wiser if not a better man than when he had set out. A few months of irregular occupation followed his return; but in September of that year he commenced that course of life in which he persevered till his death, and in the pursuit of which he visited personally the principal places, not only in England, but also in Ireland and in Scotland. The example of his friend Whitefield first induced him to commence field-preaching; a practice which he followed ever afterwards with great success. His brother Charles, who had followed him from America, became a zealous and able coadjutor; and others were speedily added to them. No systematic plan of itinerant preaching seems to have been at first contemplated by them; but their exertions in one place led to their visiting another, and thus a regular course of occasional ministrations was gradually adopted. At first both Wesley and his brother were decidedly opposed to lay-preaching; but the difficulty, or rather the impossibility, of finding individuals who had received orders to supply their rapidly increasing stations, combined with the evidence furnished by one or two remarkable examples, of the possibility of successfully employing individuals who had not been regularly educated for the ministry in itinerant preaching, led to the ultimate adoption of this as a part of their ecclesiastical machinery. An extensive agency was thus called into operation by which the Wesleys were enabled to bear in upon the mass of the people throughout the country, and in consequence very widely to diffuse their principles and augment the number of their adherents. By what steps they advanced it is impossible accurately to detail; but in a very few years they had succeeded in overcoming the persecution by which at first they were everywhere assailed, and in forming societies in all the principal towns and larger villages of England. Over all these Wesley maintained a vigilant watchfulness; and though in general lenient and patient, he yet visited with rigorous discipline those communities or preachers by whom any flagrant departure from the accredited doctrines or practices of the body had been committed. His influence among the societies was maintained partly by frequent visitations, and partly by the power which was concentrated in an annual convention of the preachers, called the Conference, of which he was the moving spring. The first meeting of conference was held in 1744, and this body has regularly held its meetings ever since.

Before Wesley's death Methodism had obtained a considerable footing not only in England and Wales, but in Ireland, America, the West Indies, and to a limited extent also in Scotland. At the time of his death "the number of members in connection with him in Europe, America, and the West India Islands, was 80,000."[1] Since that time this denomination has been making a steadily increasing progress. The number of members in Great Britain in 1853 was 270,265; and they have nearly 6000 chapels, containing accommodation for about a million and a half of persons. The number of their ministers was in 1850, 1034. On census Sunday, 31st March 1851, the attendance at their chapels was,—*morning*, 492,714; *afternoon*, 383,964; *evening*, 667,850. They raise annually upwards of L.145,000 for the support of several religious institutions connected with their body. They have extensive foreign missions on the continent of Europe, in India, Africa, British America, the West Indies, and Polynesia.

The *doctrines* taught by Mr Wesley and his preachers may be technically described as those of evangelical Arminianism. In regard to all the positive doctrines of Christianity he assented, with a few modifications, to the standards of the Reformed churches. He maintained the depravity of human nature; the necessity of an atonement for sin before it can be forgiven; the doctrine of a divine influence to lead men to Christ; justification by faith alone; and the importance of good works, not as the ground of acceptance with God, but as the evidence of faith, and the measure of the final reward. He differed from the system of Calvin chiefly in regard to the extent of the atonement, which he maintained was for all men; to the doctrine of a common grace, which he supposed was given to all, though in various degrees and in different ways;[2] to the opinion that a man who had once believed the gospel might relinquish his belief, and so perish; and to the notion that Christians might obtain salvation from all sin, or entire sanctification, before death. He also held that repentance, which he defined to be "conviction of sin, producing real desires and sincere resolutions of amendment," and fruits meet for repentance, preceded faith; and that the believer has not only the testimony of his own consciousness to persuade him that he is justified, but also the direct testimony of the Spirit of God. These opinions are still retained by the Methodist body.[3]

Of the *polity* of Wesleyanism the fundamental principle is, that all power is centred in the Conference, or annual convention of the clergy. From this body all authority emanates, and by them all regulations to be observed throughout the society are devised and appointed. In their name also are levied all the funds that are required for carrying on the operations of the society, of appointing the individuals who are to superintend the different sections into which the denomination is divided, of assigning to each preacher the station he is to occupy, and of suspending or excluding any member of the community, whom a subordinate jurisdiction, entitled a "Leader's Meeting," may have found guilty of certain faults. All their deliberations being carried on with closed doors, the people at large have no check on their decisions, nor any means of controlling their power: the results of their discussions, however, are published, after each meeting, under the title of Minutes. The management of the body is thus vested entirely in an oligarchy of clergymen, self-elected, and all but entirely uncontrolled. The security of this system is perpetuated by the careful gradation of rank which obtains throughout the whole body of functionaries. The supreme power being vested in Conference, the whole field of Methodism is divided into distinct departments, to which is given the name of Circuits. To each of these as many preachers are appointed as its exigencies may require, and at their head is placed one whose experience and reputation, but especially his fidelity to the cause of Conferential supremacy, entitle him to the distinction, and to whom, under the name of superintendent, the charge of the whole circuit is committed. The appointment of these functionaries is made annually; and no preacher or superintendent can be reappointed to the same place for more than three years successively. Besides these, each circuit has its local preachers, who are generally persons engaged in secular business, but who, having by zeal and ability obtained for themselves the approbation of a local preacher's meeting, are permitted by the superintendent to preach, throughout the vicinity of the place where they reside, in private houses and small country chapels. Out of the number of these the regular preachers are generally chosen, as they have been themselves for the most part chosen from amongst the class-leaders or superintendents of the portions into which each congregation is divided. These classes consist generally of twelve members; and it is the duty of the leader to visit, instruct, and exhort them, as well as to collect their contributions to the funds of the society, and to watch over the correctness of their general conduct. At the meetings of these classes the members state their religious experience, and confess their faults to one another. This, however, is more particularly the object of another subdivision (connection with which, however, is not deemed imperative) called Bands: the members of these are all of one condition in life; that is, the married males meet in one band, the married females in another, and so on. In these bands, which are also under the charge of leaders, there is, in consequence of this arrangement, more freedom of communication, especially in regard to besetting sins and peculiar temptations. Another portion of the members are engaged in the duties of Sunday-school teachers, and are also under the superintendence of a leader. Over all these different agencies it is the duty of the circuit superintendent to watch; and to all of them his word is law. An appeal, indeed, lies from his decision to Conference; but experience has so abundantly shown the uselessness of all such appeals, except in cases of the most glaring nature, that they are hardly ever made.

Whatever objection may be brought against the complication of the machinery of Methodism as opposed to the simplicity of the New Testament, this should not prevent our doing justice to Wesley and his followers by admitting the importance of the services which they have rendered to the cause of religion, education, and morality, throughout the empire. By no denomination of Christians, perhaps, have greater benefits been conferred, in these respects, on the nation at large, than by the Wesleyans. Impelled by an undaunted zeal, they have visited the most abandoned and instructed the most ignorant of the population. Wherever they have gone they have carried the elements of a renovated state of society with them, in the doctrines they have taught and the duties they have inculcated. In many parts of England, where before they commenced their labours the truths of Christianity were as little known as they are in heathen countries,[1] they have succeeded in raising large and active communities, amongst which the effects of Christian teaching are apparent in the good conduct, comfortable circumstances, and increasing respectability of those by whom they are composed. Their zeal has also operated beneficially on other denominations, and has called forth energies that, but for the stimulus of their example, might have continued to lie dormant. In short, it must be confessed that England and America owe an immense debt of gratitude to the illustrious founder of this powerful society; and that the loss of Methodism would be a loss to the world.

Calvinistic Methodists.

Next in order to the Wesleyan Methodists are the *Calvinistic Methodists.* Under this term are included three distinct connections, all of which, however, either arose from, or were greatly strengthened by, the exertions of Whitefield, the original companion of Wesley; and from that circumstance they are sometimes ranked under the name of *Whitefieldians.* Whitefield separated from Wesley shortly after the time when the latter commenced his regular labours as a preacher, upon his return from America. The cause of their separation was their having espoused opposite sides of the Arminian and Calvinistic controversy; Wesley ranking himself with the adherents of the former class of opinions, and Whitefield with those of the latter. This led to their carrying on their itinerant labours independently of each other, though without any attempt on either side to interrupt the peace or the usefulness of the other. Whilst Wesley, however, was skilfully availing himself of his success for the purpose of forming a sect, Whitefield, with less worldly wisdom, contented himself with merely preaching from place to place, and associating himself with any who would acknowledge him as a minister of Christ. At several places, indeed, where he had attracted much attention by his powerful and (to judge from the effects) unparalleled eloquence, he erected chapels, or tabernacles as he called them; but these he invariably left to the care of any evangelical clergyman, whether in the establishment or among the dissenters, whom he saw raised up to occupy them. Since his death the members of these congregations have been nominally, and only nominally, classed together as a distinct body, under the name of the *Tabernacle Connection.* In some of these congregations the service is conducted according to the ritual of the Church of England; whilst in others the order of worship is more in accordance with that observed by the Independents. They all, however, agree in this, that whether there is a settled minister in the place or not, a succession of supplies from the country is kept up throughout the year, each minister being engaged for a month or six weeks at a time. Where there is no settled pastor, the "supply" for the time being discharges the whole duty of the place; where there is a settled pastor the duties are divided between them. The members of this connection have of late years been gradually verging towards the Independents, and it is probable that in a short time both bodies will coalesce.

Amongst the most zealous and devoted of Mr Whitefield's adherents was Selina, Countess of Huntingdon, in whose family he at one time officiated as chaplain. After the death of her husband she employed her ample resources in the erection of chapels in different parts of the country, to the occupation of which she invited at first none but regularly ordained clergymen of the Episcopal Church. Many such accepted her invitation, and laboured in the places she had erected; but finding the supply from this source not adequate to the demand, she founded a college at Trevecca in South Wales, for the education of pious young men of talent for the university. By these means a distinct party was formed, which assumed her name, and is known as *Lady Huntingdon's Connection.* They have upwards of 100 chapels, in all of which the service is conducted strictly according to the ritual of the established church. The attendance on census Sunday was,—*morning*, 21,103; *afternoon*, 4380; *evening*, 19,159. The college has been removed since the death of its foundress to Cheshunt in Hertfordshire, where it is now in a flourishing state.

Another body, which, though not founded by Mr Whitefield, was much strengthened through his means, is that denominated the *Welsh Calvinistic Methodists.* The original founder of this body was Mr Howel Harris of Trevecca. This gentleman had intended to take orders in the Church of England, but was turned from his purpose by what he witnessed amongst the students at Oxford, who seemed to him wholly given to folly and impiety. On his return home he began to preach to his neighbours and in the surrounding parishes. This took place in 1735, and excited no small attention; numbers collected in every place where he preached, to hear him; and ultimately societies were formed, which were placed under the superintendence of experienced individuals. The preaching of Mr Harris was not only successful among the people at large, but was also followed by several clergymen, who at length gave up their livings and united themselves with him. To this party Mr Whitefield lent the aid of his powerful eloquence, and in return received from it many of his most zealous preachers. It was not, however, till the year 1785, when it was joined by the Rev. Thomas Charles of Bala, that, owing mainly to the exertions of that individual, it was organized into a regular body. Since that time its numbers and resources have been steadily increasing both in North and South Wales. It is said that there is hardly a village in the principality where one of its chapels is not to be found. The doctrines held by its members are those of high or hyper-Calvinism. Their form of church government inclines to the Presbyterian, though many practices are encouraged among them that Presbyterians in general would condemn, such as the utterance of exclamations of desire or exultation on the part of the audience during public prayer, jumping and throwing themselves into violent postures under the excitement produced by the preacher's address, and others of a similar kind. They admit also of lay-preaching, and some of their most popular orators are of this class. The sermons of their preachers are generally delivered in a slow recitative, interrupted by quick and startling appeals and interrogations. Even upon those who are ignorant of the language in which the address is uttered, this peculiar mode of delivery is productive of a powerful sensation. It is not surprising, therefore, that on those by whom the whole is understood, and who can enter fully into the highly figurative and impassioned style of sentiment in which the Welsh preachers generally indulge, the most singular effects should be produced. It is no unusual thing to see whole congregations convulsed, and thrown into the most violent agitation, almost instantaneously, by some well-managed appeal to their feelings on the part of the preacher; and this once accomplished, it is not very difficult to keep up the excitement, until both speaker and hearers are ready to sink to the ground from pure exhaustion. The prevalence of this habit cannot but be regretted; but it is characteristic of the people; and though it is doubtless productive of much that is injurious to true piety, it cannot be questioned that upon the whole the labours of these preachers have told most beneficially, as well as extensively, upon the religious and moral improvement of their countrymen. The number of chapels belonging to this body is upwards of 800. The attendance on census Sunday was,—*morning*, 79,728; *afternoon*, 59,140; *evening*, 125,244. The number of ministers in 1853 was 207; of lay-preachers, 234; and of communicants, 58,577.

---

[1] "He (Wesley) found thousands of his countrymen, though nominally Christians, yet as ignorant of true Christianity as infidels or heathens." (Bishop Coplestone, as quoted in Watson's *Life of Wesley*, p. 313.)

Other Methodists.

The other classes of Methodists have been produced by secessions from the great body of Wesleyan Methodists. The reason assigned for these secessions has been nearly the same for all, viz., the arbitrary and unconstitutional power assumed by the Conference. The only exception to this is in the case of the *Primitive Methodists*, or *Ranters*, whose ground of secession was, that the true spirit of Methodism was no longer kept up in the body. By this they meant that too much attention was paid to order and decorum in the conduct of public worship; and that sufficient zeal was not manifested in obtruding religion upon the minds of the people by street services, field-preaching, &c. They are less obtrusive now in their methods than at first, but still they occasionally parade the streets, singing hymns, and inviting the populace to their places of worship. They admit of laymen, and even females, being allowed to preach. The number of their chapels in 1853 was 1789, to which are to be added 3565 rooms rented for purposes of religious worship; the number of their preachers was—568 travelling preachers, and 9594 local, besides 6767 class-leaders. The attendance on census Sunday was,—*morning*, 98,001; *afternoon*, 172,684; *evening*, 229,646.

The first secession upon the ground of the unscriptural power exercised by the Conference (and the earliest in point of time of any of the secessions), was made by a party in 1797, very soon after Mr Wesley's death. At the conference held at Leeds that year delegates appeared from many of the societies throughout the country, who were instructed to request that the people might have a voice in the formation of their own laws, the choice of their own officers, and the distribution of their own property. These reasonable demands having been refused, the petitioners agreed to secede from the Conference connection, and to form themselves into a distinct party upon a more liberal basis. The person who took the largest share in prompting and providing for this step was Mr Alexander Kilham, and from him the body thus formed have received the name of *Kilhamites*. They style themselves the *New Connection Methodists*. Their doctrinal views are those of Wesley; but in their polity they seem to have followed in a good measure the forms of Presbyterianism as exhibited in Scotland. The people choose their officers, and appear by representatives at all the synodical meetings of the denomination. This party is not very numerous. In 1853 they had 301 chapels, 95 circuits, 814 local preachers, and about 16,070 members.

Of late there have been several considerable secessions from the general body of the Wesleyans. At least three distinct parties have been formed within a few years. These are—1. The *Bible Christians*, or *Bryanites*, so called from a Mr Bryan, their founder. They differ very slightly from the original Wesleyans, excepting in the admission of the popular element in their scheme of church government. Their ministers preach much in the open air; and females are occasionally allowed to be preachers. In 1852 they had 403 chapels, 113 itinerant ministers, 1059 local preachers, and 13,862 members. The attendance on census Sunday was, *morning*, 14,902; *afternoon*, 24,345; *evening*, 34,612. 2. *The Wesleyan Methodist Association*. This body was formed in 1835 in consequence of the old objection to the Conference, that it exercised tyrannical powers, and unjustly excluded the laity from any share in the management of the body. In 1852 this denomination possessed 329 chapels, 90 itinerant preachers and missionaries, 1016 local preachers, 1353 class-leaders, and 19,411 members. The attendance on census Sunday was,—*morning*, 32,308; *afternoon*, 21,140; *evening*, 40,655. 3. *The Wesleyan Methodist Reformers*. This should hardly perhaps be called a separate body; they are rather a portion of the original Wesleyan Methodists, who have assumed a position of protest against the overbearing authority of the Conference, and of the illegality of their proceedings in the expulsion of certain parties who had censured them. They number about 52,000, and have 2000 places of worship, 2800 preachers, and 3300 class-leaders. On census Sunday the attendance was,—*morning*, 30,470; *afternoon*, 16,080; *evening*, 44,953.

(W. L. A.)

METHODIUS, a famous missionary of the ninth century, was a native of Thessalonica, and was originally a monk in the convent of St Basilius Cyrillus at Constantinople. About 861 he was summoned to Nicopolis by a Christian princess, who was endeavouring to convert her brother Bogoris, King of Bulgaria. That monarch learning that Methodius was an adept in painting, commissioned him to represent the "Pleasures of the Chase." The artist, however, painted the "Last Judgment" with such terrible effect that Bogoris was roused from his indifference, and began to ponder seriously the admonitions he had formerly received from his pious sister. A severe famine that ensued deepened his impressions, and in 863 or 864 he was publicly baptized. Within a short time the majority of his subjects had followed his example. About this period Methodius and his brother Cyrillus went as missionaries to the Sclavonic nation of the Moravians. They began their labours in this new field by constructing a Sclavonic alphabet, and by translating the Scriptures into the Sclavonic tongue. The truth, thus presented in a form that could be received into the minds and hearts of the people, was rapidly disseminated, and in no long time Methodius was consecrated archbishop of the Moravians by Pope Hadrian I. The zeal of Methodius, however, was too intense to be confined within any prescribed limits, and soon began to be exerted in the neighbouring German provinces, which were within the see of the Archbishop of Saltzburg. The German clergy, indignant that a Greek ecclesiastic should encroach upon their jurisdiction, laid their complaint before Pope John VIII., along with a charge against Methodius for using the Sclavonic language in divine worship. The offender was accordingly summoned to Rome in 879; but he pleaded his cause so ably, that the supreme pontiff was convinced of the utility and orthodoxy of his practice, and sent him home to his diocese in 880, with a commendatory letter to Swatopluk, King of Moravia. These favours only intensified the animosity of the German priesthood, and in the following year Methodius again carried his case to the pope. At this date he disappears altogether from history. In after times he was ranked among the saints.

METHODIUS *the Confessor*, Patriarch of Constantinople, was born at Syracuse towards the end of the eighth century, and entered into orders at Constantinople. The patriarch of that city sent him on an embassy to Rome in 820. On his return he was intrusted by Pope Pashalis with a letter upbraiding the Emperor Michael for his harsh persecution of the image-worshippers. Stung by this rebuke, the emperor seized upon the unfortunate messenger, condemned him to suffer 700 lashes, and threw him into a noisome dungeon in one of the islands of the Propontis. There he would have been starved to death had not a poor fisherman contrived to relieve his daily wants. On the accession of Theophilus to the imperial throne, Methodius was released, and raised to high honours in the state. But his irrepressible zeal for image-worship subjected him to a second scourging and a second incarceration in his former dungeon. No sooner had he escaped from this trouble than his private character was assailed by the foulest and the most perilous calumnies. Outliving, however, all these attacks, he was chosen patriarch of Constantinople in 842 by the Empress Theodora, the great patroness of image-worship. The rest of his life was occupied in zealously transferring all the power of the iconoclasts to the image-worshippers. He died in 846. Methodius the Confessor is the author of five orations in praise of monkery, and a collection of *Canones Pœnitentiales*.

METHONE (*Modon*), an ancient city of Messenia, was situated on the S.W. coast. It is called Pedasus in the *Iliad*, and not until the Messenian wars is it mentioned in history as Methone. At the close of the second of these struggles it was given by the victorious Lacedæmonians to the exiled Nauplians, but was restored to its rightful owners by Epaminondas. An unsuccessful attack was made upon Methone by the Athenians in 413 B.C. It was made a free city by the Emperor Trajan.

METIUS, Adrian, an eminent mathematician, was the son of a military engineer, and was born at Alkmaar in Holland in 1571. He studied practical mathematics under his father, law and medicine at the university of Franeker, and astronomy under Tycho Brahe. After visiting Germany, and delivering astronomical lectures there with great success, he returned to Holland to assist his father in his official duties. In 1598 he was promoted to the chair of mathematics at Franeker, a position which he held during the remainder of his life. The degree of M.D. was conferred upon him in 1625. Much of his time and money was latterly spent in the fruitless researches of alchemy. Metius died in 1635. The following is a list of his works:—*Doctrinæ Sphericæ*, 8vo, Franeker, 1598; *Universæ Astronomiæ Institutio*, 8vo, Franeker, 1606; *Arithmeticæ libri duo, et Geometriæ libri sex Practicæ*, 4to, Franeker, 1611; *Praxis Nova Geometrica per usum circini et regulæ proportionalis*, 4to, Franeker, 1623; *De Gemino Usu utriusque Globi*, 4to, Amsterdam, 1611; *Problemata Astronomica Geometrice Delineata*, 4to, Leyden, 1625; *Astrolabium*, 8vo, Franeker, 1626; *Calendarium Perpetuum Articulis Digitorum Computandum*, 8vo, Rotterdam, 1627; and *Opera Omnia Astronomica*, 4to, Amsterdam, 1633

METON, an ancient astronomer, the inventor of the *Metonic Cycle*, was a Leuconian by birth, and flourished at Athens in the fifth century before the Christian era. (See Astronomy.)

METONYMY, the most various of the rhetorical tropes, is the substitution of one word for another when the objects are related as causes, effects, or adjuncts. Thus, in the phrase, "To bring down one's gray hairs with sorrow to the grave," the effect is put for the cause; gray hairs are put for old age. We employ the same figure when we use the author for his writings, the inventor for his invention, &c. This trope was included by Aristotle under the general term metaphor.

METRONOME, from μέτρον, measure, and νόμος, rule, a pendulum which marks the times of music by the slowness or quickness of its oscillations. An instrument of this kind was contrived in France in 1698, and several others followed; but the one which has obtained the preference was constructed in 1812 by the celebrated mechanician J. N. Maelzel, inventor of the panharmonicon, the automaton-trumpeter, &c., and who died in America in August 1838, aged sixty-six. The invention of the mechanical principle of this metronome was publicly and successfully claimed by Winkel of Amsterdam; it being proved that Maelzel had contrived only the scale of numbers applied to the pendulum. The mechanism consists of a vertical rod of steel, which is made to oscillate by clockwork, and of which the oscillations are rendered slower or quicker by means of a weight that slides up and down upon the rod. A scale of numbers, from 50 to 160, but with omissions, *e.g.*, 50, 52, 54, &c., is placed behind the rod or pendulum; 50 representing the greatest degree of slowness, and 160 the greatest degree of quickness of the oscillations in one minute of time. The number 60 will thus represent 60 seconds, and all the other numbers, from 50 to 160, so many fractional parts of a minute; the minute being the integer to which all these subdivisions must be referred. The sliding-weight is raised or lowered upon the rod, so that the oscillations of the pendulum may correspond with this or that number indicated upon the scale; each audible beat or tick of the pendulum forming a fractional part of the minute, but not the two beats produced by the pendulum's motion from one side to the other. The musical notes used in manuscript or printed music, along with the numbers of the metronome scale, to indicate the time of a piece of music, are in general a quaver for an adagio movement, a crotchet for an andante, a minim for an allegro, a semibreve for a presto. For example: adagio, Maelzel's metronome ♪ = 60. It is very desirable that composers should always affix metronome numbers to their compositions. In the latest metronomes the scale ranges from 40 to 208. (See Movement.) (G. F. G.)

METTRIE, Julien Offray de la, a materialistic writer, was the son of a wealthy merchant, and was born at St Malo in 1709. After he had received his classical education at Paris he began his medical studies at Rheims, and finished them under the celebrated Boerhaave at Leyden. In 1742, the Duc de Grammont, colonel of the French guards, appointed him surgeon to his regiment. It was while present in this capacity at the siege of Fribourg, that being attacked with a dangerous sickness, and feeling that his body and mind were enfeebled simultaneously, he drew the inference that the soul must perish along with the organic structure with which it is connected. On his recovery in 1745 he divulged this doctrine in his *Histoire Naturelle de l'Ame*, a book full of the grossest materialism and impiety. The death of his patron at the battle of Fontenoy, in the same year, left him exposed to the storm of indignation that his vagaries had raised. He was expelled from his situation in the guards, and on daring to attack his professional brethren in his *Pénélope, ou le Machiavel en Médecine*, 12mo, 1748, he was driven from his native country. Scarcely had he taken refuge in Leyden when the publication of his revolting opinions in a book entitled *Homme Machine*, 12mo, 1748, subjected him once more to persecution. The work was publicly burnt, and its author was glad to avail himself of an opportune invitation from Frederick the Great to fix his residence at Berlin. The society of wits and philosophers from all parts of Europe, whom the Prussian monarch entertained at Potsdam, received Mettrie with all the distinction and respect due to a victim of intolerance. A pension, the title of reader to the king, and a place in the academy, were conferred upon him. He was admitted to the most intimate familiarity with his master. When he was tired he lounged upon the royal sofas, and when he was over-heated he unbuttoned his vest and threw his peruke upon the floor. At length, however, the brilliant yet no less galling slavery under which the literary dependants of Frederick lived became intolerable to Mettrie. He besought Voltaire, with all the passionate weeping of a child, to obtain for him from the French government leave to return to France; but before that request had time to be granted he was attacked by a severe fit of indigestion. The disorder was aggravated by the absurd treatment he used, and he died in November 1751, deriving no consolation from his own philosophy, or from the maxims of his irreligious associates. After his death his friend Voltaire gave no friendly estimate either of his intellectual or moral character. "Mettrie," said he, "was a fool that never wrote except when intoxicated." The collected works of Mettrie were published in 2 vols., Berlin, 1751.

METZ, a town of France, capital of an arrondissement of the same name, and of the department of Moselle, is situated on both sides of the Moselle, at its confluence with the Seille, 180 miles E.N.E. of Paris, and 80 W.N.W. of Strasburg. The houses are for the most part well built, but the streets are generally narrow, steep, and irregularly laid out. The rivers are lined with quays, and crossed by no less than seventeen bridges. Metz is very well fortified, being the chief defence of the frontier between the Meuse and the Rhine, and, next to Strasbourg, the strongest town in France. The fortifications were constructed by Vauban and Belle-Isle; and the principal forts are Belle Croix, which protects the town on the E., and La Double Couronne on the N. The city is surrounded by walls, in which there are nine gates, only six, however, being actually used. Some of the gates are of great antiquity, having remains of the machinery for raising and lowering the portcullis. The principal building in Metz is the cathedral, a Gothic structure which was begun in the eleventh, but not completed till the sixteenth century; it is in the form of a cross, and is much admired for the boldness and lightness of its architecture. It is about 380 feet in length, and has an elegant spire nearly 400 feet high, from which an extensive and beautiful view may be obtained. Besides this, the church of Notre Dame de la Ronde, and that of the abbey of St Vincent, are remarkable for their antiquity; and the former possesses an ancient episcopal throne and other interesting remains. The military hospital is a large building, erected in the reign of Louis XV., capable of accommodating 1500 patients. Metz contains the largest school of artillery and engineering in France, the pupils of which are chosen from the École Polytechnique of Paris. The town has also a town-hall, court-house containing a large public library, market-house, theatre, barracks, arsenal, &c. The manufactures of Metz consist of woollen and cotton stuffs, hosiery, plush, linen, paper, leather, glue, hardware, cutlery, &c. There is a large gunpowder factory, one of the first in France, on an island in the Moselle. Metz has also a large cannon foundry, the machinery of which is moved by water-power. The trade consists of the articles of manufacture, together with wines, brandy, confectionaries, groceries, &c. Metz is the see of a bishop, and has a court of appeal and tribunals of first instance and commerce. Metz is an ancient town. In the time of Cæsar it was called *Divodurum*, and was the capital of the Gallic nation of the Mediomatrici, from whom, in the fifth century, it took the name of *Mettis*, whence its modern appellation. It is remarkable in ancient history for a massacre of the unsuspecting inhabitants, in a time of peace, by the army of Vitellius, in the year 70 A.D. In the fifth century Metz was destroyed by the Huns. No Roman remains have been discovered in the town; but a short distance to the S. an amphitheatre, baths, and other ruins have been found, which seem to point out this as the exact site of the ancient Divodurum. There are also some remains of the aqueduct by which the town was in ancient times supplied with water. In the middle ages Metz was the capital of the kingdom of Austrasia, but was made by the Emperor Otho II. a free imperial city, and thereafter used by the German emperors as a barrier against France. It was besieged by Charles VII. in 1444, and could only preserve its freedom by the payment of 100,000 crowns. At length Henri II. obtained possession of Metz in 1552; and although it was besieged by Charles V. with an army of 100,000 men, his efforts were completely baffled by the skill and energy of the Duke of Guise, and by the courage and constancy of the townsmen; so that the French continued in possession of the town till it, along with those of Toul and Verdun, was formally secured to them by the peace of Westphalia in 1648. Pop. (1851) 43,484.

METZENSEIFEN (OBER and UNTER), two adjacent villages of Hungary, in the county of Abaujvar, in the territory of Kaschau, and 18 miles W. of that town. The inhabitants are of German origin, and are noted for their industry throughout the country. They are chiefly employed in iron mines and iron works in the vicinity. Pop. (Ober), 1938; (Unter), 3421: total, 5359.

METZINGEN, a town of Würtemberg, circle of the Black Forest, on the Erms, 17 miles S.S.E. of Stuttgart. Wine is produced in large quantities in the neighbourhood; and the town has manufactures of linen and woollen stuffs, leather, &c. A considerable trade in horses, cattle, and agricultural produce is carried on. Pop. 4532.

METZU, GABRIEL, a celebrated Dutch painter, was born at Leyden in 1615. His life seems to have been spent in the unwearied prosecution of his art, and to have been chequered by no more striking events than the successive publications of his numerous pictures. There are indications in his works of a close study of Terburg, Gerard Dou, and Francis Mieris. In the latter part of his life he caught some of the vivacity in execution of his convivial and talented friend Jan Steen. Metzu is generally represented to have died at Amsterdam in 1658; yet some of his well-authenticated pictures bear the dates 1661 and 1667. As a mere imitator of nature, Gabriel Metzu was unsurpassed. His paintings are harmonious combinations of the various qualities of correct design, delicate pencilling, rich and harmonious colouring, and masterly perspective. Conversation-pieces were his favourite subjects. His pictures of sick or fainting ladies, musical parties, letter-writers, morning visits of fashionable gallants, and other scenes in genteel life, are executed with the most refined taste. The same delicate sense of propriety preserves him from all coarseness when he represents a fish-market, a maid-servant sitting in a kitchen with a tabby cat beside her, or a cavalier drinking his beer and smoking his pipe at a cabaret. Very high prices have been given for some of the pictures of Metzu. Some of the most valuable are found in the Louvre, and in the galleries of Berlin, Dresden, and the Hermitage of St Petersburg.

MEURSIUS, or DE MEURS, JOHN, a celebrated antiquary, was born in the year 1579 at Losdun, a town near the Hague. His father, having embraced the Reformed doctrines, took refuge in 1569 at the Hague, and some time afterwards obtained the pastoral charge of Losdun. He taught his son the principles of the Latin language, and then sent him to study at Leyden, where he made so rapid progress, that at the age of twelve he composed harangues in Latin, and at thirteen, verses in Greek. His taste having led him to cultivate philology, he particularly directed his attention to Lycophron, the most obscure of all the Greek authors, whom he undertook to illustrate; and at the age of sixteen he completed his commentary on that difficult writer, a work which astonished the greatest scholars and critics of the time. When he had finished his course of study, the grand pensionary Barneveld confided to him the education of his sons; and he was also appointed to accompany them to the different courts of Europe. He turned his travels to account by availing himself of the opportunities which they afforded for extending his knowledge; and in passing through Orleans in 1608 he was honoured with the degree of Doctor of Laws. On his return to Holland in 1610 he was appointed professor of history in the academy of Leyden; and the following year he was promoted to the chair of Greek, which he filled with great distinction. The states of Holland conferred on him the title of historiographer, and honoured him with other marks of their esteem; but after the execution of Barneveld in 1619, Meursius was innocently subjected to much persecution from his connection with that unfortunate man. But the King of Denmark came to his relief in 1625, and offered him the chair of history in the university of Sora, together with the place of historiographer, a situation which he at once accepted. The remainder of his life was divided between his official duties and literary pursuits; and he died on the 20th of September 1639, at the age of sixty.

The memory of Meursius has suffered by his being sometimes represented as the author of the infamous dialogues *De Arcanis Amoris et Veneris.* This licentious work, it is now well known, was the production of one Chorier, an advocate of Grenoble, who probably prefixed to it the name of Meursius for the purpose of throwing ridicule on the grave and learned professor. His son John was a scholar of considerable eminence, and produced some works evincing erudition and research.

Meursius rendered a most valuable service to letters by the numerous annotated editions which he published of the Greek authors. The principal works which he edited are,—the *Poems* of Lycophron; the *Tactics* of the Emperor Leo; the *Opuscula* of Hesychius; the *Elements of Music* by Aristoxenes; the *Letters* of Philostratus; the *Historia Lausiaca* of Pallades; the *Annals* of Manasses; the *History* of Theodosius Metochites; the *Tactics* of Constantine Porphyrogennetes; the *Marvellous Histories* of Phlegon Trallianus, Antigonus Carystius, and Appollonius Dyscoles; and the works of Porphyry, Procopius, Gaza, and others. The works of Meursius were collected by Lami, Florence, 1741–1763, in 12 volumes folio. This collection is rare and much prized. In the *Mémoires* of Niceron (tom. xii. and xx.) will be found a list of all the productions of this indefatigable writer, in number sixty-seven; but we shall here only indicate those which are most deserving of the attention of the curious. *Glossarium Græco-Barbarum*, Leyden, 1614, in 4to; a work which, in regard to the Greek writers of the Lower Empire, holds the same place as the Glossary of Du Cange does for the writers of the corresponding age of Latinity. Various treatises on different departments of Greek and Roman antiquities, for the most part reprinted in the *Thesaurus* of Grævius. *Rerum Belgicarum Liber Primus*, Leyden, 1612; *Historia Danica*, Copenhagen, 1630.

MEURTHE, a department of France, bounded on the N. by that of Moselle, E. by that of Bas Rhin, S. by that of Vosges, and W. by that of Meuse. It lies between Lat. 48. 20. and 49. N., Long. 5. 40. and 7. 20. W.; having a length of 70 miles, an average breadth of 35, and an area of 2353 square miles. The eastern part of the department is occupied by the Vosges Mountains, which rise to the height of 1148 feet; and the rest of the surface is diversified and undulating, being traversed by numerous low spurs of the same mountain range.

The principal river is the Moselle, which traverses the department in an irregular course from S. to N., and is joined near Nancy by the Meurthe, from which the department takes its name. The former of these rivers is navigable in this department for 21 miles, and the latter for 6. The department is also watered by the Seille and the Sarre, smaller tributaries of the Moselle; and it contains several lakes of small size. The nature of the soil is very various in different parts; but it is in general of great fertility, especially in the valley of the Seille. Of the whole area of 1,505,928 acres, 750,000 acres consist of arable land; 175,000 of pasturage; 40,000 of vineyards; 290,000 of wood; 15,000 of waste land; &c. The quantity of wheat annually raised is about 3,240,000 bushels; and the amount of wine produced in ordinary years is 20,064,000 gallons, but its quality is by no means so remarkable as its quantity. Potatoes also, and leguminous plants, thrive well here; flax and rape are cultivated largely; and the hay furnished by the meadows of this department is of great excellence. The horses and cattle of Meurthe are not remarkable for the excellence of their breed; but pigs are reared in large numbers and with considerable success. The number of horses is about 75,000; of cattle, 92,000; of sheep, 180,000; and of pigs, 110,000; large numbers of which are exported. The mineral productions are not of much importance. They consist principally in rock-salt and salt springs, from which upwards of 44,000 tons of salt and nearly 1000 tons of soda are annually obtained. There are also numerous quarries of marble, granite, limestone, slate, &c., and a small amount of iron ore has been found, but not so much as to render the working of iron mines a profitable undertaking. The principal branches of industry prosecuted here are the manufacture of iron and glass; but those of lace, cotton and woollen stuffs, paper, glue, &c., are also carried on. The manufactures were formerly in a very low condition, but of late years they have increased greatly in prosperity. The commerce of the department consists chiefly in the productions of the agricultural and manufacturing industry of the inhabitants. The people of Meurthe are partly of French and partly of German origin, and the German language is still spoken in the east of the department.

The railway from Paris to Strasbourg runs through the department for a distance of more than 80 miles. Meurthe is divided into five arrondissements, as follows:—

	Cantons.	Communes.	Pop. (1851.)
Nancy	8	187	147,978
Château-Salins	5	147	68,634
Lunéville	6	145	88,978
Sarrebourg	5	116	76,667
Toul	5	119	68,166
Total	29	714	450,423

The total population in 1856 was 424,373. The capital is Nancy.

MEURTHE, a river of France, rises near Mount Bonhomme, a summit of the Vosges range, in the department of Vosges, flows N. and N.W. through that department and the adjoining one of Meurthe, and after a course of 100 miles, falls into the Moselle below Nancy. It receives the Vezouze and the Mortagne; and is navigable as far up as Nancy, about 6 miles from its confluence with the Moselle. It frequently overflows its banks, and thus contributes greatly to the fertility of the surrounding country. Large quantities of timber are floated down this river. The chief towns on its banks are St Dié, Raon l'Etape, Lunéville, and Nancy.

MEUSE, a department of France, bounded on the N. by Belgium and the department of Ardennes, E. by those of Moselle and Meurthe, S. by those of Vosges and Haute-Marne, and W. by those of Marne and Ardennes; lies between 48. 25. and 49. 35. N. Lat., and between 4. 54. and 5. 50. E. Long.; having a length of 83 miles, a breadth of 40, and an area of 2436 square miles. The department is traversed by two ranges of mountains at no great distance from each other, which extend from the Faucilles in the S. to the hills of Ardennes in the N. The highest summit of these ranges does not exceed 1600 feet; and between the two lies the valley traversed by the Meuse, from which the department takes its name. The other parts of the department present a great variety of hills, valleys, and plains. Besides the Meuse, it is watered by the Aisne and its tributary the Aire; by the Ornain and the Saulx, which join the Marne; by the Madine and Orne, tributaries of the Moselle; and by the Chiers, which falls into the Meuse. The nature of the soil is as varied as that of the surface of the country; and in some parts, especially in the valleys, it is rich and fertile, but in the hills and plains it is in general thin and poor. Of the whole area, 875,000 acres consist of arable land; 325,000 of wood; 125,000 of meadow land; 35,000 of vineyards; &c. The quantity of grain produced is more than enough for the supply of the inhabitants; potatoes, pease, beans, flax, &c., are also largely cultivated, and with great success. The fruits are excellent; gooseberries in particular are raised with much care; and the wines of Meuse, especially those of the valley of the Ornain, are highly prized. The pasturage is very good; and the cattle are superior to those of the neighbouring country. The horses are weak and small; but the rearing of pigs is attended to with much care. It is computed that the department contains 60,000 horses, 96,000 cattle, 214,000 sheep, 98,000 pigs, &c. The principal minerals in the department are iron, good building stone, potters' clay, and slate. The inhabitants are employed to a great extent in iron mines, forges, lime-kilns, glassworks, potteries, cotton factories, paper-mills, &c.; and the trade consists of iron, timber, wines, cotton stuffs, salt provisions, &c. The railway from Paris to Strasbourg runs through this department for a distance of 42 miles. Meuse is divided into four arrondissements, as follows:—

	Cantons.	Communes.	Pop. (1851.)
Bar-le-Duc	8	128	86,358
Commercy	7	180	87,664
Montmédy	6	131	69,096
Verdun	7	149	85,539
Total	28	588	328,657

In 1856 the total population was 305,727. The capital is Bar-le-Duc.

Meuse (anciently *Mosa*, Flemish *Maes*, Dutch *Maas*), a river of Europe, which takes its rise in the plateau of Langres, being formed by the union of two small streams above the village of Meuse, in the department of Haute-Marne. It flows northward in a narrow valley across the departments of Vosges, Meuse, and Ardennes, till it enters Belgium. At Namur it takes a N.E. direction; then separates Dutch from Belgian Limburg, and enters Holland; then turns to the N.W., and afterwards to the W. At a short distance below Gorcum it divides into two arms, the northern of which gets the name of Merwe, and again divides into the Maas and the Oude-Maas, or Old Meuse, inclosing between them the island of Ysselmonde, and falling among shoals and quicksands into the German Ocean. The other arm of the Meuse, flowing farther to the S., also separates into two smaller streams, one of which, called Haring-Vliet or Herring Stream, and afterwards Flakkee, separates the islands of Voorn and Over-Flakkee, and falls by a wide estuary into the ocean; and the other enters the sea farther S., between the islands of Over-Flakkee and Schouwen, communicating also by a smaller branch with the estuary of the Schelde. The whole length of the Meuse is about 550 miles; but a direct line from its source to its mouth would not exceed 230 miles in length. It is navigable as far as Verdun, a distance from the sea of 430 miles, of which nearly 300 are in Holland and Belgium. In the upper part of its course the river flows through a narrow valley, where the scenery is wild and picturesque, the precipitous cliffs sometimes leaving only a narrow defile, through which the river flows. In the lower part the appearance of the country is of a very different nature. Here there stretch large plains, which were originally under water, but have been recovered by the laborious and persevering efforts of the Dutch. The delta formed by the Meuse is greater than that of any other river in Europe. The Meuse receives in France the Monzon, the Vair, and the Chiers; in Belgium the Sambre, the Lesse, and the Ourthe; in Holland the Roer, the Niers, and the Rhine, by its three branches the Waal, the Leck, and the Yssel. The principal towns on the Meuse are,—Neufchâteau, Verdun, Sedan, Charlemont, and Givet, in France; Namur and Liège in Belgium; and Maestricht, Venloo, Grave, Gorcum, Willemstad, and Rotterdam, in Holland.

MEUSEL, Johann Georg, was born in 1743 at Eyrichshof, near Bamberg in Bavaria. After having received his education at Coburg, he went to the university of Göttingen, where he was appointed a member of the historical institute and of the philological seminary. Professor Klotz being appointed to a chair in Halle, invited Meusel thither, and there he remained till he obtained the chair of history at Erfurt in 1769. In 1780 he was appointed to the same chair in Erlangen, where he remained till his death in 1820. He is chiefly famous for his industry and accuracy in the collection of facts; but his histories are rather inferior productions, as he seems to have been oppressed with the weight of his extensive learning and the vast amount of his materials. His principal works are,—*Gelehrtes Deutschland*, Lemgo, 1796–1806, in 12 volumes; *Lexicon der von* 1750–1800 *Verstorbenen Schriftsteller*, Leipsic, 1812–1816, in 15 volumes; *Anleitung zur Kenntniss der Europaischen Staaten Historie*, Leipsic, 1816; *Literatur der Statistik*, Leipsic, 1806–7, in 2 volumes; and *Lehrbuch der Statistik*, Leipsic, 1805.

MEXICO.

I.—HISTORY OF MEXICO FROM THE EARLIEST ACCOUNTS TILL ITS SUBJECTION TO SPAIN.

Mexico, a republic of North America, is situated between 16. and 33. N. Lat., and between 86. and 117. W. Long.; being nearly 2000 miles in length, and 1100 miles in greatest breadth.

Toltecans the first inhabitants.

The Toltecans are the most ancient Mexican nation of which we know anything. They were expelled from their own country, which is supposed to have been *Tollan*, to the northward of Mexico, in the year A.D. 472. After leading a wandering life for 104 years, they reached a place about 50 miles to the eastward of the city of Mexico, where they settled for 20 years, giving to their new residence the name of *Tollantzinco*. From thence they proceeded about 40 miles farther to the west, where they built a city, called, from the name of their country, *Tollan* or *Tula*.

After the final settlement of the Toltecans, the government became monarchical. Their first king began his reign in 667, and their monarchy lasted 384 years. During this time they reckon only eight princes, as it was a custom amongst them to continue the name of each king for fifty-two years from the time when he ascended the throne. If he died within that period, the government was carried on in his name by regency; and if he survived, he was obliged to resign his authority. During the four centuries that the monarchy continued the Toltecans increased very considerably in number, and built many cities; but when in the height of prosperity almost the whole nation was destroyed by a famine occasioned by drought and a pestilence. The few who survived abandoned the country of Tula about 1051.

Succeeded by the Chichemecas.

A century later they were succeeded by the Chichemecas, a much more barbarous people, who came from an unknown country called *Amaquemecan*, where they had for a long time resided. The motive of the Chichemecas for leaving their own country is not known. They were eighteen months on their journey, and took possession of the desolate country of the Toltecans about 100 years after the famine. Though much more uncivilized than the Toltecans, they had a regular form of monarchical government, and in other respects were less disgusting in their manners than some of the neighbouring nations. Their king, Xolotl, chose for his capital Tenayuca, about 6 miles to the northward of the city of Mexico, and distributed his people in the neighbouring territory; but as most of them went to the northward, that part obtained the name of the country of the Chichemecas, in contradistinction to the rest. Xolotl finding himself peacefully settled in his new dominion, sent one of his officers to explore the sources of some of the rivers of the country. Whilst performing this task he came to the habitations of some Toltecans, who, it seems, had still kept together, and were likely once more to become a nation. As these people were not inclined to war, and were greatly esteemed for their knowledge and skill in the arts, the Chichemecas entered into a strict alliance with them, and Nopaltzin, the son of Xolotl, married a Toltecan princess. The consequence of this alliance was the introduction of the arts and knowledge of the Toltecans amongst the Chichemecas.

New inhabitants.

When Xolotl had reigned about eight years in his new territories, an embassy of six persons arrived from a distant country not far from Amaquemecan, expressing a desire of coming with their people to reside in the country of the Chichemecas. The king gave them a very gracious reception, and assigned them a district; and, in a few years afterwards, three other princes, with a great army of Acolhuans, who were likewise neighbours of Amaquemecan, made their appearance. These, also, Xolotl allowed to settle in his country, and gave in marriage his two daughters to two of the kings, and a noble virgin of Chalco to the third. As the Acolhuans were the more civilized nation of the two, the name of Chichemecas began to be appropriated to the more rude and barbarous portion, who preferred hunting to agriculture, or a life of savage liberty in the mountains to the restraints of social laws. These barbarians associated with the Otomies, another savage nation who lived to the northward; and by their descendants the Spaniards were harassed for many years after the conquest of Mexico.

Dominions of Xolotl divided.

As soon as the nuptial rejoicings were over, Xolotl assigned a portion of his territories to each of the three princes. Acolhuatzin, who had married his eldest daughter, had Azcopazalco, 18 miles to the westward of Tezcuco; Chiconquauhtli, who had married the other, received a territory named Xaltocan; and Tzontecomatl, who married the lady of inferior rank, obtained one named Coatlichan. The country continued for some time to flourish, population increased greatly, and with it the civilization of the people; but as these advanced, the vices of luxury and ambition increased in proportion. Xolotl died in the fortieth year of his reign, at a very advanced age.

Nopaltzin, the second king.

Xolotl was succeeded by his son Nopaltzin, who at the time of his accession is supposed to have been about sixty years of age. In his time the tranquillity of the kingdom, which had begun to suffer disturbance under his father, experienced much more violent shocks, and civil wars took place. The whole province of Tollantzinco rebelled, and the king himself was obliged to take the field. As the rebels were very numerous, the royal army was at first defeated, but at length the insurgents were overcome, and their ringleaders severely punished. The king did not long survive the restoration of tranquillity to his dominions. He died in the thirty-second year of his reign and ninety-second of his age, leaving the throne to his eldest son Tlotzin, who was an excellent prince, and reigned thirty-six years.

Quinatzin. Disturbances in various parts.

Quinatzin, the son and successor of Tlotzin, was vain and luxurious. His reign, though tranquil at first, was soon disturbed by dangerous revolts and rebellions. These first broke out in two states, named Maztillen and Totopec, situated amongst the northern mountains. The king having collected a great army, marched without delay against the rebels, and after frequent engagements for the space of forty days, gained a complete victory, and punished the ringleaders of the defection with great severity. Tranquillity, however, was not yet restored; the rebellion spread to such a degree that the king was obliged not only to take the field in person, but to employ six other armies, under the command of faithful and experienced generals, in order to reduce the rebels. These proved so successful in their enterprises, that in a short time the rebellious cities were reduced to obedience, and the kingdom enjoyed the blessings of peace during the long reign of Quinatzin, who is said to have sat upon the throne for no less than sixty years. He was succeeded by his son Techotlatla; but as the affairs of the Acolhuans had now begun to be connected with those of the Mexicans, it will be proper to give some account of that people.

Migrations of the Mexicans, A.D. 1160.

The nation of the Aztecas, which comprised the Mexicans, dwelt till the year 1160 in a country called *Aztlan*, situated to the N. of the Gulf of California, as appears by the route they pursued in their journey, but how far to the northward we are not certainly informed. Betancourt makes it no less than 2700 miles, and Boturini says it was a province of Asia. The Aztecas, when they left their original habitations, were divided into six tribes; but at Culiacan the Mexicans were left with their god (a wooden image), while the five tribes of Xochimilcas, Tepanecas, Chalcese, Tlahuicas, and Tlascalans, continued their march. The remaining tribe was divided into two violent factions, which persecuted one another, but always travelled together in order to enjoy the company of their god. At every place where they stopped an altar was erected to him; and at their departure they left behind them all their sick, and probably also all that were not willing to endure the fatigue of such journeys. They stopped in Tula nine years, and eleven more in the neighbouring parts. At last, in 1216, they arrived at Zumpanco, a considerable city in the valley of Mexico, and were received in a hospitable manner by the lord of the district. He not only assigned them proper habitations, but even demanded from amongst them a wife for his son Ilhuicatl. This request was complied with, and from this marriage all the Mexican kings descended.

Persecution of the Mexicans, A.D. 1245.

The Mexicans continued to migrate from one place to another along the Lake of Tezcuco. Xolotl, who was then on the throne of the Acolhuans or Chichemecas, allowed them to settle in whatsoever places of his dominions they thought proper; but some of them finding themselves harassed by a neighbouring lord, were obliged in the year 1245 to retire to Chapoltepec, a mountain on the western borders of the lake, scarcely two miles distant from the site of Mexico. This took place in the reign of Nopaltzin, when disturbances began to take place in the Acolhuan dominions. The Mexicans, however, did not find themselves any more secure in their new place of residence than formerly. They were persecuted by the neighbouring lords, and obliged to take refuge in a number of small islands, named Acocolco, at the southern extremity of the Lake of Mexico. Here for fifty-two years they lived in the most miserable manner, subsisting on fish, insects, roots, &c., and clothing themselves with the leaves of the amoxtli, which abounds in that lake. In this miserable plight the Mexicans continued till the year 1314, when they were reduced to a state of the most absolute slavery by the king of a petty state named Colhuacan. After some years a war broke out between the Colhuans and Xochimilcas, in which the latter gained such advantages that the former were obliged to employ their slaves to assist them. The Mexicans, armed with long staves having their points hardened in the fire, with knives of the stone itztli, and with shields of reeds woven together, harassed the enemy so much by not making any prisoners, but by uniformly cutting off the ear, that the Colhuans gained a complete victory. Notwithstanding, it does not appear that the haughty masters were in the least inclined to afford their slaves easier terms than before. On a certain day, which the Mexicans had set apart for sacrificing to their god, the Colhuan prince attended with his nobility, not with a view to do honour to the festival, but to make a mockery. Their derision, however, was soon changed into horror, when the Mexicans, after a solemn dance, brought forth four Xochimilcan prisoners; and after having made them dance, cut open their breasts with a knife, and plucking out their hearts, offered them, whilst yet palpitating with life, to their sanguinary idol. This had such an effect upon the spectators, that both the king and his subjects desired the Mexicans immediately to quit their territories and go where they pleased. This order was instantly obeyed. The whole nation took their route towards the north until they came to a place named *Iztacalco*, near the site of Mexico.

City of Mexico founded, A.D. 1325.

The city of Mexico was founded in 1325 on a small island named Tenochtitlan, in the middle of a great lake, without ground to cultivate for subsistence, or even room sufficient to build habitations. To enlarge the boundaries of their island, they drove palisades into those parts of the water which were most shallow, terracing them with stones and turf, and uniting to their principal island several other smaller ones which lay in the neighbourhood. The greatest effort of their industry, however, was the construction of floating gardens, by means of bushes and of the mud of the lake; and these they brought to so much perfection that they produced maize, pepper, chia, French beans, and gourds. During the thirteen years that the Mexicans had to struggle with extreme difficulty they remained at peace; but no sooner did they begin to prosper and live comfortably, than the inveterate enmity between the two factions broke out in all its fury. This produced a separation; and one of the parties took up their residence on a small island at a little distance to the northward, which, from a heap of sand found there, they at first named *Xaltilolco*, but afterwards *Tlatelolco*, from a terrace constructed by themselves. This island was afterwards united to that of Tenochtitlan. About this time the Mexicans divided their city into four parts, each quarter having now its tutelar saint, as it had formerly had its tutelar god. In the midst of their city was the sanctuary of their great god *Mexitli*, whom they constantly preferred to all the rest. To him they daily performed acts of adoration; but instead of making any progress in humanity, they seem to have daily improved in the most horrible barbarities, at least in their religion.

Acamapitzin, the first king of Mexico, A.D. 1352.

In the year 1352 the Mexican government was changed from an aristocracy to a monarchy. At first the people were governed by twenty lords, of whom one had an authority superior to the rest. This naturally suggested the idea of monarchy; and to this change they were also induced by the contemptible state in which their nation still continued, thinking that the royal dignity would confer upon it a degree of splendour which otherwise it could not enjoy, and that by having one leader, they would be better able to oppose their enemies. Proceeding, therefore, to elect a king, the choice fell upon Acamapitzin, a man held in great estimation amongst them, and descended from Opoclitli, a noble Aztecan, and a princess of the royal family of Colhuacan. As he was yet a bachelor, they negotiated a marriage with the daughter of Acolmiztli, lord of Coatlichan, and the nuptials were celebrated with great rejoicings. In the meantime the Tlatelolcos, the natural rivals of the Mexicans, likewise chose a king. Not thinking proper, however, to choose him from amongst themselves, they applied to the king of the Tepanecos, who readily sent them his son; and he was crowned first king of Tlatelolco in 1353. In this the Tlatelolcos seem to have had a design of humbling their rivals, as well as of rendering themselves more respectable; and therefore it is very probable that they had represented the Mexicans as wanting in that respect due to the Tepanecan monarch, from having elected a king without his leave, though at the same time they were tributaries to him. The consequence of this was, that he doubled their tribute, and imposed upon them many whimsical tasks. They freed themselves, however, from all their difficulties by vigorous exertions, absurdly ascribing to the malevolent being whom they worshipped all the glory of every deliverance. Acamapitzin governed this city, which at that time comprehended the whole of his dominions, for thirty-seven years in peace.

Huitzilihuitl, the second king, A.D. 1389.

Acamapitzan died in the year 1389, lamented by the Mexicans, and his death was followed by an interregnum of four months. As the deceased monarch had formally resigned his authority into the hands of his nobles, it was necessary that a new election should take place; and the choice fell upon Huitzilihuitl, the son of Acamapitzin. The new monarch began his reign by espousing the daughter of the King of Azcapozalco. Though this princess brought him a son the first year of their marriage, the king, in order to strengthen himself by fresh alliances, married also the daughter of another prince, by whom he had Montezuma Ilhuicamina, the most celebrated of all the Mexican kings. As the Mexicans advanced in wealth and power so did their rivals the inhabitants of Tlatelolco. Their first king died in 1399, leaving his subjects greatly improved in civilization, and the city much enlarged and beautified. The rivalship which subsisted between the two cities had indeed greatly contributed to the aggrandizement of both. The Mexicans had formed so many alliances by marriage with the neighbouring nations, had so much improved their agriculture and floating gardens on the lake, and had built so many more vessels to supply their extended commerce and fishing, that they were enabled to celebrate their secular year, answering to the year 1402 of our era, with far greater magnificence than they had ever done since they left their original country of Atztlan. In 1406 Techotlala, King of Acolhuacan, died, after a tranquil reign of thirty years. No sooner had his son Ixtlilxochitl succeeded him than the Kings of Mexico, Azcapozalco, and Tlatelolco abjured their allegiance. After a disastrous contest of three years, the rebels, designing to accomplish by treachery what they had been unable to effect by force, sued for peace and obtained it.

Chimilpopoca, third king of Mexico, A.D. 1409.

In 1409 died Huitzilihuitl, King of Mexico, who left the right of electing a successor to the nobility. They made choice of his brother Chimilpopoca; and hence it became an established law to choose one of the brothers of the deceased king, or, if he had no brothers, to elect one of his grandsons. Whilst the new prince was endeavouring to secure himself on the throne, the treacherous Tezozomoc, King of Azcapozalco, employed all the means in his power to strengthen the party he had formed against the King of Acolhuacan. In this he had such success, that the unfortunate prince found himself reduced to the necessity of wandering amongst the neighbouring mountains, at the head of a small army, accompanied by the lords of Huexotla and Coatlichan, who remained faithful to him. The Tepanecans, by intercepting his provisions, distressed him to such a degree that he was forced to beg them of his enemies. At length they killed him, after they had treacherously persuaded him to hold a conference with two of their captains. This perfidious act was committed in sight of the royal army, who were too weak to revenge it. The royal corpse was saved with difficulty; and Nezahualcojotl, the heir-apparent to the crown, was obliged to shelter himself amongst the bushes from the fury of his enemies.

Acolhuacan conquered by Tezozomoc.

Tezozomoc having now in a great measure gained his point, proceeded to pour down his troops upon those cities and districts which had remained faithful to the late unfortunate monarch. The people made a desperate defence, and killed great numbers of their enemies; but at last being reduced by the calamities of war, and in danger of total extermination, they were obliged to quit their habitations and flee to other countries. The tyrant then gave Tezcuco to Chimilpopoca, King of Mexico, and Huexotla to Tlacacotl, King of Tlatelolco; at the same time placing faithful governors in others places, and appointing Azcapozalco, the capital of his own territory, the royal residence and capital of Acolhuacan. All the rest of the Acolhuacan empire submitted; and Nezahualcojotl saw himself for the present deprived of all hopes of obtaining the crown. Tezozomoc had now attained the summit of his ambition. But instead of conciliating the minds of his new subjects, he oppressed them with fresh taxes; and being conscious of the precarious situation in which he stood, and tormented with remorse on account of his crimes, he fell into melancholy, and at length expired in the year 1422, leaving the crown to his son Tajatzin.

The throne usurped by Maxtlaton, A.D. 1422.

Tezezomoc was no sooner dead than Maxtlaton, one of his other sons, without paying the least regard to his father's will, began to exercise the functions of sovereign, and compelled his brother Tajatzin to retire to Chimilpopoca, King of Mexico. This monarch, agreeably to the character of that age and people, advised him to invite his brother to an entertainment, and then to murder him. Unluckily for both, this discourse was overheard by a servant, who, in expectation of a reward, informed the tyrant of what he had heard. Maxtlaton therefore determined to rid himself of his brother without delay. This he soon accomplished in the very same way that had been projected against himself. Tajatzin, along with the Kings of Mexico, Tlatelolco, and several other feudatory princes, were invited by Maxtlaton to an entertainment. The King of Mexico prudently excused himself, but the unsuspecting Tajatzin came to the place of entertainment, and was instantly put to death. The company were greatly alarmed, but nevertheless proclaimed Maxtlaton king, being in this, no doubt, much more influenced by fear than by affection. The King of Mexico escaped a sudden death by his absence at this time, only to perish in a manner more slow and ignominious. His revengeful foe Maxtlaton, not content with heaping insults upon him, decoyed his favourite wife into his hands, and sent her home dishonoured. Chimilpopoca was so much affected by this misfortune that he resolved to offer himself up as a sacrifice to his god; but before the resolution could be executed Maxtlaton sent a body of troops, who, entering Mexico without resistance, carried off the king alive. Chimilpopoca was imprisoned at Azcapozalco in a strong wooden cage, the common prison for criminals.

Itzcoatl raised to the throne of Mexico.

In the meantime the Mexicans raised to the throne Izcoatl, the son of Acamapitzin. His election was no less pleasing to Nezahualcojotl and his party than it was offensive to Maxtlaton. An alliance was quickly concluded between the exiled prince and the King of Mexico; and when the former commenced hostilities against the tyrant of Azcapozalco, the latter agreed to assist him. Maxtlaton accordingly prepared to wage war with the Mexicans. The Mexican populace, terrified at engaging so powerful an enemy, demanded that their king should submit and sue for a peace. But Montezuma, the brave son of Huitzilihuitl, persuaded them to agree to a commencement of hostilities. Conditions of peace, however, were first sent to Maxtlaton by the hands of Montezuma. They were rejected, and the Mexican ambassador forthwith went through the ceremony of declaring war. The Mexican populace were again thrown into the utmost consternation by the news that war was inevitable; and they now requested the king to allow them to retire from their city, of which they supposed the ruin to be certain. The king encouraged them with the hopes of victory. "But if we are conquered," replied they, "what will become of us?" "If that happen," answered the king, "we are that moment bound to deliver ourselves into your hands, to be made sacrifices at your pleasure." Prince Nezahualcojotl was forthwith summoned to repair to Mexico with his army. On the day after his arrival the allied forces encountered the Tepanecan troops under a general named Mazatl. After an obstinate and bloody contest, which lasted till night, the Tepanecan general fell by the sword of Montezuma, and his forces were driven into their capital city. On the following day their defeat was even more signal, and resulted in the capture of Azcapozalco. Maxtlaton attempted to hide himself, but being quickly discovered, he was beaten to death with sticks and stones. The city was plundered, the inhabitants were butchered, and the houses destroyed by the victors. This victory proved decisive in favour of the confederates. Every other place of strength in the country was quickly reduced, until the Tepanecans, finding themselves upon the verge of destruction, sent an humble embassy to the King of Mexico, requesting to be taken under his protection, and to become tributaries to him. Itzcoatl received them graciously, but threatened them with total extirpation if they violated the fidelity they had sworn to him.

Nezahualcojotl made king of Acolhuacan.

Itzcoatl, now finding himself firmly seated on the throne of Mexico, set about performing his engagements to the Acolhuacan prince. Nezahualcojotl was accordingly seated upon the throne of Acolhuacan. Having thus accomplished the conquest of Cojohuacan, a great part of the Tepanecan country, with the title of King of Tacuba, was given by Itzcoatl to Totoquihatzin, a grandson of Tezozomoc. An alliance was then formed between the Kings of Mexico, Acolhuacan, and Tepaneca. The conditions were, that they should assist each other in war, and should divide all plunder amongst themselves according to certain specified proportions. About this time the Xochimilcas, fearing lest the Mexicans should now turn their victorious arms against them, determined to commence hostilities against that rising state, before it should become more formidable by new conquests. Itzcoatl was no sooner informed of this determination, than he sent Montezuma with a great army against them. The Xochimilcas met him with one still more numerous; but being worse disciplined they were quickly defeated, and their city taken a short time afterwards.

Montezuma I., king of Mexico, A.D. 1436.

Izcoatl died in 1436, at a very advanced age, in the height of prosperity, and was succeeded by Montezuma I., the greatest monarch that ever sat on the Mexican throne. Scarcely had he been crowned when his aid was solicited by the Tezcucans against the Chalcese. The latter were almost annihilated in one desperate battle, and their city was levelled with the ground. Montezuma, on his return, found himself obliged to encounter an enemy more formidable, on account of his vicinity, than enemies more powerful at a distance. This was the King of Tlatelolco, who had formerly conspired against the life of Itzcoatl, and finding himself disappointed in this, had tried to reduce his power by entering into a confederacy with some of the neighbouring lords. At that time his designs proved abortive, but he resumed them in the time of Montezuma; the consequence was, that he was defeated and killed. One Moquihuix was chosen in his stead; and in the election of that chief it is probable that Montezuma had a considerable share. This was followed by conquests of a much more important nature. He added to his dominions the province of Cuihixcas, situated to the southward, and comprehending a tract of country more than 150 miles in breadth. Then, turning to the westward, he conquered another province named Tzompahuacan. This success, however, was for a short time interrupted by a war with Atonaltzin, lord of a territory in the country of the Mixtacas. Against this potentate Montezuma sent a considerable army, but had the mortification to be informed of its defeat. Chagrined at this first check, he determined to command his next army in person; but before he could call together another, Atonaltzin had formed a confederacy with the Huexotzincas and Tlascalans, who were glad of the opportunity, as they supposed, of reducing the power of the Mexicans. Their numbers, however, availed them but little; as Montezuma in the first engagement totally defeated the confederate army. By this victory the Mexican monarch became master not only of the dominions of Atonaltzin, but of those of many other neighbouring princes, against whom he had made war on account of their having put to death some Mexican merchants or couriers without any just cause. The conquest of Cuetlachtan or Cotasta, however, which he attempted in 1457, proved a much more difficult task. This province is situated on the coast of the Mexican Gulf, and had formerly been inhabited by the Olmecans, whom the Tlascalans had driven out. The inhabitants were very numerous; but dreading the power of Montezuma, called in to their assistance those of Tlascala, together with the Huexotzincas and the Cholulans. Montezuma sent against them an excellently equipped army, which, however, he did not on this occasion command in person. The Cotastese fought with great valour, but were unable to resist the royal forces; and their allies were almost totally destroyed. Six thousand two hundred of them were taken prisoners, and soon afterwards sacrificed to the Mexican god of war in the barbarous manner already described.

Mexican dominions changed, A.D. 1457.

Inundation and famine at Mexico, A.D. 1446.

During the reign of this great monarch a violent inundation happened in Mexico. The lake, swollen by the excessive rains which fell in 1446, poured its waters into the city with such violence, that many houses were destroyed, and the streets inundated to such a degree that boats were everywhere made use of. The inundation was soon followed by a famine. This was occasioned by the partial failure of the crop of maize in 1448, the ears whilst young and tender having been destroyed by frost. In 1450 the crop was totally lost for want of water; and in 1451, besides the unfavourable seasons, there was a scarcity of seed. Hence in 1452 the necessities of the people became so great, that they were actually obliged to sell themselves as slaves in order to procure subsistence. Montezuma opened the public granaries for the relief of the lower classes; but nothing could arrest the progress of the famine.

Axayacatl succeeds Montezuma.

Montezuma was succeeded by Axayacatl, who, like his predecessor, instantly commenced a war, for no other reason than that he might obtain prisoners to sacrifice at his coronation. He pursued Montezuma's plan of conquest, in which, however, he was not very successful; many of the provinces reduced by that monarch having revolted after his death, so that it was necessary to reconquer them. The Mexicans sustained an irreparable loss in 1469 and 1470 by the death of their allies the Kings of Tacuba and Acolhuacan. The King of Tacuba was succeeded by his son Chimilpopoca, and the Acolhuacan monarch by his son Nezahualpilli. A short time after the accession of the latter the war broke out between the Tlatelocos and Mexicans, which ended in the destruction of the former. Moquihuix, King of the Tlatclocos, had entered into an alliance with a great number of the neighbouring states, in order to reduce the Mexican power. He then prepared for war with many horrid ceremonies, of which the drinking of human blood was one. A day was appointed for attacking Mexico. At the set time the attack began and lasted until night, when the Tlatclolcos were obliged to retire. During the night Axayacatl disposed of his troops in all the roads which led to Tlatelolco, appointing them to meet in the market-place. The Tlatelolcos, finding themselves attacked upon all sides, retired gradually before the Mexicans, until at last they were forced into the market-place. During the tumult which ensued Moquihuix was killed, and his army was compelled to submit. The Tlatelolcos being thus reduced, Axayacatl next set out on an expedition against the Matlazincas, a tribe in the valley of Toluca, who still refused to submit to the Mexican yoke. Having proved successful in this expedition, he undertook to subdue Xiquipilco, a considerable city and state of the Otomies. Encountering the chief of that people in single combat, he was overmatched, and received a violent wound in the thigh. Notwithstanding this disaster, his army gained a complete victory, carrying off more than eleven thousand prisoners, amongst whom was the chief of the Otomies himself.

Tizoc and Ahuitzotl.

Axayacatl was succeeded by his elder brother, called Tizoc, who was shortly afterwards murdered in a conspiracy of his subjects. During the reign of Tizoc the Acolhuacans made war upon the Huexotzincas, ruined their city, and conquered their territory. Ahuitzotl, the brother of Tizoc, succeeded him in the kingdom of Mexico. His first object was to finish the great temple begun by his predecessor; and so great was the number of workmen employed that it was completed in four years. During the time it was building the king employed himself in making war with different nations, reserving all the prisoners he took for victims at the dedication of the temple. The number of prisoners sacrificed at this dedication in 1486 is said by Torquemada to have been 72,324, and by other historians is estimated at 64,060. In 1487 there happened a violent earthquake; and Chimilpopoca, King of Acolhuacan, having died, was succeeded by Totoquihuatzin II. Ahuitzotl died in the year 1502 of a disorder produced by a contusion in the head. At the time of his death the Mexican empire had reached its utmost extent.

Montezuma, A.D. 1502.

His successor, Montezuma Xocojotzin, or Montezuma the younger, was a person of great bravery, and was likewise a priest, and held in great estimation on account of the gravity and dignity of his deportment. But no sooner was the ceremony of his coronation terminated, than Montezuma began to discover a pride which nobody had before suspected. He deprived all the commoners of the offices they held about the court, declaring them incapable of holding any for the future. All the royal servants were now people of rank. Besides those who lived in the palace, six hundred feudatory lords and nobles came to pay court to him. In every respect he kept up, as far as was possible, an extravagant appearance of dignity, splendour, and luxury. But in no long time his prodigality rendered him very disagreeable to a great number of his subjects, though others were pleased with the readiness he showed to relieve the necessities of individuals, and his generosity in rewarding his generals and ministers. The reign of Montezuma, even before the arrival of the Spaniards, was far from being so glorious as those of his predecessors had been. He attempted to extort tribute from Tlascala, a small republic at no great distance from the capital; but the inhabitants had already inclosed all the lands of the republic with intrenchments, to which they now added a wall six miles in length on the west side, where an invasion was most to be apprehended. Behind these fortifications so well did they defend themselves, that though they were frequently attacked by the neighbouring states in alliance with Mexico, or subject to it, they were still able to maintain their ground. Montezuma's reign was also disturbed by disastrous losses and evil omens. In 1508 an expedition against a very distant region, named Amatla, completely failed. A great part of the soldiers perished under the inclemency of the weather, and the rest were killed in battle. By this and other calamities, together with the appearance of a comet, Montezuma was so terrified that he applied to the King of Alcohuacan, who was reported to be very skilful in divination. Nezahualpilli told him that the comet presaged the arrival of a new people; but this being unsatisfactory to the emperor, he conferred with a celebrated astrologer, who confirmed the interpretation of Nezahualpilli.

Conquest of Mexico undertaken by Cortez, A.D. 1518.

Mexico was first discovered by Hernandez de Cordova, who in 1517, in sailing towards the Bahamas, was driven by a succession of severe storms on the coast of Yucatan. On the 10th of February 1519 Hernando Cortez set sail for the conquest of Mexico from the Havannah, and, after touching at Yucatan, arrived in Passion-week of the same year at the harbour of St Juan de Ulua. Here he was met by two Mexican canoes, which carried two ambassadors from the emperor of that country, and showed the greatest signs of peace and amity. Their language was translated into the Yucatan tongue by a female prisoner, whom they had recently captured; after which a Spaniard named Jerom de Aguilar interpreted the meaning in Spanish. This slave was afterwards named Donna Marina, and proved very useful in their conferences with the natives. By means of his two interpreters, Cortez learned that the other part of the embassy was to inquire what his intentions were in visiting these coasts. He accordingly informed the ambassadors that he came to propose matters of the utmost consequence to the welfare of the prince and his kingdom. Next morning, without waiting for any answer, he landed his troops, horses, and artillery, and began to erect huts for his men, and to fortify his camp. The day following the ambassadors had a formal audience, at which Cortez acquainted them that he came from Don Carlos of Austria, king of Castile, the greatest monarch of the East, and was intrusted with propositions of such moment that he would impart them to none but the emperor himself, and therefore required to be conducted immediately to the capital. This demand produced the greatest uneasiness, and the ambassadors did all in their power to dissuade Cortez from his design, endeavouring to conciliate his good will by the presents sent him by Montezuma. But Cortez insisted on being admitted to a personal interview with their sovereign. During this conversation some painters in the retinue of the Mexican chiefs had been diligently employed in delineating, upon white cotton cloths, figures of the ships, horses, artillery, soldiers, and whatever else attracted their eyes as singular. These sketches were then despatched to Montezuma by trained couriers posted at proper stations along the road. In a few days messengers arrived from the royal residence with many rich presents to Cortez, but at the same time with the intelligence that Montezuma would not give his consent that foreign troops should approach nearer to his capital, or even allow them to continue longer in his dominions.

Montezuma commands Cortez to leave his dominions, A.D. 1519.

In a short time a deputy named Teutile arrived with another present from Montezuma, and together with it delivered the ultimate orders of that monarch to depart instantly out of his dominions; and when Cortez, instead of complying with his demands, renewed his request of audience, the Mexican immediately left the camp with strong marks of surprise and resentment. Next morning none of the natives appeared; all friendly correspondence seemed to be at an end, and hostilities were expected to commence every moment. Cortez, without allowing his men time for reflection, immediately set about carrying his designs into execution. In order to give a beginning to a colony, he assembled the principal persons in his army, and by their suffrages elected a council and magistrates, in whom the government was to be vested. The new settlement received the name of Villa Rica de la Vera Cruz, that is, "the rich town of the true cross."

The government of the new colony vested in Cortez.

Before this court of his own making, Cortez did not hesitate to resign all his authority, and was immediately re-elected chief-justice of the colony, and captain-general of his army, with an ample commission, in the king's name, to continue in force till the royal pleasure should be further known. The soldiers eagerly ratified their choice by loud acclamations; and Cortez, now considering himself as no longer accountable to any subject, began to assume a much greater degree of dignity, and to exercise more extensive powers than he had hitherto done. Having strengthened himself still further by an alliance with one of Montezuma's own tributaries, the petty prince of Cempoalla, he resolved to advance into the country.

Yet, as he had thrown off all dependence on Velasquez, the governor of Cuba, who was his lawful superior, he was apprehensive of his interest at court, and thought proper, before he set out on his intended expedition, to take the most effectual measures against the impending danger. With this view, he persuaded the magistrates of his colony to address a letter to the king, containing a pompous account of their own services, of the country they had discovered, and of the motives which had induced them to throw off their allegiance to the governor of Cuba, and to settle a colony dependent on the crown alone, in which the supreme power, civil as well as military, had been vested in Cortez; humbly requesting their sovereign to ratify what had been done under his royal authority. Some soldiers and sailors, however, secretly disaffected to Cortez, formed a design of seizing one of the brigantines, and making their escape to Cuba, in order to give such intelligence to the governor as might enable him to intercept the vessel which was to carry the treasure and despatches to Spain. But before this conspiracy was ready for execution, the secret was discovered by one of the associates. To prevent such plots in future, Cortez, without any hesitation, burned his fleet, and thus rendered it necessary for his troops to follow wherever he chose to lead. He then began his march into the interior, with 500 infantry, 15 horse, and 6 field-pieces; and with a reinforcement furnished by the Prince of Cempoalla, consisting of 400 regular troops and 200 of those Indians called Tamanes, whose office was to carry burdens and perform all manner of servile labour.

Conspiracy.

Cortez engages in war with the republic of Tlascala.

Nothing memorable happened till the Spaniards arrived on the confines of the republic of Tlascala. As the inhabitants of that province were implacable enemies of Montezuma, Cortez hoped that it would be an easy matter for him to procure their friendship; but his ambassadors were detained, a circumstance which led him to infer that the Tlascalans were hostile. He accordingly approached the city, and soon found that his small force was surrounded by an army of 50,000 men. In the battle which ensued the discipline and equipments of the Europeans overcame this immense host. The loss of three other battles effectually subdued the valour of the natives, and at last peace was concluded to the great satisfaction of both parties. The Tlascalans yielded themselves as vassals to the crown of Castile, and engaged to assist Cortez in all his operations, in return for the protection which he guaranteed to extend to their republic.

Cortez prosecutes his enterprise.

As soon as his troops were fit for service, Cortez resolved to continue his march towards Mexico, notwithstanding the remonstrances of the Tlascalans, who looked upon his destruction as inevitable if he put himself into the power of such a faithless prince as Montezuma. But the emperor had informed Cortez that he agreed to receive his visit, and that he had given orders for his friendly reception at Cholula, the next place of any consequence on the road to Mexico. Cortez was received with much seeming cordiality; but 6000 Tlascalan troops who accompanied him were obliged to remain without the town, as the Cholulans refused to admit their ancient enemies within their precincts. In a short time Donna Marina, the interpreter, received information from an Indian woman of distinction, whose confidence she had gained, that the destruction of the Spaniards was concerted; that a body of Mexican troops lay concealed near the town; that some of the streets were barricaded, whilst in others deep pits or trenches were dug, and slightly covered over, as traps into which the horse might fall; that stones and missile weapons were collected upon the tops of the temples; and that the fatal hour was already at hand. Cortez, alarmed at this news, resolved to anticipate his enemies. On a signal given, his troops rushed out and attacked the multitude in front, the Tlascalans at the same time assailing them in the rear; the streets were filled with slaughter, and the temples, which afforded a retreat to the priests and some leading men, were set on fire, in consequence of which they perished in the flames. At length the carnage ceased, after the slaughter of 6000 Cholulans, without the loss of a single Spaniard.

From Cholula Cortez continued his march to Mexico with great circumspection and the strictest discipline, though without seeming to suspect the prince whom he was about to visit.

Meeting of Cortez and Montezuma.

When the Spaniards drew near the city, about 1000 persons of distinction came forth to meet them, and announce the approach of the emperor himself. Preceded by all the pomp and pageantry of an oriental monarch, Montezuma appeared in a chair or litter richly ornamented with gold and feathers of various colours, surmounted by a canopy of curious workmanship. When he drew near, Cortez, dismounting, accosted him with profound reverence, after the European fashion. He returned the salutation, according to the mode of his country, by touching the earth with his hand, and then kissing it. Nothing material passed at this first interview. Montezuma conducted Cortez to the quarters which had been prepared for his reception, and immediately took leave of him with a politeness not unworthy of a more refined court. The first care of Cortez was to take precautions for his security, by planting the artillery so as to command the different avenues which led to his quarters, and by appointing a large division of his troops to be always on guard. The three subsequent days were employed in viewing the city, the appearance of which, so far superior in the order of its buildings and the number of its inhabitants to any place the Spaniards had beheld in America, and yet so little resembling the structure of a European city, filled them with surprise and admiration.

The city of Mexico.

The access to the city of Mexico or Tenochtitlan was by artificial causeways or streets, formed of stones and earth, about 30 feet in breadth. As the waters of the lake during the rainy season overflowed the level country, these causeways were of considerable length; that of Tacuba, on the W., being a mile and a half; that of Tezcuco, on the N.W., 3 miles; and that of Cuoyacan, towards the S., 6 miles. On the E. there was no causeway, and the city could be approached only by canoes. As the approaches to the city were singular, so its construction was remarkable. Not only the temples of their gods, but the houses belonging to the monarch and to persons of distinction, were of such dimensions that, in comparison with any other buildings which had been discovered in America, they might even be termed magnificent. The habitations of the common people were mean, resembling the huts of other Indians; but they were all placed in a regular manner on the banks of the canals, which passed through the city in some of its districts, or on the sides of the streets which intersected it in other quarters. In this city, the pride of the New World, and the noblest monument of the industry and the art of man whilst unacquainted with the use of iron, the Spaniards reckon that there were at least 60,000 inhabitants.

Cortez resolves to seize Montezuma in his palace.

As soon as Cortez had entered Mexico, he had become sensible that, from an excess of confidence in the superior valour and discipline of his troops, he had pushed forward into a situation where it was difficult to continue, and from which it was dangerous to retire. At the same time he knew that the countenance of his own sovereign was to be obtained only by a series of victories. He therefore fixed upon a plan no less extraordinary than daring. He determined to seize Montezuma in his palace, and to carry him as a prisoner to the Spanish quarters. At his usual hour of visiting Montezuma, Cortez went to the palace accompanied by Alvarado, Sandoval, Lugo, Velasquez de Leon, and Davila, five of his principal officers, and with as many trusty soldiers. Thirty chosen men followed, not in regular order, but sauntering at some distance, as if they had no object but curiosity; small parties were posted at proper intervals in all the streets leading from the Spanish quarters to the court; and the remainder of his troops, with the Tlascalan allies, were under arms, ready to sally out upon the first alarm. Cortez and his attendants were admitted without suspicion; the Mexicans retiring, as usual, out of respect. He addressed the monarch in a tone very different from that which he had employed in former conferences, reproaching him bitterly as the author of a violent assault made upon the Spaniards at Cempoalla by one of his officers. Montezuma, confounded at this unexpected accusation, asserted his own innocence with great earnestness; and, as a proof of it, gave orders instantly to bring the culprit to Mexico. Cortez replied that a declaration so respectable left no doubt remaining in his own mind; but that his followers would never be convinced that Montezuma did not harbour hostile intentions against them, unless he removed from his own palace and took up his residence in the Spanish quarters. The first mention of so strange a proposal deprived Montezuma of speech, and almost of motion. At length he haughtily answered, that persons of his rank were not accustomed to give themselves up voluntarily as prisoners. At length, after he had been alternately coaxed and intimidated for the space of three hours, he complied with their request, and was carried off in silent pomp to the Spanish quarters.

Cortez rules the empire, A.D. 1520.

In a short time Cortez had entirely gained the ascendant over the unhappy monarch; and he took care to improve his opportunity to the utmost. He sent his emissaries into different parts of the kingdom, accompanied with Mexicans of distinction, who might serve them both as guides and protectors. He urged Montezuma to acknowledge himself a vassal of the crown of Castile; to hold his crown of him as superior; and to subject his dominions to the payment of an annual tribute. With this requisition, humiliating as it was, Montezuma complied. He then, at the request of Cortez, accompanied this profession of fealty with a magnificent present to his new sovereign; and, after his example, his subjects brought in very liberal contributions. Yet, although often importuned, he obstinately refused to change his religion, or abolish the superstitious rites which had been for so long a time practised throughout his dominions. In an ebullition of zeal, Cortez led out his soldiers in order to throw down by force the idols in the great temple; but the priests taking arms in defence of their altars, and the people crowding with great ardour to support them, the prudence of Cortez overruled his zeal, and induced him to desist from his rash attempt, after dislodging the idols from one of the shrines and placing in their stead an image of the Virgin Mary. Scarcely had he escaped from this danger when he was startled by the news that an armament sent by Velasquez, the governor of Cuba, had arrived at Vera Cruz. He afterwards learned that it consisted of 18 ships and 900 men, under a brave officer named Pamphilo de Narvaez, and that their instructions were, to seize Cortez and his principal officers, to send them prisoners to Velasquez, and then to complete the discovery and conquest of the country in his name.

The armament sent from Cuba against Cortez defeated.

After attempting in vain to induce Narvaez to share with him the glory and gain of subduing the country, Cortez resolved to trust his fate to the issue of a war. He therefore left 150 men under the command of Pedro de Alvarado, to guard the capital and the captive emperor; and marched with the remainder to meet his formidable opponent, who had taken possession of Cempoalla. Even af-being reinforced by Sandoval, the governor of Vera Cruz, the force of Cortez did not exceed two hundred and fifty men. He hoped for success chiefly from the rapidity of his movements and the possibility of surprising his enemies; and as he chiefly dreaded their cavalry, he armed his soldiers with long spears, accustoming them to that deep, compact, and solid order in which the use of these weapons becomes most formidable. At last he attacked Narvaez in the night-time, and having entirely defeated and taken him prisoner, obliged all his troops to own allegiance to himself.

Dangerous situation of the Spaniards left at Mexico.

A short time after the defeat of Narvaez a courier arrived from Mexico with the disagreeable intelligence that the Mexicans had taken arms, and having seized and destroyed the two brigantines which he had built in order to secure the command of the lake, had attacked the Spaniards in their quarters, and had carried on hostilities with such fury that Alvarado and his men must either have been cut off by famine or overpowered by the multitude of their enemies. This revolt had been excited by motives which rendered it still more alarming. On the departure of Cortez for Cempoalla, the Mexicans had held a consultation for restoring their sovereign to liberty, and driving out the Spaniards. The Spaniards in the city suspected and dreaded these machinations; but Alvarado, instead of attempting to soothe or cajole the Mexicans, waited the return of one of their solemn festivals, fell upon them, unarmed and unsuspicious of danger, and massacred six hundred in cold blood. An action so cruel and so treacherous, filled not only the city, but the whole empire, with rage and indignation.

Cortez returns to Mexico, but is attacked by the natives.

Cortez advanced with the utmost celerity to the relief of his distressed companions, and entered the capital without opposition. But by this time indignation and success had so intoxicated him that he refused, with strong words of contempt, a personal interview with Montezuma. His expressions being reported amongst the Mexicans, they suddenly flew to arms, and made such a violent and sudden attack, that all the valour and skill of Cortez were scarcely sufficient to repel them. After exerting his utmost efforts for a whole day, he was obliged to retire with the loss of twelve killed and upwards of sixty wounded. When the Mexicans approached the next morning to renew the assault, Montezuma, who was still at the mercy of the Spaniards, advanced to the battlements in his royal robes, and addressed his subjects in favour of the Spaniards. But they testified their resentment with loud murmurings, and at length broke forth with such fury that they wounded him with two arrows, and struck him to the ground with a stone. The unhappy monarch now obstinately refused all nourishment, and in a short time ended his days. Upon the death of Montezuma, Cortez having lost all hope of bringing the Mexicans to any terms of peace, prepared for retreat. But his antagonists having taken possession of a high tower in the great temple, which overlooked the Spanish quarters, and placed there a garrison of their principal warriors, the Spaniards were so much exposed to their missile weapons, that none of them could stir without imminent danger. In an attempt to capture this post Juan de Escobar, with a large detachment of chosen soldiers, was thrice repulsed. Cortez then caused a buckler to be tied to his arm, as he could not manage it from a wound which he had received in the hand, and rushed with his drawn sword amongst the thickest of the combatants. Encouraged by the presence of their general, the Spaniards returned to the charge with such vigour that they gradually forced their way up the steps, and drove the Mexicans to the platform at the top of the tower. There a desperate hand-to-hand struggle raged for three hours, when all the Mexicans were either slain or hurled from the battlements. As soon as the Spaniards became masters of the tower, they set fire to it, and, without further molestation, continued the preparations for their retreat.

Retreat of Cortez.

Towards midnight, they began their march in three divisions. But they had not proceeded far before they were suddenly alarmed with the sound of warlike instruments, and found themselves assaulted on all sides by an innumerable multitude of their enemies. The Spaniards advanced with precipitation. At last, overborne with the numbers of the enemy, they began to give way, and in a moment the confusion was universal. More than four hundred Spanish soldiers perished, together with many officers of distinction. All the artillery, ammunition, and baggage were lost; the greater part of the horses, and above two thousands Tlascalans were killed, and only a very small part of their treasure was saved. The first care of the Spanish general, after he had succeeded in escaping from the city, was to find some shelter for his small shattered army. At last he discovered a temple seated on an eminence, in which he found not only the shelter he wanted, but also some provisions. For six days afterwards the Spaniards continued their march through a barren, ill-cultivated, and thinly-peopled country, where they were often obliged to feed on berries, roots, and the stalks of green maize; at the same time they were harrassed without intermission by large parties of Mexicans, who attacked them on all sides. On the sixth day they reached Otumba, not far from the road between Mexico and Tlascala. Early next morning, when they reached the summit of an eminence before them, a spacious valley opened to their view, covered with a vast army of Mexicans as far as the eye could reach. At the sight of this incredible multitude the Spaniards were astonished, and even the boldest amongst them began to despair. But Cortez, without allowing time for the slightest hesitation, led them instantly to the charge. With little difficulty the small compact band pierced and shattered the mighty mass of their foes; but the broken battalions, after each successive repulse, re-formed and returned to the conflict, until the Spaniards were ready to sink under their repeated efforts, without seeing any end to their toil, or any hope of victory. At this crisis Cortez, along with four desperate cavaliers, cut his way through the chosen body of nobles that guarded the standard of the empire, bore down the Mexican general with his lance, and snatched the imperial ensign. The moment that their leader fell, and the standard, towards which all directed their eyes, had disappeared, a universal panic struck the Mexicans; every ensign was lowered, and each soldier, throwing away his weapons, fled with precipitation to the mountains.

Measures adopted by Cortez.

The day after this important action, which was fought on the 8th of July 1520, the Spaniards entered the Tlascalan territories, where they were received with the most cordial friendship. Cortez now set himself assiduously to prepare for a second invasion of Mexico. He drew a small supply of ammunition, and two or three field-pieces, from his stores at Vera Cruz. He despatched an officer with four ships of Narvaez's fleet to Hispaniola and Jamaica, to engage adventurers, and to purchase horses, gunpowder, and other military stores; and as he knew that it would be in vain to attempt the reduction of Mexico unless he could secure the command of the lake, he gave orders to prepare, in the mountains of Tlascala, materials for building twelve brigantines, so that they might be carried to the water in pieces, ready to be put together and launched when he stood in need of their service. Without giving his soldiers an opportunity of caballing, he daily led them against the people of the neighbouring provinces, who had cut off some detachments of Spaniards during his misfortunes at Mexico; and as he was constantly attended with success, his men soon resumed their wonted sense of superiority. About this period an armament fitted out by Francisco de Garay, governor of Jamaica, who had long aimed at dividing with Cortez the glory and the gain of annexing the empire of Mexico to the crown of Castile, arrived at Vera Cruz, and were soon persuaded to throw off their allegiance to their master, and to enlist with Cortez. About the same time a ship arrived from Spain, freighted by some private adventurers, with military stores; and the cargo was eagerly purchased by Cortez, whilst the crew, following the example of the rest, joined him at Tlascala. From these various quarters the army of Cortez was reinforced with one hundred and eighty men and twenty horses, by which means he was enabled to dismiss such of the soldiers of Narvaez as were most troublesome and discontented; after the departure of whom he still mustered upwards of five hundred infantry, of whom eighty were armed with muskets or cross-bows, forty horsemen, and nine pieces of artillery. At the head of these, with ten thousand Tlascalans and other friendly Indians, he began his march towards Mexico on the 28th of December, six months after his fatal retreat from that city.

Second advance on Mexico.

As soon as Cortez entered the enemy's territories, he discovered various preparations to obstruct his progress. But his troops forced their way with little difficulty, and took possession of Tezcuco, the second city of the empire, situated upon the banks of the lake, about 20 miles from Mexico. For three months part of his troops were engaged in building brigantines, and the other part in reducing the towns situated round the lake. Meanwhile several of the cities tributary to Mexico were induced, through hatred to their oppressors, to make common cause with the invaders, and not only to acknowledge the King of Castile as their sovereign, but to supply the Spanish camp with provisions, and to strengthen his army with auxiliary troops. At length intelligence arrived that the materials for building the brigantines were completely finished, and waited only for a body of Spaniards to conduct them to Tezcuco. The command of this convoy, consisting of two hundred foot soldiers, fifteen horsemen, and two field-pieces, was given to Sandoval. This brave soldier proved worthy of the confidence reposed in him, and conducted his charge safely to Tezcuco.

Mexico besieged, A.D. 1521.

Cortez determined to attack the city from three different quarters; from Tezcuco on the E. side of the lake, from Tacuba on the W., and from Cuayocan towards the S. These towns were situated on the principal causeways which led to the capital, and were intended for their defence. He appointed Sandoval to command in the first, Pedro de Alvarado in the second, and Christoval de Olid in the third. He formed the brigantines into three divisions, allotting one to each station, with orders to second the operations of the officer who commanded there. From all the three stations he pushed on the attack against the city with equal vigour, but in a manner very different from that in which sieges are conducted in regular war. Each morning his troops assaulted the barricades which the enemy had erected on the causeways, forced their way over the trenches which they had dug, and penetrated into the heart of the city, in hopes of obtaining some decisive advantage; but when the obstinate valour of the Mexicans had rendered the efforts of the day ineffectual, the Spaniards retired in the evening to their former quarters. After this plan of attack had been followed for a month without any success, Cortez resolved to give it one trial more, and if unsuccessful, to relinquish it altogether. With this view he sent instructions to Alvarado and Sandoval to advance with their divisions to a general assault, and took the command in person of that which was posted on the causeway of Cuayocan. Animated by his presence and the expectation of some decisive event, the Spaniards pushed forward with irresistible impetuosity; broke through one barricade after another; forced their way over the ditches and canals, and having entered the city, gained ground incessantly, in spite of the multitude and ferocity of their opponents. But Guatimozin commanded the troops posted in the front, to slacken their efforts, in order to allure the Spaniards to push forward. On a signal given by him, the priests in the great temple struck the great drum consecrated to the god of war; and no sooner did the Mexicans hear its solemn sound than they rushed upon the enemy with frantic rage. The Spaniards, unable to resist the fury of the onset by men maddened by religious zeal, began to retire, at first leisurely and in order, but as the enemy pressed on, and their own impatience to escape increased, the terror and confusion became general. Cortez himself would have been carried away captive by six Mexican captains, had not two of his officers sacrificed their own lives to save him. Above sixty Spaniards perished in the rout; and what rendered the disaster more afflicting, forty of these fell alive into the hands of the enemy, and were doomed to have their quivering hearts torn from their bosoms and offered up with barbarous rites to hideous idols. But the Mexicans did not rely on the efforts of their own arms alone. They sent the heads of the Spaniards whom they had sacrificed to the leading men in the adjacent provinces, and assured them that the god of war had declared that in eight days these hated enemies should be finally destroyed. This prediction gained universal credit amongst a people prone to superstition. The Indian auxiliaries of Cortez abandoned the Spaniards as a race of men devoted to destruction, and the Spanish troops were left almost alone in their stations. Cortez, however, resolved to falsify the prophecy; and accordingly suspended all military operations during the period marked out by the oracle. The fatal term thus expired without any disaster. His allies, ashamed of their own credulity, now returned to their station. Other tribes joined his standard; and such was the changeableness of a simple people, moved by every slight impression, that in a short time Cortez saw himself, if we may believe his own account, at the head of 150,000 Indians.

The capture of Mexico.

Even with such a numerous army he found it necessary to adopt a new and more cautious system of operations. He made his advances slowly and cautiously, levelling the houses and filling up the canals as he advanced, and gradually contracting the retreat of the enemy. At length all the three divisions penetrated into the great square in the centre of the city, and made a secure lodgment there. Three-fourths of the city were now reduced and laid in ruins; and the remaining quarter was wasting fast before the attacks of famine and pestilence. At this crisis the brave Guatimozin resolved to proceed in person to rouse the distant provinces of the empire to arms. With this intent he embarked in a canoe, and was speeding swiftly over the lake when he was captured by a brigantine, and delivered into the hands of Cortez. As soon as the fate of their sovereign was known, the resistance of the Mexicans ceased, and Cortez took possession of that small part of the capital which yet remained undestroyed. Thus terminated, after it had continued for seventy-five days, the siege of Mexico, the most memorable event in the conquest of America. The exultation of the Spaniards was quickly damped by the disappointment of those hopes which had animated them amidst so many hardships and dangers. Instead of the inexhaustible wealth which they expected, their rapacity could collect only an inconsiderable booty amidst ruins and desolation. Guatimozin, aware of his impending fate, had ordered what remained of the riches amassed by his ancestors to be thrown into the lake. The Spaniards, thus deprived of their expected reward, fell into a state of uncontrollable discontent. Some accused Cortez and his confidants of having secretly appropriated to their own use a large portion of the riches which should have been brought into the common stock. Others blamed Guatimozin for obstinacy in refusing to discover the place where he had hidden his treasure. To quiet this universal

Guatimozin tortured.

murmur, Cortez was driven to subject Guatimozin to torture, in order to force from him a discovery of the royal treasures, which it was supposed he had concealed. The unfortunate monarch bore the most refined cruelty with the invincible fortitude of an American warrior, until Cortez, ashamed of a scene so horrid, rescued him from the hands of his torturers.

The Spaniards become masters of the Mexican empire.

The fate of the capital, as both parties had foreseen, decided that of the empire. The provinces one after another submitted to the conquerors. Small detachments of Spaniards, marching through them without interruption, penetrated in different quarters to the great Southern Ocean, which, according to the ideas of Columbus, they imagined would open a short and easy passage to the East Indies, and thus secure to the crown of Castile all the envied wealth of those fertile regions; and the active mind of Cortez began already to form plans for attempting this important discovery. In his subsequent schemes, however, he was disappointed; but from this time until the revolutionary spirit broke out in the New World, not long after the commencement of the present century, Mexico remained in the hands of the Spaniards.

II.—HISTORY OF MEXICO FROM THE COMMENCEMENT OF THE REVOLUTION TO THE PRESENT TIME.

For nearly three centuries after the conquest of Cortez, Mexico remained quietly subject to the Spanish yoke; but the internal tranquillity thus enjoyed ceased with the invasion of Old Spain by the armies of Napoleon. But before proceeding to narrate the events which have terminated in the separation of Mexico from the mother country, it will be necessary briefly to review the system of colonial policy by which it was so long governed, and to point out the causes which ultimately led to the assertion of independence. It is to the complication of abuses, to which the old system gave rise, that we must mainly attribute those events which have changed the destiny of the New World.

Government of Spanish Mexico.

The Spanish viceroy in Mexico was endowed with the prerogatives of royalty. He was commander-in-chief of the troops, and he regulated the military operations, and filled up all vacancies. All sentences of every description bore his signature, nor was there any appeal from his decision. The only checks which interposed between him and despotic sovereignty were the *residencia*, or legal investigation of his conduct, to which the king might subject him on his return to Spain, a measure which was seldom or never enforced; and the *Audiencia*, or the court of appeal in the last resort. This body possessed considerable power and influence. It had control over all other tribunals, ecclesiastical as well as civil, in every case where the value of the subject in litigation did not exceed ten thousand dollars. It likewise enjoyed the privilege of corresponding directly with the sovereign and with the Council of the Indies, a board at which the king was supposed constantly to preside in person, and whose sanction it was necessary to obtain before orders, decrees, or projects of reform, although emanating from the crown, could acquire the force of law. This privilege might have rendered this body an efficient check upon the conduct of the viceroy if the latter had not possessed such inordinate power. He was himself honorary president of the body, and had thus every opportunity of conciliating the members, and attaching them to his interests and those of the Europeans. They were more easily swayed in this direction, as they were always exclusively natives of old Spain.

Municipal corporations.

Besides the boards already noticed, the municipal corporations, called sometimes the *Cabildo*, sometimes the *Ayuntamiento*, and sometimes the *City*, had a considerable share of influence. Their members, called *regidors*, their president, the *corregidor*, and their executive officers, the *syndics*, were chosen from the people, and originally by the people. But in a short time the situations of alcalde and regidor were disposed of to the highest bidder, the purchaser having the power of relinquishing them in favour of relatives or friends. These functionaries, however, uniformly proved the friends of the Creoles; for they were connected with them by numerous ties, and by a community of interest.

State of the laws.

The *Recopilacion de las Leyes de las Indias*, or general collection of the laws of the Indies, was the name given to that chaotic mass of contradictory statutes by which the decisions of the tribunals were supposed to be determined. These statutes were originally merely decrees upon different subjects, emanating from the king or from the Council of the Indies. But it was not long before many of these decrees were annulled by others subsequently issued, so that it was scarcely possible to know which statutes were in force, and which had fallen into disuse or been suspended. An appeal to judicial authority had thus in it all the uncertainty and hazard of a game of chance; and this was further increased by different professions and corporate bodies enjoying various special privileges or *fueros*. Each of these exempted the persons who chose to plead it from the jurisdiction of the ordinary authorities, and made them amenable in all civil and criminal causes to the tribunal of the head of the body to which they belonged. It thus happened that the native American was generally the sufferer in cases in which his opponent was a European; for the difficulty of obtaining redress in any dispute was augmented by the circumstance of the latter enjoying a double or triple *fuero*, as a merchant, a government officer, a dignitary of the church, or at least as holding some rank in the militia.

Ecclesiastical establishments.

To complete the outline of that mighty fabric by which the authority of Spain in the New World was so long supported, it is necessary briefly to advert to ecclesiastical establishments. These were altogether independent of the see of Rome, and the pope could neither fulminate bulls nor hold any sort of intercourse with Spanish America, unless through the medium of the court of Madrid and the Council of the Indies. As might have been expected under such circumstances, a traffic in bulls became an important branch of the royal revenue. The king bought of the Holy See indulgences and dispensations of all kinds, and retailed them to his American subjects at an enormous profit. The business was managed with as much strictness and regularity as an ordinary commercial transaction, the monopoly of tobacco, for example; and so jealous was the king of his right, that the most severe penalties were not only enacted, but enforced against ecclesiastics who dared to infringe the regulations.

Evils of the Spanish colonial system.

Such is the general view of the colonial system of Spain; and when we consider that all the great offices of state, not excepting the viceregal dignity itself, were open alike to Americans and Europeans, every subject of the crown being eligible, its defects, in theory at least, are scarcely so glaring as they are sometimes represented. The evils, many and grievous, consisted in the practice and in the maintenance of a system of laws by which the colonies were sacrificed to the mother country. Every situation, from the highest to the lowest, was bestowed upon Europeans. Indeed, the colonial offices were disposed of in Madrid to the highest bidder; and at one time the proceeds, like the traffic in bulls, formed a not inconsiderable item of the royal revenues. Of the fifty viceroys who governed Mexico from 1535 to 1808, only one was an American, and even he was born in Peru. But as the exclusive enjoyment of these privileges could only be preserved to the Spaniards by the ignorance of the natives, almost every species of learning was not only discouraged, but prohibited, and pains and penalties were annexed to the infringement of the laws relating to it. The Latin grammar, the philosophy of the schools, and civil and ecclesiastical jurisprudence, were the only subjects which the Inquisition allowed to be taught. No book could circulate among the people until it had been thoroughly tested and sanctioned by the monks. But whilst ignorance was ranked amongst the virtues, some branches of industry were degraded into crimes. The Americans were prohibited, under severe penalties, from raising flax, hemp, or saffron, and growing tobacco was a government monopoly. The cultivation of the olive, the mulberry, and the vine, was also frustrated by the same blind policy; and even the growth of the more precious articles of what we term colonial produce, such as cacao, coffee, and indigo, was only tolerated under certain limitations, and in such quantities as the mother country might require annually to import. The colonists were also forbidden to manufacture anything which could be supplied by the mother country. Even foreign trade was for a long time prohibited on pain of death. At the same time licenses were granted for the introduction of any article of foreign produce during a limited period. For these enormous sums were paid by the leading commercial houses; and a share in the profits accruing from the speculation commenced with the viceroy, and extended to the meanest offices. But the exclusion of foreign vessels from the Mexican ports was not all that the rapacity of Spain laid claim to. Even ships in distress were by a royal ordinance ordered to be seized as prizes, and their crews thrown into prison. Nothwithstanding all the efforts of Spain, the exclusion of foreign vessels from her colonies gave rise to one of the most extraordinary systems of organized smuggling which the world ever witnessed. This was known under the name of the contraband or forced trade, and was carried on in armed vessels which often bade defiance to the coast blockades of Spain, and, fighting their way to the American ports, landed great quantities of European goods.

Other evils of the Spanish colonial system.

Such was the colonial system of Spain, which on all hands is admitted to have been worse even than that of the Portuguese or of the Dutch; and such were the evils to which it gave rise. When, therefore, in connection with these evils we further consider that the civil, fiscal, and criminal administration was tyrannical, unjust, or partial; that exactions in the shape of taxes, duties, and tithes, were levied with unexampled severity; that amongst the taxes was one which has justly been called "the horrible *alcavala*," and pressed heavily on all classes, being levied *in infinitum* on every transfer of goods; that nothing escaped tithes, and that every individual was compelled to purchase annually a certain number of the papal bulls, under a penalty of forfeiting various important advantages; that every stage of legal procedure was in the most corrupt and deplorable state, and that the administration of justice had scarcely any existence whatever; that imprisonment was the grand recipe for every malady; that in the most horrible dungeons ill diet, filth, infectious diseases, and corporal punishment, including occasional torture, all combined to unhumanize the fettered victim; and, finally, that the Inquisition bound in chains of darkness the minds of all classes of the community from the viceroy downwards;—he would be a bold theorist who should venture to affirm that Spain did not deserve that fate which eventually befel her possessions in the New World.

Events in Spain; their effect in America, A.D. 1808-1810.

How long an indisposition upon the part of the Creoles to assert their rights might have continued, had not the events of the year 1808 occurred, it is impossible to say; but it is generally admitted that the insurrection of Aranjuez, which led to the dismissal of Godoy, Prince of the Peace, and to the abdication of Charles VI., gave the first shock to the royal authority in America. Authentic intelligence of the resignation of the Spanish monarch arrived in Mexico on the 15th of July 1808. The inhabitants were thrown into a ferment of indignation. Crowds eagerly assembled in the squares and public walks, and threats of vengeance against France were mingled with strong expressions of adherence to the cause of the deposed monarch. The municipality and the popular party demanded the immediate creation of a *junta* in imitation of the mother country, composed of representatives of the different corporations of the kingdom. The Audiencia were adverse to such a course; and finding that the viceroy, Don Jose Iturrigaray, was inclined to favour their opponents, they contrived to arrest him and throw him into prison. For the time their plans proved completely successful. Iturrigaray, after remaining a short time in the dungeons of the Inquisition, was conveyed to Vera Cruz, and sent a prisoner to Cadiz charged with a design to establish himself upon an independent throne, and with having acted independently of the authority of the central junta. Not a few influential members of the Cabildo, who had voted for a Mexican junta, were arrested and either banished or otherwise disposed of. The viceregal authority was for the time confided to the Archbishop Lizana. In 1809, however, the archbishop was replaced by the Audiencia, to whom the central junta transferred the reins of government. The violent and contemptuous conduct of this body only served to bring matters more speedily to a crisis. A general feeling of hostility towards the Spaniards spread throughout the country, and on the morning of the 16th September 1810 the standard of revolt and independence was publicly unfurled by Don Miguel Hidalgo y Costilla, curate of the village of Dolores, in the province of Guanajuato. Seven Europeans, resident in Dolores, became the first victims of the revolutionary movement. They were thrown into prison, and their property seized and distributed amongst Hidalgo's followers. The news of this first exploit spread throughout the country with the rapidity of lightning, and was everywhere hailed as a propitious omen. His force increased so suddenly, that on the 18th he found himself in possession of two towns, each containing 16,000 inhabitants, in both of which places the confiscated property of the Europeans enabled him to reward his partizans as well as to add to their numbers.

Capture of Guanajuato, A.D. 1810.

His next object was Guanajuato, the capital of the province, and also the emporium of the Spanish treasures in that part of the country. Little opposition was offered to the entrance of his troops, who were immediately joined by the whole population of the town, and carried all before them. The town was given up to pillage; the Europeans were butchered without mercy; their property was eagerly seized; and before next morning there was not left standing a single house which had belonged to a Spaniard. An enormous quantity of money, estimated at five millions of dollars, was found in the alhondiga or granary, to which the inhabitants had transported their most valuable effects. During his stay at Guanajuato, Hidalgo established a sort of government, a mint with all the appurtenances for coining money, and a foundry for casting cannon.

Proceedings of the new viceroy.

The intelligence of the fall of Guanajuato, whilst it gave celebrity to the name of Hidalgo, created great consternation amongst the Spaniards of the capital. The new viceroy, however, Don Francisco Xavier Venegas, by his judgment and firmness, preserved public tranquillity in the capital. Don Felix Maria Calleja, who headed a brigade of troops stationed at San Luis Potosi, was intrusted with a command, and ordered to pursue Hidalgo. Nor was the superstition of the people overlooked; for some doubts having arisen with respect to the justice of the sentence of excommunication which had been pronounced against the leader of the insurgents, it was confirmed by Lizana and by the Inquisition. After remaining at Guanajuato until the 10th of October, Hidalgo, at the head of his army, advanced upon Valladolid, which was quietly taken possession of on the 17th of the same month. His army was now about sixty thousand strong, a force which he considered as sufficient to conquer the capital, and thus, by one decisive blow, to terminate the revolutionary struggle. He accordingly left Valladolid on the 19th; and at Las Cruces encountered a corps of observation under the command of Colonel Truxillo, assisted by Don Augustin Iturbide, then a lieutenant in the service of Spain. After a sanguinary contest, the royalists were defeated, and compelled to fall back upon the capital. Alarmed at the recent success and the near approach of the insurgents, Venegas drew upon the superstition of the people in support of the Spanish cause. The famous image of the Virgin of Remedios was brought and placed in the cathedral of Mexico. Thither the viceroy went in full uniform, and with all due pomp; and after imploring the Virgin to take the government into her own hands, he wound up his appeal by laying his staff of command at the feet of her image. But the aid of the Virgin was not required, for Hidalgo, after appearing before the city, to the astonishment of every one, withdrew his troops without striking a blow, and retreated towards Guanajuato. On the 7th November he came in contact with the outposts of the royal army at Aculco. A sanguinary action ensued, in which, from the superiority of their discipline and arms, the royal forces gained a complete victory. Hidalgo retreated to Valladolid, and then proceeded to Guadalaxara, where he was received with the greatest pomp and enthusiasm.

Capture and execution of Hidalgo, A.D. 1811.

At Guadalaxara Hidalgo proceeded with his usual activity to replenish his stores, recruit his forces, and bring cannon from San Blas, the principal Spanish arsenal on the western coast. He then advanced to the bridge of Calderon, which is 16 miles from Guadalaxara, and having fortified himself in a strong position, he awaited the approach of the royalists. On the 16th January 1811 the two armies were once more in sight of each other, and on the following day a general action took place. After various attacks, which the Mexicans repulsed with spirit, Calleja at last succeeded in carrying all their batteries; and Hidalgo was forced to withdraw them from the field. He withdrew to Saltillo, followed by about 4000 men. But on the 21st of March 1811 he was captured while setting out to the United States for the purpose of collecting arms and other necessaries. After a protracted trial he was shot on the 27th of July.

National junta.

After the death of Hidalgo, a guerilla war was carried on in various parts of the country; but as the leaders acted without concert, and no general engagement took place, it is unnecessary to follow it in its irregular course. Rayon being now left in command of the insurgent troops at Saltillo, retreated first to Zacatecas, and afterwards to Zitacuaro in the state of Valladolid, which he entered about the end of May 1811. At this period in the history of the revolution disaffection towards the Spaniards had become very general. Armed bands of insurgents overran the open country, and hardly a day passed without being signalized by a skirmish. Meanwhile Rayon was busily employed in furthering the scheme of a national junta, and on the 10th of September 1811 he accomplished his purpose. A junta, or central government, was installed, consisting of five members, who were elected by the ayuntamiento, in conjunction with the principal inhabitants of the town and district. Amongst the principles adopted by this new junta was the acknowledgment of Ferdinand VII. as sovereign of Mexico, provided he would quit his European dominions. But from documents published after the struggle for independence had terminated, we learn that these professions of adherence had no deeper origin than expediency. The intelligence of the formation of the junta of Zitacuaro excited enthusiastic hopes throughout Mexico; and from the first moment of its establishment, the Spaniards considered it as their most formidable enemy. Accordingly, towards the end of the year Calleja marched with all his forces against Zitacuaro, and arrived before it on the 1st of January 1812. On the following day he captured the town, and drove the junta to Sultepec, where it established a new seat of government; but Calleja inflicted signal vengeance on that place for affording shelter to the fugitives. He ordered the inhabitants to be decimated, the town to be burned, and the walls of the buildings to be levelled with the soil, the churches and convents alone being spared. By forced marches the royal forces now proceeded to Mexico, where they were anxiously expected by the viceroy, in order to check the progress of the curate Don Jose Maria Morelos.

Exploits of Morelos.

In October 1810 Morelos had been appointed captain-general of the provinces of the south-western coast, and had entered upon his duties at the head of about 1000 men. Advancing with this force upon Acapulco, he surprised and routed a well-appointed body of troops under Don Francisco Paris, the commandant of the district. By this brilliant exploit Morelos obtained so much celebrity, that numbers from every quarter flocked to his standard, and amongst others, Galeana, Matamoros, and three persons of the name of Bravo, one of whom, Don Nicolas, afterwards became so famous. The whole of the year 1811 was spent in a series of skilful manœuvres and petty engagements, in which the insurgents were generally successful.

Meanwhile intelligence reach Morelos of the arrival of the victorious royalists under Calleja; but nothing daunted by the circumstance, he determined to await the attack at Cuautla Amilpas, which is distant about 22 leagues from the city of Mexico. On the 19th of February Calleja made a general attack upon that town, but after a conflict which lasted eight hours, he was compelled to retreat, leaving five hundred dead behind him. From this day he abandoned all thought of risking another general assault; but erected batteries, and began to cannonade and bombard the town. Disease and severe famine soon began to diminish the numbers of the besieged, so that the commander-in-chief formed the resolution of retreating; and this he succeeded in accomplishing, with equal ability and success, on the night of the 2d of May. Calleja entered Cuautla some hours after his opponent had left it, and there, as usual, he perpetrated barbarities which will for ever leave a stain upon his reputation.

Subsequent proceedings of Morelos, A.D. 1812–13.

The bravery and resources which Morelos had displayed at the siege of Cuautla extorted admiration even from his enemies, whilst they became the theme of universal praise amongst his countrymen. Leaving Izucar, he proceeded to Tehuacan, into which he made a triumphal entry on the 16th of September 1812, having defeated three divisions of the Spanish army on his way. In the beginning of November he began to execute his design of conquering the whole province, and accomplished it by the capture of Acapulco in August of the following year.

Declaration of independence A.D. 1813.

During the absence of Morelos everything had been prepared by Matamoros for the meeting of the National Congress, which took place accordingly on the 13th of September 1813 in the town of Chilpanzingo. This assembly consisted of the original members of the junta of Zitacuaro, the deputies elected by the province of Oaxaca, and others again selected by them as representatives for the provinces in the possession of the royal troops. Exactly a month after the opening of the session, an act was published, declaring the absolute independence of Mexico.

Morelos defeated, A.D. 1813.

Besides the achievements already recorded, the years 1812 and 1813 had been distinguished by several other victories gained by the insurgent generals, Don Nicolas Bravo and Matamoros. But the time had now arrived for Morelos attempting a more decisive blow than any which had yet been struck. With seven thousand men and a large train of artillery, he left Chilpanzingo on the 8th of November, and after sustaining incredible fatigue and privations, arrived before Valladolid on the 23d of December.

History.

This place was defended by a formidable force under Brigadier Llano and Colonel Iturbide. Confident of success, Morelos ordered his troops immediately to advance to the attack, but they were driven back with loss. Next morning, during a general review which took place within half a mile of the walls, Iturbide made a sudden attack upon the Mexicans, and succeeded in totally routing the whole army, which lost its best regiments, and all its artillery. Morelos retired to Puruaran, where he was again completely defeated by Iturbide, on the 6th of January 1814. Here a number of prisoners were taken by the royalists, and amongst the rest Matamoros. Some Spaniards who had been taken in former engagements were offered by Morelos in exchange for him; but Calleja, who on the 4th of March 1813 had superseded Venegas as viceroy, refused to accede to any such proposal. Matamoros was accordingly shot, and by way of reprisal the Mexicans put to death all the prisoners in their hands.

Further reverses, and death of Morelos, A.D. 1814–1815.

Morelos now withdrew to the southern coast, and there began to recruit his forces with his characteristic activity and resolution. But his cause was destined to experience defeat upon defeat. Oaxaca fell into the hands of the royalists on the 28th of March 1814; whilst the Congress itself, expelled from Chilpanzingo, was forced to take refuge in the woods of Apatzingan, where it continued its labours, and on the 22d of October sanctioned the constitution known by that name. Morelos resolved to undertake an expedition to Tehuacan, where Teran had assembled a considerable force, for the purpose of placing it in greater safety. With only five hundred followers he commenced a journey of 60 leagues through a country occupied by several divisions of the royalists. He was surprised by two parties of Spaniards under Concha on the 5th of November 1815. He ordered Bravo immediately to continue his march with the main body, whilst he with a few men endeavoured to check the advance of the enemy. Most of his fifty followers abandoned him when the firing became warm; but not until only one man remained by his side did the royalists venture to advance upon one so far-famed for his personal courage. He was taken prisoner, and transferred to the capital after experiencing the most brutal treatment at the hands of the Spanish soldiery. After a trial, he was condemned to be shot, which sentence was carried int effect on the 22d of December 1815. He walked to the place of execution with the most perfect serenity; and after pronouncing this short prayer, "Lord, if I have done well, thou knowest it—if ill, to thy infinite mercy I commend my soul," he bound a handkerchief about his eyes, and met death with as much composure as he had ever shown when facing it on the field of battle.

The affairs of the insurgents fall into confusion, A.D. 1815–1817.

The loss of Morelos was irreparable, for he was the only patriot chief who could maintain unity of plan, concentration of purpose, and combination of movement. For several years, therefore, the history of the revolution consists only of disjointed details of a wide-spread guerilla war, in which success on either side led to no important results.

The Congress, which had escaped under the protection of Don Nicolas Bravo to Tehuacan, was dissolved by General Teran in December 1815. This step has been generally blamed as at least precipitate. There can be no doubt that it was attended by disastrous circumstances; for from that moment confusion became worse confounded; Victoria, Guerrero, Bravo, Rayon, and Teran, confining themselves each to his own separate circle, where they were crushed in succession by the superiority of the common enemy. Teran attempted to establish a government himself, but none would acknowledge it. Rayon, after he had commanded with great success in the mountainous parts of Valladolid, was taken prisoner, and confined in the capital until 1821. The fate of Don Nicolas Bravo was exactly similar to that of Rayon. Guerrero occupied the western coast, and here he maintained himself in the fastnesses of the Sierra Madre until 1821, when he joined Iturbide. Guadalupe Victoria was driven from his strongholds in his province of Vera Cruz, was deserted by all his followers, and was forced to skulk in the forest like a wild beast. For several years he lurked in the wildest recesses, never seeing the face of man, and living on the raw fruits of the earth and the bones of putrefying animals. When every one had thought him dead, he appeared in 1821, covered with hair and emaciated almost to a skeleton.

State of the country.

Some facts relative to the state of the country require to be mentioned. The cause of independence had been gradually gaining ground amongst the people, particularly since 1812, when the constitution, which was sanctioned by the Cortes of Cadiz, was extended to the transatlantic dominions of the crown. By the new constitution several important privileges had been conceded to the natives; amongst the rest, the right of electing the members of the Cabildo and the deputies to the Cortes. In law, also, matters underwent so complete a reform, that a Creole might now hope for a favourable decision, provided his cause was a good one. Thus by the new constitution the reverses sustained by the Creole leaders in the field were more than counterbalanced. Under the mild sway of Admiral Apodaca, who succeeded Calleja in the viceregal authority, all was done that could be done to secure the allegiance of the natives. The arrival of fresh troops from the Peninsula enabled him to extend his military ramifications throughout the whole country, and enforce obedience even at the most distant points. Thus, as we have seen, the revolutionary chiefs were successively crushed; and the facilities afforded to all who had embarked in the enterprise for reconciling themselves with the government by accepting pardon, reduced the number of those actually in arms in 1816, and the three following years, to a very inconsiderable amount.

Career of Mina, A.D. 1817.

After her last patriotic chiefs had quitted the open field, and sought refuge in the mazes of the forests, a deep gloom hung over the affairs of Mexico, which remained for a long time unbroken save by the sudden inroad of Mina.[1] This remarkable individual landed in Mexico on the 15th of April 1817. With about 200 men he left Soto la Marina, the place of his landing; and pushing forward to the confines of the table-land, defeated a body of 400 royalist cavalry. About the middle of June 1817 he reached the Hacienda de Peotillos; and on a little eminence which commanded the plain he cut to pieces a royal army 2000 strong with a force of only 172 men. On the 24th of June he reached Sombrero, having in thirty days traversed a tract of country 220 leagues in extent, and been three times engaged with an enemy greatly superior in numbers. In conjunction with the advanced guard of the insurgents and some recruits, he advanced upon San Juan de los Llanos, and on the 29th of June totally defeated the royalists under General Castañon. On the 24th of October, at nightfall, he took Guanajuato by storm, and penetrated into the very centre of the town. At this critical moment his troops refused to advance a step farther; and time being thus allowed the garrison to arm themselves, they attacked the insurgents, who, by the general's orders, dispersed with the utmost precipitation. Mina himself was taken prisoner three days afterwards, and sent to the head-quarters of General Linan, and there he was executed on the 11th of November, in his twenty-eighth year. Not long after his death the insurgent chiefs were driven off the field, and gradually disappeared; so that in July 1819 not one remained of those who had taken any lead in the revolution.

---

[1] Don Xavier Mina, a famous Spanish guerilla chief, still more celebrated in Old Spain for his patriotic efforts to create a rising in favour of the Cortes at Pampeluna, subsequently to the dissolution of that assembly by the king.

State of the independent cause, A.D. 1819–1821.

The cause of Mexican independence seemed now to have sunk to such a low ebb, that the viceroy wrote in great confidence to the court of Madrid, representing the country as so tranquil and submissive to the royal authority, that he would answer for its safety without the assistance of a single soldier from Europe. But the appearances on which he relied proved altogether fallacious. The disbanded insurgents, mingling freely in the ranks of the Creoles, made proselytes to the principles of the revolution even in the royal camp itself. In private the bulk of the people were as warmly attached to them as ever. About the middle of 1820 accounts arrived in Mexico of the revolution in Spain, occasioned by the revolt of the army in the Isla de Leon; and it soon became public that orders had been sent to Apodaca to proclaim the constitution which Ferdinand VII. had been compelled to adopt. The era of 1812 was revived, and the public mind thrown into a ferment, which the viceroy, from his restricted powers, found it impossible to allay. Besides, the Mexicans were divided amongst themselves, one party professing a sincere adherence to the constitution, whilst another class was as strongly attached to the old system. Necessity of course compelled the viceroy to take the oath to the constitution; but he favoured those who were opposed to it, and took secret measures for effecting its subversion. General Armigo, who was partial to the constitution, was dismissed from the command of the army stationed between the capital and Acapulco, and his place offered to Don Augustin Iturbide, a native Mexican, to whom allusion has already been made. The proposal was accepted, and Iturbide left the capital in February 1821 with half a million of dollars, destined for embarkation at Acapulco, but with intentions very different from those by which the viceroy supposed him to be actuated.

Second Mexican revolution, A.D. 1821.

Having arrived at a town called Iguala, situated about 120 miles from the capital, Iturbide took possession of the money; and on the 24th of February he commenced the second Mexican revolution by proposing a new government, which is well known under the title of "the plan of Iguala." His force of 800 men unanimously took the oath of fidelity to the "plan," whilst a copy was transmitted to the viceroy and to all the governors of provinces. This celebrated document consisted of twenty-four articles, the principal points embodied in which were,—a declaration of Mexican independence; the recognition of the Catholic religion as the national creed; the establishment of a constitutional monarchy; the formation of a junta of government; an offer of the crown to Ferdinand VII., and in the event of his refusal, to the Infantes Don Carlos and Don Francisco de Paula, provided any of them would consent to occupy the throne in person; an abolition of castes and of the despotism of military commandants; the formation of an army for the support of religion, independence, and union, and for guaranteeing these three principles, whence it was to be called the army of the three guarantees; a general amnesty to all who should give in their adhesion to the "plan;" and other provisions of less importance.

Success of Iturbide.

When the viceroy learned the defection of Iturbide, he concentrated a force upon the capital for the purpose of defending it; but hesitating to put himself at the head of the troops, the Europeans deposed him, and placed at the head of affairs Novella, an officer of artillery. By this unwise proceeding a schism was created in the capital, which afforded Iturbide time for prosecuting his scheme. He effected a junction with General Guerrero, and from this moment his success became certain. On his route to the Baxio, great numbers of men and officers joined his standard. Before the month of July, the whole country had recognised his authority, with the exception of the capital. On his march to invest the city of Mexico, intelligence reached Iturbide that the new constitutional viceroy and political chief, O'Donoju, had arrived at Vera Cruz. He immediately requested an interview with this functionary, and allowed him to advance as far as Cordova, where a meeting took place. O'Donoju agreed to the plan of Iguala, and in the name of his master he recognised the independence of Mexico. Such was the treaty of Cordova, which was signed by Iturbide, "as the depository of the will of the Mexican people," and by O'Donoju, as the representative of Spain, on the 24th of August 1821. By virtue of this treaty Iturbide obtained possession of the capital, which he entered in triumph on the 27th of September. A provisional junta of thirty-six persons then elected a regency of five, with Iturbide at their head. He was at the same time created generalissimo and lord high admiral, and had assigned to him a yearly salary of L.24,000.

Usurpation of Iturbide, A.D. 1822.

The career of Iturbide had hitherto been triumphant; but scarcely had the first Mexican Cortes met on the 24th of February 1822, when its members split into three distinct parties: first, the Bourbonists, or those who wished to establish a constitutional monarchy with a prince of the House of Bourbon at its head; secondly, the Iturbidists, who aimed at elevating Iturbide himself to the throne; and, thirdly, the republicans, who desired a central or federal republic. The Bourbonists soon ceased to exist, the Cortes of Madrid having declared the treaty of Cordova "to be illegal, null, and void, in as far as the Spanish government and its subjects were concerned." A protracted contest ensued between the two remaining factions, and resulted in the defeat of the Iturbidists. Nevertheless, the republican party were forced to yield to the wishes of the mob and the army, and to declare Iturbide emperor on the 19th May 1822. The new monarch assumed the title of Augustin I.

Conduct of the new emperor.

Iturbide began his reign by demanding the right of appointing and removing at pleasure the judges of the supreme court; he claimed a veto upon all laws, not excepting the articles of the constitution then under discussion; and he recommended the establishment of a military tribunal in the capital, with powers very little inferior to those exercised by the Spanish commandants during the revolution. This attack upon their liberties the Congress indignantly repulsed. Such decisive conduct led at once to an open rupture. Upon the night of the 26th of August, fourteen deputies of liberal principles were, by the emperor's orders, arrested and thrown into prison. This bold step was followed by a series of reclamations and remonstrances on the part of the Congress; but Iturbide sent an officer to the hall of the Congress with a simple notification that the assembly had ceased to exist, and an order to dissolve it by force should any resistance be offered to his authority. But no compulsion was required. The deputies dissolved their sessions at once, and the doors of the chamber were closed by the officer. This took place on the 30th of October 1822. On the same day a proclamation appointed a new legislative assembly, called the Instituent Junta, consisting of forty-five members, selected by Iturbide himself. This assembly, however, never possessed any influence in the country; and the tranquillity which Iturbide enjoyed proved of short duration. Matters were brought to a crisis by the defection of General Santa Anna, governor of Vera Cruz, towards the close of the year 1822. The far-famed Victoria, quitting his hiding-place in the mountains, was invested by the rebels with the chief command, and rallied the natives in great numbers round his standard. General Echavari, who had been despatched by the emperor to invest Vera Cruz, made common cause with the garrison of that city, and induced his whole army to follow his example. On the 1st of February 1823 the act of Casa-Mata was signed, by which the armies pledged themselves to effect the re-establishment of the national representative assembly. Bravo, Guerrero, and Negrete now joined the republican army, and the defection became so general that Iturbide tendered his resignation on the 19th of March, and stated at the same time his intention of quitting the country. The Congress refused to accept of the abdication, as that would have implied that he had legal right to the crown; but they willingly allowed him to quit the kingdom with his family, and assigned him a yearly pension of about L.5000. He set sail in a ship freighted by government to convey him to Leghorn.

His death, A.D. 1824.

The old Congress was immediately convoked; a provisional government was established; and an executive, composed of Generals Victoria, Bravo, and Negrete, was appointed. They conducted the affairs of the country until a new Congress was assembled in August 1823; and in October 1824 the federal constitution was definitively settled by the latter. Meanwhile Iturbide, the ex-emperor, had proceeded to Leghorn, had subsequently visited London, and on the 11th of May 1824 had embarked with his family for Mexico. Disregarding the sentence of the Congress which had outlawed him, he landed about the middle of July at Soto la Marina, where he introduced himself in disguise and under a feigned name. But he was apprehended by General Garza, and shot a few days afterwards.

Form of government.

The form of government adopted by the representatives of Mexico was that of a federal republic, upon the plan of that of the United States, with a few unimportant deviations. The confederation, consisting of nineteen states and four territories, was cemented into one body politic by certain general laws and obligations, contained in the federal constitution of the 4th of October 1824, of which an outline will be afterwards given. Each state and territory, however, retained the uncontrolled management of its own internal affairs. Victoria was elected president and Bravo vice-president.

Subsequent disorders and revolutions.

But the hopes which had been formed regarding the peace and prosperity of Mexico proved altogether fallacious. Repeated revolutions continued to disturb and agitate the country. From the moment at which the war of independence commenced the nation became divided into two parties,—natives and Guachupines, or European Spaniards. The former consisted of those who wished to establish the independence of Mexico; the latter were warmly attached to the dominion of Spain. To these two parties succeeded the Imperialists and Republicans; and, lastly, came the Centralists and Federalists, which went under the sobriquets of Escosses and Yorkinos, appellations derived from two masonic societies, and synonymous with *aristocrats* and *democrats*.

Pedraza elected president, A.D. 1828.

The time was now approaching when it became necessary to find a successor to Victoria as president of the republic; and General Gomez Pedraza, a very efficient member of the Mexican cabinet, was brought forward as a candidate by the Escosses party. After an arduous contest, he was elected president by a majority of two votes over Guerrero, the representative of the Yorkinos. But the disappointed party was loud in its denunciation of the successful candidate. His friends were accused of bribery and corruption, and even charged with procuring the interference of the military in some of the states. By a singular anomaly in the constitution of Mexico, a period of nearly seven months is allowed to elapse before the president who has been elected can take possession of the government; so that time was thus afforded the defeated party to collect its strength, and prepare for a vigorous effort to annul the election by an appeal to arms. It was at this time that General Santa Anna set out from Jalapa at the head of about 800 men, and took possession of Perote. There he published a manifesto charging Pedraza with having succeeded in his election by fraudulent means. He further proposed that the people and army should annul the election of Pedraza; that the Spanish residents should be banished as the primary cause of the grievances from which the Mexicans suffered, and that Guerrero should be declared president. This audacious "plan" was vigorously protested against by Victoria; and addresses reprobating the conduct of Santa Anna poured in from all quarters. The mass of the population, however, remained undisturbed, and Guerrero himself resolved quietly to await the course of events.

Expulsion of the Spaniards, A.D. 1828.

From a feeling of hostility towards the natives of Spain, which prevailed pretty generally throughout Mexico, matters were very speedily brought to a crisis. On the night of the 30th November 1828, a battalion of militia, headed by the ex-Marquis of Cadeña, and assisted by a regiment under Colonel Garcia, took possession of the artillery barracks at the Acordada, surprised the guard, and seized the guns and ammunition. Next morning the insurgents were joined by General Lobato a partizan in the revolutionary war, Zavala the ex-governor of Mexico, the Yorkino deputy Cerecero, a party of militia, and a number of officers. By the 2d of December the insurrection had made alarming progress, and a sanguinary contest ensued, which ended on the 4th in the overthrow of the government troops. The city was then given up to be pillaged. Vengeance was chiefly directed against the Spaniards; but all who were supposed to possess wealth fell victims to the rapacity of an unbridled mob. These disgraceful scenes continued for two days, and property to a very great amount was destroyed or changed owners. Pedraza formally resigned his office, and was allowed to quit the territories of the republic. At a new Congress, assembled on the 1st January 1829, Guerrero was declared duly elected, and General Anastasio Bustamante, a distinguished Yorkino leader, was associated with him as vice-president. Santa Anna was invested with the supreme military command of the republic.

Invasion of Barradas, and abdication of Guerrero, A.D. 1829.

The first event which disturbed the country after the elevation of Guerrero, was the arrival of an invading force from Cuba, under Barradas, in the summer of 1829. Santa Anna, however, routed the invaders, and took Barradas himself prisoner. But Guerrero was now destined to taste the cup which he had mixed for his predecessor. Early in December 1829 Bustamante, the vice-president, flew to arms, and having placed himself at the head of the army of Mexico, which was stationed in the state of Vera Cruz, he advanced upon the capital, everywhere denouncing the abuses and usurpations of Guerrero. Guerrero appealed to the Congress for support; but it was all in vain: he was ultimately compelled to abdicate. The army then elected Bustamante as his successor; whilst Santa Anna, following the example of Guerrero, retired to his estates, and tranquillity was soon restored.

Fall of Bustamante; election of Santa Anna, A.D. 1833.

At this period it required no great gift of prophecy to predict that even the shadow of the constitution of 1824 would not long survive. Mexico was now beyond all doubt subjected to a military despotism; and a pretext or cause for prostrating Bustamante in his turn could not long be wanting. It was enough that the daring, crafty, and cruel Santa Anna was living in retirement and hatching new schemes of revolt. From that period Mexico has presented a kaleidoscopic exhibition of factions and parties. It would require volumes to detail the series of manœuvres, of *gritos* and insurrections, which seated Santa Anna ultimately in power, and made him the representative of that amalgam of all parties which has been designated by a cant term in which the most incongruous ideas are jumbled together. In July 1832 the Ayuntamiento and people of San Felipe de Austin unanimously gave in their adherence to the plan of Vera Cruz, and to the principles of the republican party, headed by General Santa Anna. This example was followed by other states; and Santa Anna assumed the reins of government. In April following he expelled the Congress; and in 1835 Gomez Farias, who had been elected vice-president, was driven into exile. Santa Anna was also successful in his new "plan;" and centralism, with a *de facto* dictatorship, succeeded to the federal republic. The states were converted into departments, and the legislatures cut down to a council of five. This new order of things was acknowledged by the whole country, with the exception of Texas, which was warmly attached to federalism. It will appear, however, from the sequel, that the disaffection of this lately settled territory led to important results.

Proposed separation of Coahuila and Texas, A.D. 1833.

At a meeting of the people of Texas in 1833 a constitution had been drawn up in which, amongst other important matters, they pointed out the necessity of a separation from Coahuila. The chief reasons assigned for the contemplated disunion were, the dissimilarity between Coahuila and Texas, in soil, climate, and productions, in common interests, and partly in population, so that laws happily constructed for the benefit of Coahuila, and conducive to its best interests, might be ruinous to Texas. The seat of government was also stated to be too remote, being fixed at Saltillo, and the inhabitants of that part of the state were almost exclusively of Spanish descent. Colonel Austin, who had for many years been member of Congress for Texas, was charged with the duty of submitting to the general government in Mexico the new constitution which had been formed; but finding it difficult or impossible to effect his object, he wrote a letter to some of his friends in Texas, in which he did not conceal his sentiments as to the necessity of Texas taking matters into her own hands, and doing herself justice. This letter was intercepted, and first awakened the jealousy of the Mexican government.

Causes of the rupture with Mexico.

But before proceeding to narrate the leading incidents of the struggle with Mexico it is necessary to premise, that the unappropriated lands, although state property, could not be granted to any one without the sanction of the general government. At this time a great rage for land speculation existed, not only in Mexico, but in the United States, and an extensive system of fraud was the consequence. In 1834 a company of speculators, many of whom belonged to or had come from the latter country, induced the legislature of Coahuila and Texas to grant them 400 square leagues of public land for the sum of 20,000 dollars. The transaction was disavowed, and the grant annulled, by the Mexican government; and it led to the dispersion of the local legislature, and the temporary imprisonment of the governor Viesca.

About the same time an attempt to establish customs was forcibly resisted by the colonists. This, together with a demand for the persons of those who had been concerned in the grant of the 400 leagues of land, were the immediate precursors of hostilities. Viesca issued proclamations and addresses calling the inhabitants of the state to arms against the encroachments of that military power which threatened, he said, their very existence, not only as a state, but as a people. Santa Anna was stigmatized as a dictator, and death was denounced against all his supporters who should enter Texas. Taxes were refused; the custom-house officers were expelled; and the laws of Mexico were set at defiance. In these circumstances Santa Anna, who had succeeded in gaining all the other states of the republic, found it necessary to turn his attention to Texas.

Hostilities; declaration of independence, A.D. 1835–1836.

In September 1835 General Cos, the confidential friend and brother-in-law of the central chief, landed at Compano at the head of 400 men destined to reinforce the garrison of San Antonio de Bejar. But he was foiled in his attempt to defend that city against the Texians, and was forced to retire from the province in October. Early in March 1836 a convention of delegates from the various settlements of Texas, having assembled at Washington, issued a formal declaration of independence, setting forth the grievances which impelled the people to take that step. This declaration was signed by forty-four delegates, of whom only three or four were Mexicans by birth. When this decisive step was taken, the people of Texas undoubtedly supposed that the internal divisions of the country would afford sufficient employment for the arms of Santa Anna; forgetting that there existed in Mexico an inveterate prejudice against the United States colonists, which might induce them to overlook for a time all minor differences, and unite as against a common enemy. Hence the defeat of Cos actually extended the influence of Santa Anna, and he was thus enabled to bring nearly the whole resources of Mexico to bear upon Texas. Early in February 1836 he established his head-quarters on the Nueces, to the eastward of the Rio del Norte. By his plan of operations he proposed to advance in two columns, one directed against San Antonio, and the other against La Bahia, which place was lower down the coast; intending by this means to intercept all communication between the Americans and the Gulf. His troops in the first of these enterprises were repulsed; in the second they were successful, but disgraced their triumph by massacring 500 captives in cold blood.

Total defeat of the Mexican army, A.D. 1836.

This military execution caused much excitement, and exasperated the Texians in the highest degree. They suddenly ceased to retreat, and General Houston, having rapidly counter-marched a distance of about 60 miles, came up with Santa Anna. On the 21st of April, near the banks of the San Jacinto, a fierce and sanguinary conflict took place, in which the Mexicans were defeated with great slaughter, and above 700 taken prisoners, amongst whom was the commander-in-chief himself. This unexpected event totally changed the aspect of affairs; and the success of the Texians stimulated their zeal and activity. Many of the more pacific of the colonists had sought refuge in the neighbouring states; but their place was speedily supplied by numerous adventurers from the United States. On the 15th of May a convention was held at Velasco in Texas, where it was stipulated that hostilities should cease; that the Mexican army should quit Texas; and that Santa Anna should be sent to Vera Cruz, upon condition of his agreeing neither to take up arms against the Texians, nor to exercise any influence to cause them to be taken up during the struggle for independence.

The Texians assert their distinct nationality.

The inhabitants of Texas now set themselves to assert their distinct nationality, by electing their own officers, equipping their own army and navy, and guarding their own frontiers. At the same time their independence was publicly recognised by Great Britain, France, and the United States. For several years Mexico was too much engrossed with internal disturbances, and with the political contests of her magnates, to attempt to reconquer her lost province. At length, in 1844, the commencement of negotiations for engrafting Texas on the American Union roused her from her lethargy. She protested loudly against the unjust attempt of the United States to rob her of part of her dominions. The president Herrera attempted, at the request of the American government, to settle the difficulty by negotiation; but so violent was the popular indignation against such lenient measures, that on the 30th December 1845 he was forced to resign the presidential chair to General Paredes, the darling of the Mexican mob.

Hostilities between Mexico and the United States, A.D. 1846–47.

The new president began his sway by raising money and levying troops for the invasion of Texas. To General Ampudia was intrusted the protection of the northern frontiers. Accordingly, on the 11th April 1846 he settled down with a large force at Matamoros on the Rio Grande, and confronted an American army stationed, under General Taylor, on the opposite bank of the river. In a short time skirmishes between these two bodies of troops began the war, and were the signal to the United States for despatching a large force against Mexico. "An army of the West" and an "army of the Centre" were organized under the respective commands of Generals Kearney and

Wool. Commodore Conner in the Gulf of Mexico, and Commodores Stockton and Sloat in the Pacific, were ordered to co-operate with the land forces. Meanwhile General Taylor had occupied Matamoros on the 18th May, and was actively engaged in levying recruits and in establishing a base line of operations along the Rio Grande. He then advanced southward along the main highway into the interior, and sat down before the strong city of Monterey, the key of the northern provinces of Mexico. After a desperate assault, which lasted two days, his force of 7000 strong captured the town from nearly 10,000 Mexicans on the 24th of September. By this time Santa Anna, with the connivance of the American Congress, had returned to Mexico, and had supplanted General Paredes in the chief power. But contrary to the expectation of the United States, he allowed himself to be swayed by the popular feeling, and began to muster the full strength of the nation for the war. Advancing northward towards the close of 1846, he concentrated a force of 20,000 at San Luis Potosi, with the evident intent of attacking Taylor's extended base of operations in the valley of the Rio Grande. It was not long therefore before he set out with his entire army along the road to Saltillo. On the 22d of February 1847 he came up to Taylor's army of 5000, closely drawn up in the narrow gorge of Angostura, and ready to dispute his advance. A desperate attempt to outflank the American army was immediately made, and was successfully repulsed. On the morrow the mighty force of Santa Anna shattered itself by vain efforts to force the pass, and towards evening commenced a retreat to San Luis Potosi. Shortly before this California had been finally wrested from Mexico by Captain Fremont and Commodore Stockton. New Mexico had also been subdued in the preceding year by General Kearney.

Capture of the city of Mexico, and conclusion of the war, A.D. 1847–48.

In the meantime the American Congress, intent upon striking a blow at the heart of Mexico, had intrusted the command of an expedition against the Mexican capital to General Scott. With the most patient foresight, that eminent commander occupied a considerable time in mustering all the available strength of his country, and in providing resources against every possible emergency. At length, on the 9th of March 1847, he landed near Vera Cruz, and invested that city both by sea and land. After a close bombardment of eight days the besieged garrison were forced to capitulate. Scott then pressed forward towards the capital, and, as he approached Jalapa, found the army of Santa Anna entrenched within an elaborate line of defences on the wild road at Cerro Gordo. After a hard-fought assault of two days the Mexican troops were cut to pieces, and driven in a headlong flight towards the metropolis. The American general advanced without further opposition to La Puebla. There he lay for some time recruiting his forces and concerting his plans for the assault upon the city of Mexico. On the 7th of August he was again on the march. After overwhelming several attempts to check his advance at Contreras, Churubusco, El Molino del Rey, La Casa Mata, and Chapultepec, he began the final assault upon the capital on the 12th of September, and penetrated within the walls on the following day. By retreating during the night, the Mexican army left the fate of their country in the power of the Americans. On the 2d of February 1848 the war was closed, and New Mexico and Upper California were ceded to the United States by the peace of Guadalupe Hidalgo.

Soon after the conclusion of this treaty, Santa Anna, seeing that his power was on the wane, sought an asylum in Jamaica. General Herrera was elected president of the republic. But both under him and under his successor, General Arista, the country continued in a state of the wildest anarchy. At length, in 1852, it had become a prevalent opinion among the Mexicans that a strong central government alone could save them from ruin. Santa Anna was allowed to be the fit instrument for effecting the desired change. Accordingly, in the same year, that dexterous politician and able general was recalled from exile by common consent. In December 1853 he was elected perpetual president, with the authority of dictator, and the title of Most Serene Highness. But the extraordinary powers with which he was invested failed to harmonize those discordant feelings which sprung from difference of political opinion on the one hand, and difference of race on the other. On the 22d of January 1854 a revolution, under General Juan Alvarez, broke out at Acapulco, absorbed within its ranks malcontents of every description, and spread with resistless rapidity through several states in the direction of the capital. Force and policy were alike unable to check it, and at length, on the 9th of August 1855, Santa Anna abdicated and retired to Havanna. In September Juan Alvarez was raised to the provisional presidency, but resigned in December in favour of Ignacio Comonfort, who received the title of president-substitute. Scarcely had the new potentate formed his ministry, when he was assailed by conspiracy. Early in 1856 an insurrection, headed by Haro y Tamariz, enlisted in its cause a formidable number of the clergy, magistrates, and destitute workmen. It was suppressed, however, by Comonfort on the 22d of March.

III.—STATISTICS OF MEXICO.

Mexico is bounded on the N. by California, New Mexico, and Texas; E. by the Gulf of Mexico and the Caribbean Sea; S.E. by British Honduras and Guatemala; and S.W. and W. by the Pacific Ocean. Its greatest length in a N.W. and S.E. direction, from San Diego to the extreme S. part of Chiapas, is about 1987 miles, and its greatest breadth about 1128 miles. Its area is estimated at 829,900 English square miles, and it has a coast line of about 5830 miles in length. A great portion of Mexico is occupied by the Cordilleras, which run through its whole length, rendering the surface extremely varied. On entering this country from the S. the chain divides into two great branches, the western extending along the coast of the Pacific, and the eastern along that of the Gulf of Mexico, and afterwards subsiding into the plains of Texas. The vast tract of country between these branches, comprising about three-fifths of the entire area of the territory, consists of a central table-land called the plateau of Anahuac, 6000 to 8000 feet in general elevation; and hence its climate, though mostly within the tropics, is decidedly temperate. This region is crossed in various directions, or divided into sub-plateaus by numerous chains of mountains, some of which rise to the height of 17,000 feet above the level of the sea. The surface, however, is not broken by many transverse valleys, and in some parts there are extensive districts quite destitute either of depressions or elevations. Some of the peaks rise to a great elevation, towering far above the central plateau: the principal of these are Popocatepetl, 17,735; Orizava, 17,388; Yxtaccihuatl, 15,700 feet above the sea-level. These and many others of the Mexican mountains are volcanoes; the first is continually burning, but for centuries has ceased to eject from its crater anything but smoke and ashes. Luminous exhalations constantly irradiate the summit of Orizava. In 1545 an irruption took place, and the crater continued to burn for twenty years. In the same province (Vera Cruz) is the volcano of Tuxtla, in which a considerable irruption took place in 1793, the ashes of which were carried as far as Perote, a distance of 57 leagues. On the western side of the city of Mexico are the volcanoes of Jorulla and Calima, the latter of which throws up smoke and ashes, but has not been known to discharge lava. Jorulla, which is situated between Calima and the city of Mexico, is of much more recent origin than any of the others. It was thrown up *en masse* from a fertile plain having an elevation of 2890 feet, to the height of 4149 feet above the sea-level.

Geology. While in the Old World granite, gneiss, mica schist, and clay-slate often form the central ridges of the mountain chains; these rocks seldom appear at the surface of the Cordilleras of America, being there covered by masses of porphyry, greenstone, amygdaloid, basalt, obsidian, and other rocks of the same class. The granite, which here generally forms the lowest stratum, appears at the surface in the little chain that borders the Pacific Ocean, and which on the side of Acapulco is separated from the mass of high country by the valley of Peregrino. The beautiful port of Acapulco is a natural excavation in granitic rocks. As we ascend towards the table-land of Mexico, we see it rise through the porphyry for the last time, between Zumpango and Sopilote. Farther to the east, the mountains of Mixteca and of Zapateca, in the province of Oaxaca, are formed of the same rock, which is there traversed by veins of auriferous quartz. The great central plateau of Anahuac, between the fourteenth and twenty-first degrees of latitude, appears like an enormous dyke of porphyritic rocks, distinguished from those of Europe by the constant presence of hornblende and by the absence of quartz. These rocks contain immense deposits of gold and silver. Basalt, amygdaloid, trap, gypsum, and primitive limestone, however, form the predominating rocks. The strata succeed each other here in the same order as in Europe, excepting that syenite alternates with serpentine. The secondary rocks equally resemble those of the Old World; but hitherto no considerable beds of rock-salt or of coal have been discovered in the plateau of Mexico. In some parts the porphyry presents itself in gigantic masses, which assume extraordinary shapes, resembling ruined walls, bastions, towers, and the like. The porphyritic traps which terminate the mountains of Jacal and Oyamel appear in columns, and are crowned with pine trees and oak, which materially add to their picturesque appearance. It is from these mountains that the ancient Mexicans obtained the obsidian, of which they formed their sharp-edged instruments. The Cobre de Perote is a porphyritic mountain, resembling an ancient sarcophagus surmounted by a pyramid at one end. The basalts of La Regla, of which the prismatic columns, 100 feet in height, have their central parts harder than the rest, form the native decorations of a very beautiful cascade.

Mines. The mines of Mexico were wrought long before the arrival of the Spaniards; the natives of Mexico, like those of Peru, being well acquainted with the use of metals. Nor were they contented with such specimens as they found scattered on the surface of the earth or in the ravines of mountain torrents, but had also learned to dig for them, and to trace the metallic veins in the interiors of the mountains. Gold and silver vases, and other specimens of jewelry, made in Mexico, were sent to Spain by the first conquerors as evidence of the mineral wealth of the country. The dependent tribes paid their tributes to the sovereign in a species of metallic currency, which, though not stamped, was yet the representative of a standard value. The mines of Mexico are nearly all on the top or on the western slope of the great Cordillera, and the mining region occupies an area of about 12,000 square leagues. On the country becoming settled after the revolutionary disturbances, especially about the year 1825, the Mexican mines were eagerly seized as objects of speculation by British and American capitalists. In consequence, however, of bad management, or the wild spirit of gambling which assumed the place of prudent commercial enterprise, the holders of stock were disappointed in their expectations, and sometimes ruined. The enormous cost of transporting heavy materials in a country where there are no navigable rivers extending into the interior, and where the usual mode of carriage is on the backs of mules, by wretched roads, over mountains, and through ravines, has often absorbed large portions of the original capital before the proprietors could even commence the working of their mines. Many of the first British and American speculators were thus ruined; but their successors are beginning to reap the benefit of their expenditure, and throughout the republic steam-engines and the best hydraulic apparatus are now employed. The annual average produce of the mines before the revolution was estimated at about L.5,000,000, and between the revolution and the year 1825 at nearly L.2,300,000. The annual produce of silver alone is now estimated at about L.7,000,000, and of gold about L.6,500,000. There are also some twenty-five quicksilver mines, yielding from 250,000 to 300,000 lbs. of metal annually. Besides the precious metals, Mexico abounds in other ores. Iron is plentiful in the states of Valladolid, Zatatecas, and Jalisco, but has hitherto been little worked. Copper is found in a native state in Valladolid, and also to some extent in Guanajuato. Tin, though obtained in mines, is principally extracted from the water-carried earth found in the deep ravines. A combination of these two metals was used by the ancient Mexicans to form their tools and weapons; and they had acquired the art of tempering them so as to render them equal in utility to iron, or even to steel. Lead is found, but the mines are very little worked. Zinc, antimony, and arsenic also exist; but neither cobalt nor manganese have as yet been discovered.

Rivers. Mexico is singularly deficient in large rivers. The Rio Grande del Norte, which forms its N.E. boundary, is the largest, having a length of about 1800 miles. The principal affluents of the Rio Grande are the Conchas, the Salado and Sabinas, and the San Juan rivers. The Santander, Tampico, Panuco, and Usumasinta, are the chief of those flowing into the Gulf of Mexico; while the Rio Yompex, the Balsas or Zacatula, the Aztla, Santiago, Culiacan, and the Rio del Fuerta, fall into the Pacific. A small portion of the lower course of the Colorado is in this territory.

Lakes. The lakes of Mexico are numerous, and some of them are of considerable size. Lake Chapala in Jalisco covers an area of 1300 square miles, and Lake Terminos, which, however, is more properly an arm of the sea, has an area of about 2200 square miles. Lakes Pascuara in Michoacan, and those of Mextitlan, Cayman, and Parras, are all of large size. The valley of Mexico contains five lakes, into which the various streams of the district flow. These cover an area of 160 square miles, and are drained by a canal cut through rock 12 miles in length, 150 feet deep, and 300 feet wide, having its embouchure in the Rio Panuco.

Climate. Mexico, as regards climate, is usually divided into the *tierras calientes*, *tierras templadas*, and *tierras frias*. The first, or hot regions, include the low grounds, or those under 2000 feet elevation, on the east and west coasts. The *tierras calientes* of the west are less extensive than those of the east, as the western arm of the Cordilleras approaches nearer to the sea. The mean temperature of this region may be estimated at 77° Fahr. It is especially suited for the growth and cultivation of sugar, indigo, cotton, and bananas. The *tierras templadas*, or temperate regions, are of comparatively limited extent, and occupy the slope of the mountain chains which bound on either side the central table-land. They extend from about 2500 miles to 5000 feet in elevation, and the mean temperature is from 68° to 70° Fahr. Extremes of heat and cold are there equally unknown. The Mexican oak, and most of the fruits and cereals of Europe, flourish in this genial climate, the humidity of which produces great beauty and strength of vegetation. The *tierras frias*, or cold regions, include all the vast plateau elevated 5000 feet and upward above the sea, and have a mean temperature of about 62° Fahr. In the city of Mexico, at an elevation of 7400 feet, the thermometer has sometimes, though rarely, fallen below the freezing point.

In the coldest season the mean temperature of the day varies from 45° to 50° Fahr., while in summer the thermometer seldom rises above 75° Fahr. At a greater elevation than 8000 feet the climate is severe and disagreeable. Under the parallel of Mexico the line of perpetual snow varies from 14,000 to 15,000 feet above the sea-level. Vegetation here is not so vigorous as in the other two regions, and the plants of Europe do not succeed so well as in the *tierras templadas*. In the tropical regions, and as far north as 28° N. Lat., there are only two seasons; that of rain, lasting from June or July to September or October, and the dry season, continuing from October to the end of May. From the parallel of 24° to that of 30° the rain falls less frequently, and continues a shorter time, but the deficiency is compensated by the snow, which, from the 26th degree of latitude northwards, is deposited in considerable quantities.

The climate of the provinces denominated *internas*, and which are situated within the temperate zone, is distinguished by a striking inequality in the temperature of the different seasons; the winters being very cold, whilst the summers are comparatively very warm. To this, as well as to other local causes, must be attributed the aridity which characterizes a considerable portion of the plateau of Anahuac. There are few springs in the mountains; and the water, instead of collecting in little subterranean basins, filters through the earth or porous rocks, and loses itself in crevices formed by volcanic eruptions. The evils arising from aridity have increased since the Europeans first took possession of Mexico. The conquerors not only destroyed trees without supplying their place by young plants, but by artificially drying up extensive tracts of country, they occasioned a still more important evil. The muriates of soda and of lime, the nitrate of potass, and other saline substances, cover the surface of the soil. Still a great part of Mexico may be classed with the most fertile countries of the earth, for there every species of vegetable production is found, or may be successfully cultivated. On the ascent from Vera Cruz, climates, to use an expression of Humboldt's, succeed each other in layers; and the traveller passes in review, in the course of two days, the whole scale of vegetation, from the parasitic plants of the tropics to the pines of the arctic regions. In some parts, however, the climate is very insalubrious. The humidity of the coasts favouring the putrefaction of a prodigious mass of organic substances, originates diseases which attack Europeans and others not familiarized to the climate; indeed, under the burning sun of the tropics, the unhealthiness of the air is almost invariably a sure indication of extraordinary fertility in the soil. Nevertheless, excepting the seaports and some of the deeper valleys, where intermittent fever is very prevalent, Mexico ought, upon the whole, to be considered as a healthy country.

Zoology. The zoology of this interesting country has only hitherto been partially explored, and what is known relates chiefly to ornithology. Of one hundred and thirteen species of land birds ascertained to be natives of Mexico, sixty-eight seem to be peculiar to that country, eleven likewise natives of South America, and thirty-four of other parts of North America. The water birds that have been examined present no novelty, as all can be identified with the species distributed generally over North America. Among the wading birds are two beautiful species of tiger bitterns, formerly unknown to naturalists. The quadrupeds, insects, &c., are as yet little known. Deer and several varieties of antelopes are found on the table-lands, and the bison ranges in vast herds through various parts of Mexico. The domestic animals introduced by the Spaniards have increased to such a degree, that immense numbers of them run wild through the country. The wool of the sheep is of inferior quality; but this is attributable more to neglect and mismanagement than to any peculiarity in the climate. Mules are very abundant, especially in the mining districts.

Agriculture. From the great range of climate in Mexico, the vegetable productions must necessarily be very varied. "Indeed," says Humboldt, "there is scarcely a plant in the rest of the world which is not susceptible of cultivation in one or other part of Mexico; nor would it be an easy matter for the botanist to obtain even a tolerable acquaintance with the multitudes of plants, scattered over the mountains, or crowded together in the vast forests at the foot of the Cordilleras." The soil is in many parts of extraordinary fertility, and, where well watered, produces abundant crops with very little labour. The most important of the agricultural productions is maize or Indian corn, which constitutes the principal food of the inhabitants as well as of most of the domestic animals. This valuable grain is almost everywhere cultivated with success, and in some favourable spots its fecundity is very remarkable; eight hundred *fanegas* for one of seed having occasionally been obtained. Where irrigation is practicable, from three to four hundred for one is the ordinary ratio of increase; but where the crop depends upon the season it is more variable, and in some parts one good year in ten is all that is expected, the intervening years producing only forty or fifty bushels for one sown. Oats are little cultivated in Mexico, but the wheat and barley of Europe have been naturalized here. The former succeeds well throughout the table-land; but both in the *tierras calientes* and on the eastern and western slope of the Cordilleras, the ear does not form. The success of the crop on the table-land depends almost entirely upon the timely commencement of the rainy season; for if the dry weather continue beyond the middle of June, unless the grounds can be watered by artificial means, the crops of wheat, barley, and maize are destroyed by drought. Irrigation is therefore the great object of the Mexican farmer; and in the formation of reservoirs, canals, and the like, vast sums have been expended on the principal estates. The average annual produce of the whole of the corn lands of Mexico is estimated at twenty-five bushels for one; while in certain parts of the country, during favourable years and where the irrigation is good, from sixty to eighty bushels for one have been produced. At Chilula, near Puebla, the increase is stated at forty for one; and at Zelaya, Salamanca, and Santiago further N., in average years, from thirty-five to forty are produced. Rye and barley are raised at higher elevations than wheat, as they are less liable to be injured by cold. The potato is much cultivated in Mexico. It is not an indigenous plant, but was introduced from the mountainous parts of Peru at a very early period after the conquest of that country by the Spaniards. It grows to a large size, some of those found by Humboldt having measured from 12 to 13 inches in circumference. The banana, which flourishes up to the point where the mean temperature is 75° Fahr., produces more nutritious substance in a less space than any other plant. Humboldt calculates that an acre of ground planted with bananas is sufficient to support fifty men, whilst the same extent of land in wheat would barely supply the wants of three. It is propagated by cuttings, and requires no labour in cultivation, except that of cutting off the stems when the fruit is ripe, and occasionally digging round the roots. The same temperature necessary to the development of the banana produces also the *manioc* or *cassava*, which is also abundantly productive of aliment. Its cultivation requires more care than that of the banana, and in some measure resembles that of the potato: it arrives at maturity about eight months after the slips have been planted. Of the *manioc* there are two kinds, the sweet and the bitter; both are made into bread, but the consumption is not considerable. Rice is but little cultivated, and not very generally known. Before the year 1810 the cultivation of the olive was prohibited lest the interest of the mother country should thereby be injured. During the revolution, however, a great number of olive trees were planted, and at present there are several large plantations in the country. The vine was also a prohibited plant, but now flourishes in many parts. Among the other vegetable productions of Mexico are the yam, which is confined to the *tierras calientes;* the *capsicum,* which is extensively cultivated, and universally used for seasoning food; and the sarsaparilla, tomato, pine-apple, pomegranate, guava, orange, lemon, melon, pear, apple, peach, &c. One of the most valuable plants of the country is the *maguey,* a species of aloe, which is by Humboldt designated the vine of Mexico. It furnishes a spirituous liquor called *pulqué,* which is the chief beverage of all classes of the people. The *maguey* plantations are principally in the states of La Puebla, Mexico, Guanajuato, and a small portion of Valladolid. The most celebrated are those in the vicinity of Cholula, and in the Plains of Epam and in the valley of Toluca; but in general the plant is found wild in every part of Mexico. The plants in the plantations are arranged in rows, with an interval of 2 or 3 yards between each, and when arrived at maturity the leaves are from 5 to 8 feet in length, and the stem frequently attains a height of 20 or even of 30 feet. The *maguey,* however, often delays florescence for many years, when it pushes up its flowering spike with extraordinary rapidity. At the flowering season the exact time is watched when the stem of the flower is about to shoot up; the top is then cut off, and a hole scooped in the stalk for the reception of the sap, which is regularly drawn off, generally two or three times in a day. The plants are extremely productive; a vigorous one will yield as many as 150 gallons in a season of four or five months. The sap is placed in a situation to ferment, an operation which takes place in a few days, when it becomes fit to be drunk. Its taste is said to resemble that of cider, but its smell is disagreeable. A kind of brandy, called *mexical,* very much resembling whiskey, is produced by the distillation of *pulqué.* The *maguey* plant is useful in other respects; its fibres furnish the inhabitants with a thread called *pita,* and is also employed in making ropes and paper; its juice is used as a caustic application for wounds; and its prickles serve for pins and needles. The soil of Mexico is in many parts remarkably favourable to the production of sugar, which has become one of the most valuable products of the republic. A considerable quantity of rum is annually distilled from molasses. The Mexican soil has also been found well adapted for the cultivation of coffee, extensive plantations of which exist near Orizava and Cordova. The average produce of each plant is estimated at about two and a half pounds weight throughout all parts of the country where the berry is cultivated, though there are districts in Mexico in which it is said three or four pounds are yielded. The slope of the eastern Cordillera is supposed to be best adapted for coffee estates. Tobacco is a government monopoly, and grows well in a small district near Orizava and Cordova; but the best quality comes from Simojovel in the state of Chiapas, and from some districts of Oajaca. In Yucatan and Tabasco the plant is also successfully cultivated, and produces a mild and fragrant leaf, which is not included in the national monopoly. A large portion, however, of the tobacco sold in the country is contraband. Indigo was known and cultivated by the Mexicans previous to the conquest. It is found in Yucatan, Chiapas, and about Tehuantepec, in the state of Oajaca, and grows wild in some of the very warm districts in Tabasco. Cotton was among the indigenous products of Mexico at the time of its invasion, and formed almost the only clothing of the natives. The Aztecs possessed the art of spinning it to a very high degree of fineness, and of imparting to it beautiful and brilliant colours; but these arts have been lost. The hot regions are remarkably favourable to the growth of the plant, and it requires but little attention from the proprietor. The quantity of cotton produced in the whole country is estimated at about seven millions of pounds. Vanilla, yielding the highly esteemed spice of that name, grows wild along the eastern coast and in other parts of the republic. The cultivation, however, of this valuable product is left almost entirely in the hands of the Indians. Jalap, whose roots furnish a valuable medicine, is a native of Mexico, and grows plentifully in the neighbourhood of Jalapa, whence its name. The *opuntia,* or Indian fig, a species of cactus, supports here an insect from whose body the well-known cochineal is made. The female alone produces the dye; and the process of rearing is complicated, and attended with much difficulty. The plantations of the cochineal cactus are confined to the state of Oajaca. Soon after the independence of Mexico was secured, the cultivation of the mulberry tree was attempted, for the purpose of feeding silk-worms, but without success. In 1841 an association was formed for the encouragement of silk culture, and the mulberry tree was extensively introduced, but has been found to prosper only in certain localities. The state of Oajaca is said to be exceedingly well adapted for its culture. Flax and hemp have also been introduced into the country.

Trade.

The chief exports from Mexico are cochineal and the precious metals. Of the latter of these products it is estimated that the one-half is remitted to England, and that the other is divided equally between the United States and the continental states of Europe. The greater portion of the silver is shipped from Tampico, which is the nearest port for the mineral productions of Guanajuato, Zacatecas, San Luis Potosi, and the principal mining districts of Northern Mexico. Large quantities are also sent from Vera Cruz, as well as from Mazatlan, on the Pacific coast. In 1845, before the war with the United States broke out, and when the Mexican trade was in its ordinary condition, the value of the precious metals, coined and uncoined, shipped from these ports through the regular channels amounted to L.2,279,187. We have, however, no means of estimating the contraband exportation; but it may be safely said that at least one million sterling more found its way clandestinely to Europe and the United States. The value of cochineal exported is estimated at about L.200,000. The other exports are principally dyewoods, vanilla, sarsaparilla, jalap, hides, horns, and a small quantity of pepper indigo, and coffee. The imports consist chiefly of linen, cotton, woollen, and silk goods, paper, glassware, ironware, quicksilver, cocoa, wine, brandy, and gin. The aggregate value of the exports and imports does not exceed L.5,000,000. For the year ending 30th June 1850 the duties on importations amounted to L.1,090,227, and on exportations to L.125,780. The total shipping in 1850 amounted to 256,692 tons. Of the vessels that arrived at the various ports 68 belonged to Mexico, 435 to the United States, 108 to England, 69 to France, 60 to Spain, 13 to Hamburgh, and 24 to Peru.

Manufactures.

The manufactures of Mexico chiefly consist of woollen, cotton, and silk goods, glass, paper, sugar, oil, wine, and brandy. In 1850 there were in the republic 4 glass factories, 8 paper mills, 72 large cotton factories, 6 large woollen factories, and upwards of 70 machines worked by the hand in the manufacture of silk. In the cotton manufacture there were also a number of hand machines for making *rebosos* or long cotton shawls, bed-coverings, &c. The woollen manufactures likewise employ numerous small establishments in the country, where coarse cloths are made. In the larger mills fine cloths, carpets, flannels, &c., are produced. The annual value of the manufactures is estimated at about L.20,000,000. The Indians excel in working jewelry, carving, sculpture, and indeed in all the ornamental arts; they are likewise good masons, painters, and musicians. They make beautiful vases, somewhat similar in form to the Etruscan, as well as toys of all kinds, wax figures, ornamental cloths of great value, and the like.

Revenue. The revenue of the republic for the year ending 30th June 1852 amounted to L.1,683,000, and the expenditure to L.2,405,000. The public debt, which has been steadily increasing since the year 1827, amounted in 1854 to L.24,600,000, of which sum nearly a half was owing to foreign bondholders, these consisting principally of English and Americans. This wretched state of the public money is naturally owing to the long dissensions among the political parties, and the peculations of many of their leaders. The armed force is fixed by law at 26,353 men in the regular service, and 64,946 militia in actual service; but in 1855 not more than half of these were organized. The navy consists only of 9 small vessels, having in all 35 guns, and manned by about 300 men.

Government. The government of Mexico is a representative federal republic. The legislative power is vested in a Congress consisting of a Senate and Chamber of Deputies. The Deputies are chosen every two years by the citizens of the states, in the ratio of one for every 50,000 souls, or for any fraction above 25,000. The Senate is composed of two members from each state and the federal district, while a number equal to that of all the states is elected by the Senate, Deputies, and Judges of the supreme court conjointly, the Deputies deciding the election in the case of the candidate not receiving a majority of all the votes. The executive power is vested in a president elected for four years. Judicial power resides in the supreme court of justice, and in circuit and district courts. Each state government is independent within its local jurisdiction, and, like the federal government, is composed of executive, legislative, and judicial departments.

Religion. The Roman Catholic religion was established here by the Spaniards, and is still maintained with the utmost rigour. At the time of the revolution the pope actively espoused the cause of Spain, and anathematized the revolutionists; but on the petition of the new government they were readmitted into the bosom of the Catholic Church. The constitution of 1847 declares that "the religion of the Mexican nation is and shall be perpetually the Roman Catholic Apostolic. The nation protects it by wise and just laws, and prohibits the exercise of any other whatsoever." The ecclesiastical government is under the jurisdiction of an archbishop and eleven bishops. The dioceses contain 184 prebends and 1229 parishes, with 3223 ecclesiastics; there are besides 146 monasteries, with 1130 inmates; 59 nunneries, with 3160 inmates; and 8 colleges of the Propaganda, with 238 inmates. The revenue of the church is estimated at L.4,000,000.

Education. Education is still at a very low ebb, though of late years some progress has been made. Several of the states have established primary schools, and many higher schools and private seminaries have been opened in the cities. In the city of Mexico, in 1850, there were 129 primary schools, attended by 7151 scholars. The other educational institutions are,—First, seminaries sustained and directed by the clergy; second, national colleges in the capital, sustained partly by their own funds and partly by government aid; and third, colleges and institutions in the states supported by local funds. Of the first class there are 10 distributed in the capitals of the several dioceses, and in 1850 these contained 3024 students; of the second class there are six, viz., the college of San Ildefonso, San Gregorio, and San Juan de Letran, the School of Medicine, the Military Academy, and the College of Mining; and of the third class there are 20, including six preparatory schools.

Population. The republic of Mexico comprises 21 states, 1 federal district, and 3 territories. It has 85 cities and towns, 193 villages, 4709 hamlets, 119 communities and missions, 175 *haciendas* or estates, and 6092 farms. According to the census of 1850, it contained a population of 7,661,919, and an estimate in 1854 gives it at 7,853,395, showing an increase of 191,476 persons within these years.

States.	Population in 1851.	Area in Square miles.
Chiapas,	144,070	18,680
Chihuahua	147,600	97,015
Cohahuila	75,340	56,571
Durango	162,218	48,489
Guanajuato	713,583	12,618
Guerrero	270,000	32,003
Jalisco	774,461	48,590
Mexico	973,697	19,535
Mechoacan	491,679	22,993
Nuevo-Leon	133,361	16,688
Oajaca	525,101	31,823
Puebla	580,000	13,043
Queretaro	184,161	2,445
San Luis Potosi	368,120	29,486
Sinaloa	160,000	33,721
Sonora	139,374	123,467
Tabasco	63,580	15,609
Taumaulipas	100,064	30,335
Vera Cruz	264,725	27,595
Yucatan	680,948	52,947
Zacatecas	356,024	30,507
Federal District	200,000	90
California, Lower Territory	12,000	60,662
Colima Territory	61,243	3,020
Tlaxcala Territory	80,171	1,984
Total,	7,661,520	829,916

Of the total population, it is estimated that only about 1,000,000 are pure whites, 4,000,000 Indians, and 6000 negroes; the remainder consisting of Mestizos, Zambos, Mulattoes, Quadroons, Quinteroons, and other mixed races. The whites in Mexico are divided into two classes—Creoles, or those born in the country, and Gachupines, or native Spaniards. The Spanish population in this country still forms a numerous and important body, though the Spaniard no longer holds his former rank in the social scale. The Creole or native Mexican is commonly proud, indolent, and often vicious. An aristocratic feeling, founded on their complexion, which gives them distinction, prevents them from pursuing those kinds of labour which are deemed degrading to gentlemen. The consequence is, that their poverty is often even greater than that of the Indians; whilst from indolence, added to pride, they are prevented from following any employment beyond that of the gaming-table, or becoming the flatterers of the richer members of their own class. Throughout Mexico there is a universal predisposition to dependence upon others, or a blind reliance upon chance. The Indians form the next class of the Mexican population. They are the unmixed descendants of the aboriginal inhabitants, and consist of various tribes, resembling each other in colour, and in some general characteristics which seem to announce a common origin, although differing entirely in language, manners, and dress. No less than twenty languages are known to be spoken in the Mexican territory, and many of these are not dialects which may be traced to a common root, but differ as much as the languages of Sclavonic and Teutonic origin in Europe. Some possess letters which do not exist in others, and in most there is a difference of sound which strikes even the most unpractised ear. In colour the Indians of Mexico are darker than those of South America, although they live in a climate of lower temperature. They have more beard and more hair on other parts of their body than those of the southern continent, while almost all are free from personal deformity. The different tribes are scattered over the greater part of the country, and are mostly cultivators of the soil. A number of them, however, find employment in the mines; some are engaged in the manufacture of certain elegant fabrics of wool and cotton; and some in the formation of articles for domestic use. The Indian is remarkable for his patient endurance of fatigue and pain, and is exceedingly tenacious of old customs. After three centuries of constant intercourse with Europeans, he still keeps aloof from the foreigner, and continues to live in his native village. He speaks his hereditary language, delights in his old pastimes, and, according to the report of reliable travellers, occasionally worships in private his ancestral idols. Though the Mexican laws prohibit slavery, yet upon the plantations the Indians are in reality slaves. The tenacity with which he adheres to old habits and customs, and the strong attachment which he manifests for the place of his birth, render migration to another state or district never a voluntary act on his part. So helpless is the Indian, if placed beyond the limits of his habitual neighbourhood or accustomed haunts, that he feels himself perfectly lost and miserable if compelled to change either his residence or occupation. The Mexican planter can inflict no greater punishment on his Indian serf than to expel him from the estates on which he and his ancestors have worked from time immemorial. The Indian is also frequently mortgaged to the landed proprietor. The extravagant and licentious outbursts in which he occasionally indulges bring him under pecuniary obligations, leading him to sell himself for a number of years, or even for life, to the landholder; and this condition the latter is ever ready and willing to bring about.

The middle races have, in process of time, become a very important part of the population of Mexico. In a country where rank depends more on the complexion than on those endowments which in other countries confer distinction, it is not surprising that almost every shade has its limits defined by terms which, though apparently only expressing the colour, do in reality signify the rank of the individual. The son of a white, whether Creole or European, by an Indian female, is called *Mestizo.* His colour is almost a pure white, and his skin is of a peculiar transparency. The small hands and feet, and a certain obliquity of the eyes, are more frequent indications of the admixture of Indian blood than the nature of the hair. If a Mestizo marry a white man, the next generation scarcely differs in anything from the European race. They are, however, generally accounted of a more mild character than the Mulattoes descended from whites and Negresses, who are distinguished by the violence of their passions, and the singular volubility of their tongues. The issue of Negroes by Indian females bear in Mexico the singular name of *Chinos*, or Chinese in common language, although by law they are denominated Zambos. The term Zambo, however, is generally applied to the descendants of a Negro and a female Mulatto, or of a Negro and a female Chinese. Another gradation, called *Zambo prieto*, or blackish Zambo, is the offspring of a Negro and female Zambo. From the union of a white man and a Mulatto woman the class of Quadroons is derived. When a female Quadroon marries a white man, the children are denominated Quinteroons. The issue of a white man by a female Quinteroon is considered a white. Next to the pure Indians the Mestizos are the most numerous caste. It is, however, impossible to ascertain the exact proportion which they bear to the whole population, many of them being included amongst the pure whites. The proportion of the other mixed breeds to the whole population is equally uncertain.

It was the policy of Spain to foster a spirit of rivalry between the different classes of inhabitants, by creating little imaginary shades of superiority amongst them, which prevented any two from having a common interest. Whiteness of skin was the patent of nobility; and even the Creole, whom the Spaniard despised, looked with the contempt of a European upon the rest of his countrymen. The revolution, however, put an end to castes, the differences of which were all swallowed up in the grand distinction of Americans and Europeans. The Creoles were compelled to court the allegiance of the mixed classes, without whom they could make no effectual head against the Spaniards. Many of the most distinguished characters of the revolutionary war belonged to the mixed breeds; and under the system now established, all are equally entitled to the rights of citizenship, and equally capable of holding the highest dignities of the state. There is neither a pure African population nor a slave in the republic of Mexico.

Antiquities and ancient inhabitants

Of the ancient inhabitants of Mexico some very interesting monuments remain. The work of Humboldt on New Spain first excited the curiosity of Europeans, and rescued the antiquities of Mexico from the oblivion to which they had so long been consigned; but it was not until recently, that their value as works of art, and as indications of a considerable advance in civilization, was fully appreciated. Pyramids having even a larger base, and being otherwise scarcely inferior in magnitude to those of Egypt, are found in many parts of Mexico. Amongst the most celebrated is that of Cholula, the base of which is 1423 feet on each side, and the height 177 feet. It consists of eight graduated square towers, each rising above the other, and terminating in a species of sanctuary. Here vestiges of noble sculpture are visible, as well as at Otumba, Oajaca, Mitlan, Tlascola, and Palenque. The ruins of the latter, in particular, have attracted a considerable degree of attention, and are worthy of description. They extend, says Colonel Galindo, of whose description we shall avail ourselves, for more than 20 miles along the summit of the ridge which separates the country of the wild Maya Indians from the state of Chiapas, and must anciently have embraced a city and its suburbs. The principal buildings are erected on the most prominent heights; and several of them, if not all, have been provided with stone stairs. The principal edifice, which has been sometimes styled the palace, is built in several squares; but the main halls or galleries run in a direction from the N.N.E. to the S.S.W.; and this position has been observed in all the edifices hitherto examined, be their situation what it may. The houses have all been substantially built of stone, cemented with mortar; but symmetry has been little studied in their construction, it is supposed less from ignorance than from design. Other ruins of considerable magnitude, and distinguished by numerous sculptures, are found upon the neighbouring hills. In the vicinity there is one building in particular, apparently a religious edifice, which deserves notice. Two galleries constitute its foundation; the front one occupying its whole length, whilst the back one is divided into three compartments. Of these, the eastern has the appearance of a dungeon; the western is a small room with a chapel ornamented with elegant relievos. These consist of representations of the human figure, in various attitudes, and adorned generally with boughs and feathers. There are other very interesting ruins in this part of Mexico, but they have not as yet been sufficiently described.

The Mountain of Tezcoca is nearly covered with ruins of ancient buildings. At Mitlan there are the remains of a large palace, the architecture of which possesses a stately grandeur, and melancholy beauty of a peculiar character. The roof of the portico is supported by plain cylindrical columns, and the façade of the palace is covered with a beautiful matwork, or basket scroll, such as is found in Egyptian sepulchral chambers. Many of the statues found at Otumba, Mitlan, Jochichalo, and the magnificent flower-temple of Oajaca, are sculptured in a purely classical style; whilst vases rivalling those of Egypt and Etruria have been discovered in sepulchral excavations. Roads are to be met with, not only in the vicinity of great cities, but at a vast distance from them, artificially constructed, like the Roman military roads, of large squared blocks of stone. These roads present a continued level, and may be called viaducts, in contradistinction to aqueducts, which were also constructed by the ancient inhabitants of Mexico. Where they traverse acclivities, they are parapeted; and the indications may still be observed, both of regular posting stations at certain intervals, and of the regular division of the distances. upon the principle of the milestones of our turnpike roads. Bridges constructed of the same durable materials, and thrown across torrents, are also to be found. In these bridges there is occasionally an approximation to the principle of the arch and keystone; but in general they only display the primitive and obvious form of architraves of stone superimposed on two or more piers of the same massy character and durable materials. Every feature of these structures is at once singular, ingenious, and colossal.

With regard to the period at which these remarkable edifices were constructed, and the people to whom the labour is to be attributed, the learned are as yet not agreed. One point, however, seems pretty generally admitted, viz., that their erection must be traced to a race who inhabited the country prior to the invasion of the Mexicans, and who had attained to a considerable degree of civilization. An attempt has been made to prove that this people lived at a time prior even to the Toltecans, who preceded the Mexicans by 600 years; and a close analogy between the antiquities of Mexico and those of Egypt has been shown to exist. The hypothesis advanced regarding the people is, that they were a branch of the Anakim or Cyclopean family of Syria, the shepherd kings of Egypt, the Oscans of Etruria, and the Pelasgians of Greece, the Titans or giants of classical romance, and who are recorded to have been severally expelled from Egypt and Syria.

In reference to these questions, an able writer observes:—"The first and strongest conviction which will flash on the mind of every ripe antiquarian, whilst surveying the long series of Mexican and Toltecan monuments, preserved in the various works to which we have alluded, is the similarity which the ancient monuments of New Spain bear to the monumental records of ancient Egypt. Whilst surveying them, the glance falls with familiar recognition on similar graduated pyramids; on similar marks of the same primeval Ophite worship; on vestiges of the same triune and solar deity; on planispheres and temples, which, though characterized by some distinctions entirely American, are not less worthy of the notice of the Egyptian antiquarian; on relics of palaces at once noble in their architecture and beautiful in their proportions and decorations; on monuments sepulchral, domestic, religious, or warlike, which deserve the designation of Cyclopean as much as any that are now extant in Italy or Greece; on idols and sculptures, some of rude and some of finished workmanship, exhibiting different eras of civilization, and often presenting the most striking analogy in posture and gesture to the monumental style of sculpture, and of statuary pre-eminently called Egyptian. Lastly, the eye of the antiquarian cannot fail to be both attracted and fixed by evidences of the existence of two great branches of the hieroglyphical language; both having striking affinities with the Egyptian, and yet distinguished from it by characteristics perfectly American. One is the picture-writing peculiar to the Mexicans, and which displays several striking traits of assimilation to the anaglyphs, and the historical tablets of the Egyptian temples. The second is a pure hieroglyphical language, to which little attention has been hitherto paid, which appears to have been peculiar to the Toltecans, or some still more ancient nation, that preceded the Mexicans, which was as complete as the Egyptian in its double constituency of a symbolic and phonetic alphabet, and which, as far as we can judge, appears to have rivalled the Egyptian in its completeness, whilst, in some respects, it excelled it in its regularity and beauty."

"The pyramid of Cholulas," says the same writer, "exhibits a most singular identity with the model of the temple of Belus, described by Herodotus, and which, by many scholars, has been considered to be the Scriptural tower of Babel. But in the internal economy of the pyramids, the analogy between those of Egypt and Mexico is still more remarkable. In both, descending galleries, at a particular astronomical angle of declination, lead to central chambers, either for the purpose of mystery or sepulture. Amongst other marks of architectural identity may be mentioned those traced amongst the ruins of Palenque, where the well-known Cyclopean arch, consisting of receding steps of stone in a triangular form, is seen, and where a rectangular square is surrounded by cloisters built in this manner, and lighted by windows bearing the exact form of the Egyptian face. With regard to the personal characteristics and costume, the sculptures bring to light a people of a very remarkable appearance. Their physiognomy is unlike that of any of the various families of mankind that at present inhabit the globe, or have been rendered familiar to us by ancient sculptures. Their receding forehead, their low facial angle, and the conical form of their heads, is quite unique; and the large long nose, the facial line receding in the same singular manner from the base of the nostrils to the termination of the chin, grotesquely broken off by an unsightly protrusion of the under lip, present a physiognomical outline revolting to the European standard of beauty. The costume shows some striking analogies with that of the Egyptians; but there are at the same time differences from it as remarkable. The Egyptian apron, for instance, was different. It was generally of striped cotton, and folded in a peculiar manner; a portion of it forming a girdle, and passing between the legs, resembling a similar article of dress worn by the East Indians at the present day. But the Toltecan apron resembles the Roman military apron or the Scotch philabeg. It descends from the waist and covers the thigh down to the knee; it is, however, distinguished by one Egyptian appendage, namely, by the mimic tail of an animal, which appears to have adorned the Toltecan hero as it adorned the Egyptian demigod. The apron is supported by a baldric, which descends from the right shoulder to the left side, and joins the girdle at the waist. The dress of the military and superior class of Egypt is not to be found in the Toltecan costume, but the following strong resemblances exist:—The breast-plate and collar of the Toltecans were sometimes decorated with a symbol of the sun; the armlets, bracelets, and anklets, are strikingly analogous to those of the Egyptian. The legs of the Toltecan heroes, however, are invested with sandals, some of them reaching above the ankle, others like greaves, covering the leg to the knee; whilst others in every respect resemble the Highland sandal. All these parts of dress would appear to have been richly ornamented; and the whole dress, it is said, may be safely described as at once gorgeous and elegant, and in these respects nowise inferior to the Egyptian. The head-dresses, however, are in general extravagantly grotesque, without regularity or taste, although, like the Egyptian, constructed out of certain combinations of symbols."

With respect to the religion and religious rites of this ancient race, a striking analogy with those of Egypt has likewise been traced. The gods of the Toltecans appear sculptured, as usual in bas-relief, in the dark inner rooms of temples. He who would appear to be the chief-god is portrayed on the inner wall of the adytum of one of the sanctuaries belonging to the great temple of Palenque, and is worshipped symbolically under other forms and in other localities. He is supposed to be identical with the Osiris of Egypt and the Adonis of Syria, or the well-known classical combination of both divinities, the ancient god *Adoni-Siris*. The manner in which he is enthroned, the cushion on which he reposes, the cap, the symbols, and various appurtenances, show an analogy with the Egyptian deity. But there is a column affixed to the cap which is not found on any Egyptian head-dress; it was, however, an unquestionable symbol of Osiris. "Various characteristics of the worship of Osiris and Adonis are complete in the sculptured tablets of Mexico. A priestess kneels before the Toltecan god in the attitude of adoration, and offers him a pot of flowers, not the mint offered to Osiris, but the blood-stained hand-plant or *manitas*, which all the monuments attest was anciently held sacred throughout Mexico. On the sculptured tablet over the head of the divinity appear, precisely in the Egyptian fashion, the phonetic characters of his name, in an oblong square, which in Egypt was devoted to the names of gods. Of the phonetic or symbolic character, however, nothing as yet is known. The same divinity is represented on one of the walls at Palenque, not in a human, but in an animal form. Instead of the hawk of Egypt, however, the Toltecans chose as their sacred bird the rainbow-coloured pheasant of Central America, which is perched on the Toltecan cross, resembling the Christian, and with its lower extremity terminating in a heart-formed spade. The subject of the sculpture shows the simplicity of the worship. Two Toltecan heroes, chiefs, or priests, stand beside the sacred bird; one of them supports an infant in his arms, probably for baptism, which was a rite practised by the votaries of Adonis, and at other places there are indications of a similar ceremony."

Of the temples we have already given a cursory notice. Their architecture has a theological character like that of Egypt and of Greece; and although their forms are peculiar to the country, the original type of them is extant in Syria, Palestine, and Judæa. Like those of the Egyptians, they are all distinguished by architectural peculiarities, exclusively appertaining to the people by whom they were erected. A high-place of three successive terraces or steps generally constitutes the platform of the temple. The terraces are distinguished by that sloping form which the Egyptian architects peculiarly affected, and they are generally constructed of large blocks of stone, covered with stucco equally hard and durable. On the top of the high-place was an oblong rectangular court; and in the centre of this court stood the temple, divided, like the rock temples of Nubia, into three dark rooms built of stone, and having an ark or barn-shaped roof. The innermost of these rooms constitutes the sanctuary. The apartments are occasionally decorated with painted sculptures. Sometimes the staircase ascends the high-place in front, traversing the curvilinear terraces in a straight line to the door of the temple. Occasional variety was given to the square form of the area, and to the triple form of the terraces, by staircases ascending to the sanctuary from each of the cardinal points. The high-place has sometimes a circular instead of a square ground-plan, and in that case, it may remind antiquarians of the well-known *Tepes*, or high-places of Syria, which is a presumptive proof of the Syrian origin of these structures.

The writer already quoted thus speaks of Palenque:—"It may be appropriately termed an ecclesiastical city rather than a temple. It seems to be the locality of the chief cathedral church of the Toltecan religion. Within its vast precincts there appear to be contained a pyramidal tower; various sanctuaries; sepulchres; a small and large quadrangular court, one surrounded, as we have said, by cloisters; subterranean initiatory galleries beneath; oracles, courts of justice, high-places, and cells or dwellings for the various orders of the priests. The whole combination of the buildings is encircled by a quadrilateral pilastered portico, embracing a quadrangular area, and resting on a terraced platform. This platform externally exhibits the same architectural model, which we have described as characterizing the single temples. It is composed of three graduated stucco terraces, sloping inwards, at an angle of about seventy degrees, in the form of a truncated pyramid. Four central staircases, one facing each of the cardinal points, ascend these terraces in the middle of each lateral façade of the quadrangle; and four gates, fronting the same cardinal points, conduct from the top of each staircase into the body of the building, or into the great court. The great entrance, through a pilastered gateway, fronts the east; and descends by a second flight of steps into the cloistered court. On the various pilasters of the upper terrace are the metopes, with the singular sculptures we have described. On descending the second staircase into the cloistered court, on one side appears the triple pyramidal towers, which may be inferred, from the curious distribution of little cells which surround the central room of each storey, to have been employed as a place of royal or private sepulture. On another side of the same cloistered court is the detached temple of the chief god, to whom the whole religious building appears to have been devoted, whom we have described as bearing all the characteristics of the Syrian god Adoni-Siris, and who appears to have been the great and only god of the nations who worshipped in this temple. Beneath the cloisters, entered by well-staircases from above, are what we believe to be the initiatory galleries. These opened into rooms, one of which has a stone couch in it, and others are distinguished by unintelligible apparatus carved in stone. The only symbol described as found within these sacred haunts is, however, perfectly Asiatic and perfectly intelligible; we mean two contending serpents. The remnant of an altar, or high-place, occupies the centre of the cloistered quadrangle. The rest of the edifice is taken up with courts, palaces, detached temples, open divans, baths, and streets of priestly cells or houses in a greater or less degree of dilapidation."

It appears that the creed of this ancient people was a form of deism, which permitted some varieties of symbolic representation. From the few records of their religious rites which have come down to us, and which are principally derived from the extraordinary rolls of American papyrus, formed of the prepared fibres of the *maguey*, on which their beautiful hieroglyphical system is preserved, we learn that they were as simple as their creed. No human or even animal sacrifices appear to have been offered up to the presiding divinity of their temples; nothing, indeed, but fruits and flowers. Such a religious system was therefore quite different from the hideous idols and sanguinary sacrifices which were in use amongst the Mexican people.

IV.—POLITICAL DIVISIONS.

Mexico. The republic of Mexico, as has already been stated, is divided into twenty-one states, a federal district, and three territories, each of which we shall now proceed to give a short account of. Mexico, the most populous of the whole, and which also contains the metropolitan city and the federal district, extends from 18. 30. to 21. 57. of N. Lat., and from 98. to 101. W. Long., and includes an area of about 19,535 square miles. It is bounded on the W. by the state of Michoacan, S.W. by the state of Guerrero, N. by that of Queretaro, E. by Puebla, and N.E. by Vera Cruz. This state is situated on the high lands of the interior, and its surface is almost entirely mountainous. Only one of its peaks, however, attains the height of perpetual snow, namely, that of Toluca, upwards of 15,000 feet above sea-level. The climate is necessarily cool and salubrious. This upland region embraces a large proportion of valuable mines. To the N. and N.E. of the central valley of the state are the great silver-mining districts of Real del Monte, Moran, and Atotonilco el Chico. Iron, lead, and carbonate of soda are also found in the state. But rich as the mines

Political divisions.

of this country are, the fertility of its soil is even more remarkable, producing every variety of plant with rapidity, and in the greatest luxuriance. The most valuable land, however, is what is called the Valley of Mexico, a splendid region, variegated with extensive lakes, and surrounded by high volcanic peaks. Its general figure is an oval of about 200 miles in circumference, and forms the very centre of the great table-land of Anahuac, elevated from 6000 to 8000 feet above the level of the ocean.

The most interesting object in the Valley of Mexico is the vast system of drainage by which the capital is protected against the periodical inundations of the Lake of Tezcoco, which, during the first two centuries after the conquest, threatened it repeatedly with destruction. The Valley of Mexico serves as a receptacle for the water which filters from every part of the lofty ridge of mountains by which it is environed. Only one stream issues from it, whilst it receives the waters of several rivers, which, accumulating in the immense basin, form respectively the great lakes Tezcoco, Zumpango, San Cristobal, Chalco, and Jochimilco. The city being situated on a lower level than some of these sheets of water, particularly that called Zumpango, during the rainy season they occasionally burst the dykes which inclose them, and rush towards the capital, filling the lower parts of the city with water. A rapid succession of misfortunes arising from these inundations compelled the Spanish government to adopt measures for averting the danger. Hydraulic works of immense magnitude were begun in 1607; canals were cut; and other artificial means were adopted to convey the waters of the lakes in another direction. The *desague*, or great canal which was constructed to carry off the waters of the Lake of Zumpango, is of stupendous dimensions, being 12 miles in length, 300 feet in breadth, 150 in depth, and for a distance of 1000 yards cut through the solid rock. During the revolution these works were much neglected; nor have they yet been properly finished or put in a good state of repair. In the Lake of Chalco there are a number of *chinampas*, or what have sometimes been called floating gardens. They are artificial islands, about 50 or 60 yards long, and not more than 4 or 5 wide, on which the finest culinary vegetables, fruits, and flowers are raised, and from which the markets of the capital are amply supplied.

In the centre of this valley stands Mexico City, capital of the republic and of the federal district. Tenochtitlan, the ancient capital of the Aztecs, was built on several islands in the Lake of Tezcoco, and connected with the land by four long causeways; but the drainage of the marshes and the removal of the forests, combined with other causes, have produced a great diminution in the water of the lake; so that the modern city of Mexico, which is believed to occupy the same site, is removed from its shores by a distance of 2½ miles, although in the rainy season of the year the easterly winds occasionally cause the water to overflow the outskirts of the city, which is protected from such incursions by dykes. The city is generally reputed by travellers to be the most beautiful on the American continent, and never fails to excite the admiration of those who view it for the first time. It is regularly built in the form of a square, with its streets, which are both long and wide, intersecting each other at right angles. They are well paved, but not lighted, and often very imperfectly cleaned, though the town is well supplied with water brought by splendid aqueducts from the neighbouring hills. The houses, built of hewn stone, have a massive and sometimes rather forbidding appearance. They generally inclose an open court, round which the different apartments are situated, the entrance being by an iron gate in front. Opposite to this is placed the staircase by which access is gained to the upper storeys and to the roof, which is flat, surrounded by iron balustrades, and sometimes ornamented with bronze and mosaic work of glazed porcelain. The style of architecture in the city resembles that of southern Europe; and the public buildings are in many instances very imposing in their appearance. Mexico contains several squares, the principal of which, the Plaza Mayor, which occupies the centre of the town, is of very large extent, and is surrounded by the chief public buildings. The centre of this square was formerly occupied by a large statue in bronze of Charles IV.; but this has been removed to the quadrangle of the university. On the north side of the Plaza Mayor is the cathedral, which stands on the alleged site of the ancient *teocalli*, or temple of the Aztec war god Mexitli, from whom the city derives its name. The cathedral is 500 feet in length and 420 in breadth; and though the style is irregular, and not in strict accordance with any architectural order, its appearance, especially in the interior, is very imposing. The front is profusely ornamented with carving; and is partly in an inferior Gothic style and partly in the Italian. There are also two lofty towers, adorned with pilasters and statues. In the outside wall of the building is the *Kellenda*, a circular stone of basaltic porphyry, covered with hieroglyphical representations of the months of the year, which is supposed to have been used by the Aztecs as a calendar. The interior is very richly decorated with carved work, columns, statues, shrines, pictures, &c., but these are distinguished rather for their rich and gorgeous character than for elegance or beauty. The high altar is laden with a vast number of candlesticks, crosses, and religious reliques of gold and silver, and surmounted by an image of the Virgin so richly adorned with jewels as to be valued at more than half a million sterling. From the sacristy, extending round the choir for about two hundred feet, runs a railing, between four and five feet high, composed of the precious metals, very slightly alloyed with copper. It is said to be worth its weight in silver. The east side of the great square is occupied by the National Palace or Government House, formerly the residence of the viceroy, but now that of the president. It is a large quadrangular building with four interior courts, and contains, besides the apartments of the president, the public offices, the Senate-house, the two Chambers of Deputies, the mint, two barracks, two prisons, several shops, and a botanic garden. This edifice is believed to occupy the site of the ancient palace of Axayacatl, which was allotted by Montezuma to Cortez as his residence. The remaining sides of the square are formed by private dwellings, with the exception of the south-eastern corner, which is occupied by the City Hall, part of which is used as an exchange. The university of Mexico is situated near the square, and contains the National Museum; opposite which is the extensive market constructed in 1842. The Mineria, or School of Mines, in which occasional lectures are given, is an elegant building situated a little to the west of the square. These institutions, however, as well as the Academy of Fine Arts and the public library, have been very much neglected since the revolution, and are now in a declining condition. The Acordada, or public prison, is an edifice of great size and strength, capable of containing 1200 prisoners; and there is a large and well-built artillery barracks, which was formerly used as an hospital. Besides the cathedral, Mexico is said to contain between fifty and sixty churches and convents, most of them in a mixed style of architecture, and remarkable chiefly for the richness of their ornaments. The church of San Domingo is light and elegant, with a spire and dome; and near it is situated the building formerly occupied by the Inquisition, which was abolished here in 1822. The largest and most wealthy convents are those of the Franciscans and of the Dominicans; and these, along with the convents of St Augustine and La Merced, are the most remarkable edifices of that sort in Mexico. There is also a handsome theatre, and a

Political divisions.

large circular arena for the exhibition of bull-fights, called the Plaza de Toros, which has accommodation for 2000 or 3000 spectators. At the west end of the town there is a park called the Alameda, which is a great place of public resort, and has an area of 10 or 12 acres, laid out in walks and labyrinths, and adorned with numerous fine trees. There are also two other promenades or *paseos*, as they are called, one on the E. and the other on the W. of the city. These consist of the roads leading from the town, which are raised several feet above the surrounding country, and lined with double rows of fine trees, thus affording delightful promenades, which are frequented by great multitudes of the inhabitants. The one which leads to the east, called the Paseo de la Viga, skirts the Lake Chalco Canal, which adds much to the appearance of the promenade. In the city also there are several covered colonnades or arcades, which form a favourite place of resort in the evening, and are often crowded long after the other promenades are deserted. The city is supplied with water by means of two aqueducts; one of which, 11,155 yards in length, extends from Santa Fé to the Alameda, and is carried for one-third of its course on arches of stone and brick. This aqueduct supplies the city with water of an excellent quality; while the suburbs to the S. are supplied by that of Chapoltepec, which is 3608 yards in length. The manufactures carried on in Mexico are remarkable neither for quantity nor for quality; the most important being those of tobacco and plate, together with that of gold and silver lace, which is well made, and sold at a very cheap rate. Jewelry, upholstery, coachmaking, as well as the manufacture of soap, and woollen and cotton stuffs, are also carried on in Mexico; but the demand for manufactured goods is chiefly supplied by the importation from Europe of articles of all sorts, and of silks from China. These constitute the staple of the import trade; and the products of the mines are the chief articles of export; indeed, the commercial as well as the manufacturing industry of Mexico is very small, and the city derives its importance almost exclusively from its being the capital of the confederation and the residence of the president. The markets are supplied with provisions by small boats, which bring them over the Lake of Tezcoco, or over the Lake and through the Canal of Chalco.

The inhabitants of Mexico City are of several different races and characters. They consist of Creoles or descendants of the Spaniards, of Mestizos or half-castes, of copper-coloured natives, of Mulattoes, and of Europeans. Of the higher classes, many have acquired considerable wealth; but the great bulk of the people are very poor; and the lower orders, in their idleness and dirty habits, as well as in their general character, have a striking resemblance to the lazzaroni of Naples. Pop. (1850) estimated at 170,000.

There are a number of other towns in the state of Mexico. Acapulco, on the S.W. coast, was once celebrated for its wealth, and is described as a very fine seaport. It was from this place that the richly-freighted Spanish galleons took their departure to distribute the spoils of the Western over the Eastern Hemisphere. It has since sunk into comparative insignificance, and now contains only about 4000 inhabitants. Zacatula is likewise a good port on the same shore, but has little trade. Toluca, the nominal capital, is a considerable town, situated at the foot of two steep barren hills, about 27 miles S.W. from the federal metropolis. It has considerable soap and candle factories, and is noted for its hams and sausages. Tezcoco, on the eastern shore of the lake of that name, 12 miles from Mexico, is now almost desolate, and only interesting for its historical associations and ancient remains. Amongst other small towns may be mentioned Otumba, once large and flourishing, but now a mere village; Lerma, which is surrounded by an extensive morass, traversed by fine raised causeways; Chalco, a pretty large town, situated in a lake of the same name, about 20 miles S.E. of the metropolis; San Augustin, at which a great annual fair is held, frequented by vast multitudes from Mexico; Tacubaya, a village about four miles from the gates of the capital, and formerly the country residence of the Bishop of Mexico; Pachuca and Cuyoacan. Besides these places there are a number of farm-hamlets, of which Chapingo is considered as one of the finest specimens in Mexico. It is distant about a league from Tezcoco; and the lands around it are exceedingly rich and well irrigated. The buildings erected to receive the grain are on a magnificent scale; while the vicinity of the capital, in affording a ready market for the crops, renders the estate one of great value. About 60 miles from the metropolis is Cuernavaca, a place of no importance in itself, but deriving interest from the richness of the surrounding district. In the neighbouring valley of Cuautla stands the town of Cuautla Amilpas, where Morelos made so noble a stand against the royal army. In the neighbourhood of Cuernavaca is the village of Acapantzingo, entirely inhabited by Indians, who have ever kept themselves apart from the Spanish population.

Queretaro.

QUERETARO.—To the N.W. of Mexico is the small state of Queretaro, the territories of which were formerly comprehended in the neighbouring intendancies of Mexico, La Puebla, and Guanajuato. They are now divided into the six *partidos* or districts of Amealco, Cadereyta, San Juan del Rio, San Pedro Toliman, Queretaro, and Jalpam. Queretaro lies entirely on the central plateau of the Cordillera, and is intersected by numerous mountain spurs and elevated hills, some of which are entirely bare, while others are covered with forests of various kinds of wood. The agricultural portions of the state are chiefly confined to the valleys, in which the soil is frequently of great fertility. The chief mining district, and the only one of any note in the state, is that of El Doctor, in the district of Cadereyta. The inhabitants, with the exception of those of the capital, are mostly employed in agriculture. The wool of the sheep is highly prized; but agriculture here is not so important a speculation as it is in other parts of the republic. Queretaro, the capital, is a finely-situated and well-built town, with about 50,000 inhabitants. It contains some fine churches and convents, particularly that of Santa Clara, which is an immense building, said to resemble a little town in the interior, being regularly laid out in streets and plazas. This place has quite the air of a manufacturing town. More than half the houses contain shops; and the population is engaged either in small trades, or in the wool manufactories, which are very extensive. The town is well supplied with water by means of an aqueduct about 6 miles in length, for 2 of which it is elevated on arches 90 feet high. The only other towns of importance are San Juan del Rio, San Pedro de la Cañada, and Cadereyta.

Guanajuato.

GUANAJUATO.—To the westward of Queretaro is Guanajuato, the smallest state in the republic, with the exception of Queretaro, but at the same time having proportionally the greatest number of inhabitants. Large portions of the soil are of great fertility, especially the magnificent plains of the Bajio, in the southern part of the state, which extends for more than 100 miles from Apasco to beyond Leon; and in the N., where the splendid plains or *llanos* of San Felipe spread far and wide. The only river of any size is the Lerma or Tolotlan; and the only lake is that of Yurirapundaro, about twelve miles in length by two in width. The state contains three cities, four market-towns, and thirty-seven villages. The manufactures of wool and cotton, which formerly abounded in many of the towns, have recently much declined. Mining and agriculture now constitute the chief sources of wealth. The mineral productions are very valuable. The town of Guanajuato, in the vicinity of which the principal mines are situated, contains numerous splendid memorials of the former wealth of its inhabitants. Many of the private dwellings are magnificent, as are the churches, chapels, and other religious edifices. The town contains a cathedral, two chapels, several monasteries and nunneries, a college, a theatre, barrack, mint, university, gymnasium, and about 50,000 inhabitants. Celaya City is a considerable town, containing about 15,000 inhabitants. The town of Irapuato has a population of about 16,000 souls, and contains some fine public buildings, particularly the nunnery called De la Enseñanza. There are a few cotton-spinners and weavers, but the bulk of its population consists of agriculturists, who reside in the town, and have estates in the vicinity. Salamanca is likewise a considerable place, situated in a rich part of the country, and has a population of about 15,000. San Miguel Allende, formerly San Miguel el Grande, is a pleasantly situated town on the river De la Laja, and contains about 5000 inhabitants.

Jalisco.

JALISCO or GUADALAJARA.—To the westward of Guanajuato, and stretching along the Pacific for 480 miles, is the large state of Jalisco, formerly Guadalajara. It is divided into eight districts, viz., Guadalajara, Lagos, La Barca, Sayula, Etzatlan, Autlan, Tepic, and Colotlan; and these, again, are subdivided into 26 departments, containing in all 318 pueblos, 387 haciendas, and 2534 ranchos. The greater part of Jalisco lies on the western slope of the Cordillera; and its table-lands, which resemble those of the great plateau of Mexico, are somewhat broken up by mountain ranges. The upper regions are consequently comparatively sterile, while the low lands are rich and fruitful. The sierras of Bajona, in the N.E. of the state, are its most remarkable mountain ranges. The principal stream is the Rio Grande de Santiago; but during the six months of the dry season its waters are either extremely shallow or disappear altogether. The Lake of Chapala, about 45 miles from the city of Guadalajara, is about 100 miles in length by 15 to 25 in breadth. The city of Guadalajara, capital of Jalisco, is situated upon an extensive plain about 450 miles from Mexico. It is built with great regularity, the streets running at right angles, being well paved, and having raised pathways on each side. The houses, with the exception of those in the suburbs, are finely built. There are fourteen squares, twelve fountains, and a number of convents and churches, the principal of which, the cathedral, is still a magnificent building, although it suffered severely in an earthquake which occurred in 1818. The Alameda, or public walk, is very prettily laid out, with a fountain in the centre, and a stream of water all round. Within the town the Portales de Comercio, erected on every side of those immense squares of houses, are the principal rendezvous; as, besides a number of handsome shops well provided with European and East Indian manufactures, they contain a number of stalls covered with a great variety of domestic productions. Considerable quantities of shawls of striped calico were formerly made here; but these home manufactures have been superseded by importations from the United States. Jalisco derives little benefit from its foreign trade, San Blas, the only seaport which it possesses, being nearly abandoned. Foreign goods are introduced overland from San Luis or Mexico. The population of the capital amounts to about 50,000 souls. The town of San Juan de los Lagos, situated in a deep ravine upon a river of the same name, is noted for an annual fair held here, which lasts for eight days, commencing on the 5th December. The town of Tepic is, next to the capital, the finest and most populous town in the state, and has a population of about 15,000. The only mining region of any note in this state is that of Bolaños.

Mechoacan.

MECHOACAN.—The state of Mechoacan is bounded on the N. by Guanajuato, N.E. by Queretaro, S.E. by Mexico, W. by Jalisco, and S.W., for a short distance, by the Pacific. It lies chiefly on the western slope of the Cordillera, and its surface is considerably broken by mountains and valleys. The land is abundantly watered by streams and rivers, and incloses a great number of lakes. This state contains 2 cities, 3 towns, 256 pueblos, 333 haciendas, and 1356 ranchos, and is distributed into 83 parishes and 21 districts. The former riches of the state consisted almost entirely in its agricultural produce, the most ordinary manufactures being introduced from the neighbouring towns of the Bajio. But the agricultural interest is by no means in so flourishing a condition as it once was, nor are the mines remarkable either for their extent or their value. The whole western declivity of the Sierra Madre, comprehended within the province of Mechoacan, is noted for its insalubrity; and the sea-coast, as might be expected, is likewise very unhealthy. The *tierra caliente*, at the foot of the Cordillera, which is fertilized in part by the Rio Balsas, is rich in all the ordinary productions of the tropics; and even in the more elevated valleys sugar was grown to a very considerable extent before the revolution. The best sugar lands are now about 36 miles S. of Pasquaro, the ancient capital of the Indians. At the foot of the Mountain of Jorullo there are plantations of cocoa and indigo; and in several parts of the state the various productions of the table-land can be raised in abundance. The mining districts of the state are Tlalpujahua, Angangueo, and Ozumatlan. Mechoacan has been called the cradle of the revolution, from which it suffered severely.

Morelia, the capital of the state, formerly called Valladolid de Mechoacan, is delightfully situated at the height of 6300 feet above the level of the sea. It consists chiefly of one long, broad street, well paved, and kept in good order. The plaza is remarkable as having broad piazzas on three of its sides, and the fine cathedral, isolated from all other buildings, bounding it on the east. Here there is a crowded market, where the venders display their goods, as is the general custom throughout the republic, beneath the shade of rude mat umbrellas. All the houses have flat roofs, with long water-spouts projecting most incommodiously over the streets. Besides the cathedral, which is crowded with a profusion of ornaments, there are several other churches, two nunneries, and four monasteries, for all which, besides an hospital and other public edifices, the inhabitants are indebted to the munificence of the bishops of the see. The population has been estimated at 25,000.

Guerrero.

GUERRERO.—This state was created by virtue of the 4th article of the Acta de Reformas, passed in May 1847, amending the constitution of 1847. By this article it was agreed that the state of Guerrero should be formed of the districts of Acapulco, Chilupa, Tasco, and Tlapa, and the municipality of Coyucan,—the first three of which belonged to the state of Mexico, the fourth to Puebla, and the fifth to Mechoacan. The physical character and productions of this state correspond with those of the three states to which this region originally belonged. Its capital is Tixtla, and contains about 4000 inhabitants.

La Puebla.

LA PUEBLA.—The state of La Puebla, which is situated to the E. of that of Mexico, and stretches nearly across the continent, is divided into 25 districts, and possesses 5 cities and towns, 126 parishes, 590 villages, 412 haciendas, and 875 ranchos or farms. The territory of the state extends beyond the western ridge of the Sierra Madre, and down to the shores of the Pacific; consequently it produces in abundance the fruits either of the *tierras calientes*, or those common to the rest of the table-land. There are, however, no mines which uniformly create a home market; and as the foreign trade is comparatively of but little importance, the agricultural interest is in a depressed condition. Manufactures of wool and cotton are carried on to some extent in the state. Some parts of the state, particularly the plains of Apam, are remarkable for their fertility. La Puebla contains Popocatepetl, the loftiest mountain in North America, situated near its S.W. boundary. The capital and largest city of this state is Puebla de los Angelos, the seat of the richest bishopric in the country, and that of the most extensive manufactures of cotton, earthenware, and wool. Glass and soap are also made; the latter to a considerable extent. The streets, like those of Mexico, are rectangular, spacious, airy, and paved with large stones in a highly ornamental manner. In the centre of the town is a large well-paved public square surrounded by *portales*. The houses are low, but commodious, and the apartments are mostly paved with porcelain, and adorned with paintings in fresco. There are a great number of churches and convents, religious colleges, and a magnificent cathedral, richly ornamented, and held in high veneration, in consequence of a tradition that it owes its origin to divine interference. The principal other towns in the state are Cholula, Atlixco, Guauchinango, Tehuacan de las Granadas, Tepeaca, and Huajocingo. La Puebla City contains about 71,600 inhabitants.

Tlascala.

Tlascala, which was declared a federal territory in 1847, has an area of about 2000 square miles, and contains 1 city, 109 villages, 18 settlements, 168 haciendas, and 94 ranchos. It is divided into 3 partidos or districts, called Tlaxco, Huamantla, and Tlascala. Its soil is of considerable fertility, and its climate mild and genial. Its productions are chiefly of a cereal character. The capital, of the same name, is situated on the Rio Atoyac or Papagallo, the only stream of importance in the territory. It is well and regularly built; and has a town-hall, bishop's palace, a tastefully-built church, and a Franciscan convent. Many relics and ruins of its former glory are still to be found in the town and vicinity. At present it contains probably not more than 5000 inhabitants.

Oajaca.

Oajaca.—Oajaca is a very fine state, the southern boundary of which extends along the coast of the Pacific Ocean a distance of about 360 miles, from La Puebla to Guatemala. Agriculture is highly favoured by the fertility of the soil and the salubrity of the climate. The Cordillera, which here forms two branches, one extending along the shores of the Pacific, the other along those of the Gulf of Mexico, incloses the beautiful and fertile region termed the Valley of Oajaca, which constitutes a great part of this state. The staple productions are,—corn, chile, agave, cotton, coffee, sugar, cocoa, vanilla, tobacco, cochineal, wax, honey, and indigo; while gold, silver, copper, quicksilver, iron, rock-salt, limestone, gypsum, &c., are found in the state. In the two mountain regions separated by the valley have dwelt two Indian races from the earliest periods, known as the Mixtecas and Zapotecas, the former of which is characterized by activity, intelligence, and industry. This state is divided into 8 departments and 23 cantons, and contains 1 city, 8 towns, 913 villages, 137 haciendas, and 235 ranchos. In ancient times this state was the seat of two independent kingdoms, viz., those of Mixteca and Zapoteca. Oajaca, the capital, called *Antequera* at the time of the conquest, is a flourishing place, although it suffered severely during the revolution. It contains about 25,000 inhabitants. The best seaport in the state is Tehuantepec. About 30 miles from the capital, on the road leading to Tehuantepec, are the remains of what antiquarians have styled the sepulchral palaces of Mitla, lying in the midst of a rocky granitic region, and surrounded by sad and sombre scenery. According to tradition, they were erected by the Zapotecas as palaces or tombs for their princes. They consist of three edifices symmetrically arranged, the principal and finest having a front of nearly 150 feet. The walls are covered with figures and ornaments. The stones that compose the building are of immense size,—one of them, above one of the principal entrances, is said to be 19 feet 4 inches long, 4 feet 10½ inches broad, and 3 feet 9 inches thick, and there are others of similar dimensions. About 90 miles N. of the capital, near the village of Quiotepec, is an eminence covered in almost every direction with remains of military works of a defensive character.

Vera Cruz.

Vera Cruz.—Vera Cruz comprises a narrow strip of land stretching along the Gulf of Mexico from the state of San Luis Potosi to that of Tabasco, a distance of about 400 miles, whilst its breadth on an average does not exceed 50 or 60 miles. The eastern part of the state is generally level, low, and sandy; but it gradually rises inland until the country is broken into an uninterrupted series of lofty mountains and beautiful valleys. The coasts are rich in rivers, streams, inlets, and lagoons, but unfortunately they are of little practical use in navigation. There are several mineral springs in the state; and at Atotonilco, near Calcahualco, in the district of Cordova, there are warm baths celebrated for their efficacy in nervous and rheumatic complaints. The state is divided into four departments, viz., Vera Cruz, Jalapa, Orizava, and Acayucam.

The productions of this state are rich and varied; the differences in its altitude render it capable of yielding fruits and grains both of the temperate and torrid zone. Tobacco, coffee, sugar, cotton, corn, barley, wheat, jalap, sarsaparilla, vanilla, oranges, citrons, pine-apples, lemons, pomegranates, bananas, grapes, peaches, apricots, pears, plums, tamarinds, mahogany, ebony, cedar, oak, dyewoods, and numerous other trees, plants, and shrubs, spring almost spontaneously from the soil, and render the labour of man almost unnecessary. As the traveller ascends from the sandy tract on the sea-shore, he beholds on every side magnificent forests filled with majestic trees, and adorned by the splendid colours of flowers and blossoms. In the midst of these are farms and plantations, which gleam with the freshest verdure of cane or corn; while over the levels roam innumerable herds of cattle. There are numerous ancient remains in this state.

The city of Vera Cruz, the capital of the state, is situated on the shores of the Gulf of Mexico, in Lat. 19. 11. 52. N., and Long. 96. 8. 45. W. It is well and handsomely built of madrepore; and its red and white cupolas, towers, and battlements have a splendid effect when viewed from the sea. Many of the houses are large, being built in the Moorish or old Spanish style, and generally inclosing a square court, with covered galleries. They have flat roofs, glass windows, and are well adapted to the climate. There is a tolerably good square, of which the Government House forms one side, and the principal church another. There are other churches, as well as monasteries and nunneries. Opposite the town, at the distance of about 800 yards, is a small island containing the strong castle of San Juan de Ulloa, which commands the town. The harbour lies between the town and the castle, and is very insecure. Vera Cruz is extremely unhealthy at all times; and during the warm season Europeans are exceedingly liable to become the victims of the *vomito prieto*, or black vomit. The city is surrounded by sand-hills and ponds of stagnant water; there is neither garden nor mill near it; and the only water fit for use is that which falls from the clouds. The trade of Vera Cruz is very considerable. Alvarado, a port about 36 miles to the S.E., and which constituted the seat of maritime commerce during the revolution, is built upon the left bank of a river of the same name, at the mouth of which there is a bar, rendering it inaccessible to vessels drawing more than 10 or 12 feet of water. Large ships must consequently be loaded or unloaded by means of lighters. The trade of Mexico, however, has either reverted to its old channel, or is shared by Tampico, a port which has risen into importance within these few years. It is situated about 120 miles N.N.W. of Vera Cruz, in Lat. 22. 15. 30. N., Long. 97. 52. W., being about 312 miles from Mexico. The population of Vera Cruz amounts to about 8000.

Another town in this state is Jalapa, from which a well-known drug takes its name. Formerly it was the great mart of New Spain for European goods, as the unhealthiness of Vera Cruz compelled traders to transfer their merchandise at once to this city, where a great annual fair was held. It has now, however, little commerce of its own, and is only a sort of resting-place between Vera Cruz and Mexico. Jalapa is indebted to the peculiarity of its position for the extreme mildness of its climate. The town stands upon a little platform 4500 feet above the level of the sea, and is protected from the N.W. winds by a ridge of mountains. The height is exactly that at which there is a continual humidity in the atmosphere; but this only imparts a balmy feeling to the air, whilst it gives a delightful freshness to the face of nature. The town is neatly built, although the streets are irregular; and the houses, without being remarkable for their size, are of a superior order. Jalapa is the seat of government for the state of Vera Cruz, and here a large garrison is kept. The population is about 16,000.

San Luis Potosi.

San Luis Potosi.—To the N.W. of Vera Cruz lies the state of San Luis Potosi, under which name, as a Spanish intendancy, were included Cohahuila and Texas, New Leon, Tamaulipas, and San Luis. The western portion of the state is quite mountainous, but towards Tamaulipas the Cordillera is somewhat broken, and a lower hilly country stretches out towards the S.E. The Panuco and the Santander are the only rivers, and the lagoons of Chariel and Chila the only two lakes of importance in the state. The climate of the mountain region and table-land is cold; while that of the lower elevations and flats towards the eastern boundary is much warmer, and at certain seasons very unhealthy. Maize, wheat, barley, and fodder are the principal agricultural productions of this state. Cattle are raised in large quantities. Wool and cotton fabrics, glass, leather, pottery, and hard wares are manufactured here to a considerable extent. The state of San Luis Potosi is divided into four departments, ten cantons, and fifty-two municipalities. In this state there are a number of rich mines, particularly those of Catorce, where a metalliferous ridge of mountains extends for many miles. Recently a profitable quicksilver mine was discovered in the jurisdiction of the hacienda of Villela, S. of the capital. With the exception of the capital, which bears the same name, it possesses no large town. San Luis, including the suburbs, contains about 35,000 inhabitants. It is well built, and contains a number of churches, monasteries, and public buildings. The exterior architecture of the sacred edifices is generally heavy, being overloaded with carved ornaments and ill-executed statues of saints; yet at a short distance they give a magnificent appearance to the town. The palacio, now the house of the provincial Congress, forms one side of the Plaza de los Armas, which has an excellent fountain of water in the centre. The *parroquia*, or cathedral, occupies a portion of the opposite side, and on its right are the soldiers' quarters. The two other sides are filled with shops and dwelling-houses. San Luis derives great advantage from its situation, as the natural depôt for the trade of Tampico with the northern and western states. Zacatecas, Durango, and other states receive through this channel a large proportion of their foreign imports; and since the building of the new town of Tamaulipas, which, from being on a more elevated spot than the old town (*pueblo viejo*) of Tampico, is less subject to the vomito, there is every appearance of a rapid increase in this branch of commercial intercourse.

Zacatecas.

Zacatecas.—To the W. and N.W. of San Lúis Potosi is situated Zacatecas, a state divided into eleven districts, viz., Zacatecas, Aguas Calientes, Sombrercté, Tlaltenango, Villanueva, Fresnillo, Jerez, Mazapil, Nieves, Piños, and Juchilipa. Zacatecas is a mountain country of the high plateau of Mexico, cut up by spurs of the Cordillera, and mostly arid and inhospitable. The region between San Luis Potosi and Sombrereté, and Mazapil and Zacatecas, is a broad plain, interspersed with a few swelling knolls and an occasional group of hills or small mountains. There are no rivers of any size in this state, and the country is unusually dry; water-tanks, draw-wells, and reservoirs are established on all the estates. The country, however, is particularly rich in its mineral productions, which constitute almost its sole wealth. Manufactures there are none, excepting in the capital, where there are a few cotton-spinners, as also at Aguas Calientes.

Zacatecas, the capital, is situated at the foot of an abrupt and picturesque porphyritic mountain, upon the rugged summit of which is perched a neat church and a small fortress. From the inequalities of the ground on which it stands the streets are short and crooked. Besides a very noble cathedral, it contains a number of churches and convents. Amongst the public buildings worthy of notice may be mentioned the mint, the finest in Mexico, and La Casa del Ayuntamiento, a magnificent edifice, where all the public offices are established, and where the Congress of the state assembles. This town contains about 25,000 inhabitants; and Veta Grande, a village in its immediate vicinity, numbers about 6000. Aguas Calientes is a small town situated on the banks of a stream of the same name, in a broad and fertile valley, 75 miles S. of Zacatecas. It is celebrated for its woollen manufactures; and in the neighbourhood are several thermal springs.

Yucatan.

Yucatan.—The state of Yucatan occupies the greater portion of the peninsula which separates the Gulf of Mexico from the Caribbean Sea. It is a vast alluvial plain, intersected by a mountain ridge which does not exceed 4000 feet in height. Upon some parts of this extensive territory maize, frijoles, rice, cotton, pepper, tobacco, and the sugar-cane are produced, besides dyewood, hides, and other articles. In the central parts the want of water is a very serious drawback to agriculture: the rainy season is very uncertain, and in many parts not even a stream is known to exist; so that in unfavourable years the inhabitants are compelled to have recourse for subsistence to the roots which the woods supply. This state contains numerous remains of ancient cities, which have been recently visited and described by Mr John L. Stephens and Mr Catherwood. The capital of Yucatan is Merida, situated on an arid plain 40 miles from the coast. It enjoys little trade, and contains only about 12,000 inhabitants. Campeachy is the principal commercial town; and here the logwood, which goes by the same name, attains its greatest perfection. The town contains about 9000 inhabitants.

Tabasco.

Tabasco.—Adjoining Yucatan is Tabasco, one of the smallest in the confederation, and previous to the revolution a province of the intendancy of Vera Cruz. A great portion of the state is extremely flat, and during the rainy season is laid under water, so that intercourse between the villages has to be carried on by canoes. The state is watered by numerous streams; but they are generally short and shallow, and have their mouths obstructed by bars. On the eastern boundary of Tabasco is the Laguna de Terminos, which is 45 miles long by 30 broad, and contains several large and beautiful islands. The climate of this state is exceedingly hot. Cacao, coffee, pepper, sugar, tamarinds, arrowroot, and some tobacco are cultivated; while indigo and vanilla grow wild in the forests. Game is very abundant, and the streams are well stocked with excellent fish. The capital, San Juan Bautista or Villa Hermosa de Tabasco, lies on the left bank of the Tabasco River, 70 miles from its mouth, and contains about 7000 inhabitants. Vessels of light draught can reach it from the sea; but its chief intercourse is carried on with the adjacent states and Guatemala.

Las Chiapas.

Las Chiapas.—Between Tabasco and Guatemala is situated the state of Las Chiapas, which formerly belonged to Guatemala, but which in 1833 joined the Mexican confederation. Comprehending the northern slopes of the table-lands of Guatemala, Las Chiapas is, throughout a considerable part of its territory, cut up into successions of ridges and valleys, which are rich in many of the finest tropical productions. It is divided into four departments and nine districts. The most important of the numerous rivers flowing from the mountains near the state of Tabasco to the Gulf of Mexico, are the Tabasco River, the San Pedro, the Usumasinta, and the Pacaitun. The climate of Las Chiapas is mild and temperate; and the chief productions are corn, cacao, sugar, tobacco, figs, apricots, and other fruits and vegetables; but a great part of the state is uncultivated and unexplored. The state is divided into four departments, and the capital is Ciudad Real, or San Cristoval de los Llanos, a handsome town, containing a cathedral, two chapels, four monasteries, a nunnery, and an hospital; with a population of 6000. The state of Las Chiapas, like that of Yucatan, contains many ancient remains.

Durango. DURANGO.—The state of Durango is bounded on the N. by Chihuahua, W. by Sinaloa, E. by Coahuila, and S. by Zacatecas and Jalisco. The main branch of the Great Cordillera runs through this state in a N.W. direction. The north-eastern portion of the state slopes gradually downwards towards the waters of the Rio Grande, while the south-western part consists chiefly of lofty table-lands and mountain spurs. The climate is healthy and cool; and its agricultural productions are similar to those of the other states in like circumstances. The chief rivers are the Rio Nasas, Rio Guanavas, and the Rio Florida; and the lagoons of Cayman and Parras are on its borders. Immense quantities of horses, mules, sheep, and cattle are reared in this state; indeed, its cattle and minerals constitute its chief wealth. Iron, silver, gold, lead, and other minerals are likewise abundant.

Durango, or, as it is often called, Victoria, the capital of the state, is situated 180 miles to the N.W. of Zacatecas, in the midst of a vast plain. Both the city of Victoria and most of the other towns of Durango, as Tamasula, Sianori, Mapimi, San Dimas, Canelas, Cuencamé, and others, take their origin from the mines. Before the discovery of those of Guarisamey, Victoria was a mere village, and in 1783 it contained only 8000 inhabitants. Its population now amounts to about 22,000. The principal streets, the Plaza Mayor, the theatre, and most of the public edifices, were built by Zambrano, a wealthy proprietor, who is supposed to have drawn from his mines at San Dimas and Guarisamey upwards of 30,000,000 of dollars. The towns of Villa del Nombre de Dios, San Juan del Rio, and Cinco Señores de Nazas are almost the only considerable places in the state unconnected with the mines. The great mineral wealth of this state holds out the most encouraging prospect of ample remuneration to those who engage in mining speculations; and there can be little doubt that ere long the advantages which Durango possesses will be duly appreciated by foreign or native associations of capitalists.

Chihuahua. CHIHUAHUA.—The state immediately adjoining Durango to the N. is that of Chihuahua. The great mountain chain of Mexico, which forms the connecting link between the Rocky Mountains of the north and the Andes of the south, is here known as the Sierra Madre, and occupies chiefly the western part of the state, where its elevation attains a great height, and at length descends abruptly till it is lost in the plains of Sonora and Sinaloa. The highest point of the Sierra Madre is said to be 8441 feet above the level of the sea. The greater portion of the state consequently lies on the plateau of Mexico, and only a small part of it on the western slope of the Sierra Madre. It is watered by a considerable number of rivers and streams; and the principal of its lakes or lagoons are those of San Martin, Guzman, Patos or Candelaria, Encinillas, and Castilla. Large numbers of the aborigines still occupy the lonelier portions of this state, and frequently annoy the peaceful settler. Chihuahua possesses a mild and temperate climate, a fertile soil, and vast mineral resources. Agricultural operations are not much carried on here, the chief source of its wealth being the mines and cattle. The gold, silver, and copper mines are exceedingly productive. Veins of iron, cinnabar, lead, sulphur, coal, and nitre have been found and explored, but owing to the disturbed and insecure condition of the state, are altogether abandoned. (For an account of CHIHUAHUA, the capital, see the article under that head.)

Sinaloa. SINALOA.—The state of Sinaloa is bounded on the S. by Jalisco, E. by Durango, S.W. by Chihuahua, N. by Sonora, and W. by the Pacific and the Gulf of California, along the shores of which it extends for about 200 leagues. The River Cañas divides it from Jalisco, and the River Mayo from Sonora. It is about 540 miles in length from S.E. to N.W., and has a breadth of about 150 miles. The surface is partly mountainous and partly level coast land. The coast region is little cultivated and thinly inhabited, being scorched by a burning sun; the central and eastern parts contain numerous table-lands and valleys; while the slopes of the mountains are thickly wooded with excellent timber. In the interior the air is mild and genial: in those parts where irrigation is practised abundant crops of grain are raised. Wheat, Indian corn, and barley, with cotton, sugar, and tobacco, are its chief agricultural productions. This state is also rich in minerals. The principal town is Mazatlan, a seaport-town and a place of considerable trade. It contains about 6000 inhabitants.

Sonora. SONORA is situated on the Gulf of California to the N. of Sinaloa. The western and southern portions of the state are generally flat. The eastern portion is mountainous, but contains many fine and productive valleys; this portion of the state is likewise rich in valuable mineral deposits. In the S., between the Rivers Mayo and Yaqui and the Presidio of Buena Vista, there is a fruitful region, which is also enhanced by a number of small lakes which form in different parts during the rainy season, and which are turned to good account by the agriculturists in the irrigation of their farms. The climate is warm throughout the year, but in spring is subject to rapid changes in temperature. A great portion of this state is still in the possession of the Indians, most of whom are still in a wild and savage state. The trade of Sonora is principally carried on at Guyamas, which is situated in a healthy region, and possesses one of the best harbours in Mexico. It contains about 3000 inhabitants. Petic, about 120 miles N.N.E from Guyamas, is a larger town, containing about 8000 inhabitants. It is the depôt for goods imported at the Guyamas, and designed for the northern district of Mexico.

Tamaulipas. TAMAULIPAS.—This state extends along the shores of the Gulf of Mexico, southward from the Rio Grandé del Norte, which separates it from the North American state of Texas. It has a coast-line of about 350 miles, and its breadth varies from 50 to about 160 miles. The coast is low and sandy, and fringed with lagoons varying from 4 to 18 miles in width, and divided from the gulf by banks of sand. The shallowness of the shores, and the dangerous bars which obstruct the mouths of the rivers, render navigation difficult and dangerous. In the northern part of the state, in the neighbourhood of the Rio Grandé, the country is comparatively level. South of this, however, and at some distance from the coast, the surface is varied by a succession of mountains, hills, and valleys, which gradually slope westwardly to the flats and sands of the sea-coast. The Cerro de Martinez, the Cerro de Jeres, the Cerro del Coronel, and the Sierras de la Palma and del Carico, are the

Political divisions.

most remarkable elevations. The territory is in general well watered; and fine valleys extend along the Rio Grandé, the Tigré, Borbon, Panuco, and Dolores. On the coast are the lagoons of La Madré, Morales, and Tampico. The climate of the interior is mild and healthy, but on the coast an intense heat prevails during the greater part of the year, which, combined with the rank vegetation and moisture, renders this region very unhealthy. The principal ports are Tampico de Tamaulipas and Metamoros, where a large coasting and foreign commerce is carried on to supply the middle and northern states of the republic. Matamoros is situated on the right bank of the Rio Grandé, about 30 miles from its mouth, and contains about 12,000 inhabitants. Tampico stands on the northern bank of the Panuco, about 5 miles from its mouth. The capital of the state is Victoria, formerly Santander, and contains about 12,000 inhabitants. Numerous remains of ancient edifices, &c., exist in this state.

New Leon.

New Leon.—To the westward of Tamaulipas lies the state of Nuevo Leon, which was colonized in the end of the sixteenth century by the Viceroy Monterey, who bestowed upon it the proud title of El Nuevo Reyno de Leon, or the New Kingdom of Leon. It lies among the first spurs or ridges of the Sierra Madré, and is interspersed with wide plains and fruitful valleys. The principal rivers, all of which flow easterly towards the Gulf of Mexico, are the Rio Tigré, San Juan, Rio Blanco or Borbon, and the Sabinas. The climate, except among the higher mountain ranges, is warm but salubrious. Agriculture has not been much practised in the state, the chief occupation of the landholders being the grazing of cattle. Lead and silver are said to be abundant; but mining operations are only carried on at two places, Cerralvo and Vallecillo. Salt is made at the salt mines on the banks of the Tigré. The capital of the state is Monterey, estimated to contain about 13,000 inhabitants.

Colima.

Colima.—This territory lies along the shores of the Pacific, and is bounded on the other sides by Jalisco and Mechoacan. Its surface is generally level, and here and there broken by ranges of hills. On the N.E. corner of the territory is the Mountain of Colima, the most western of the Mexican volcanoes, and which rises to the height of 9200 feet above the level of the sea. The climate is warm, and on the coast hot, but not unhealthy. Cotton, sugar, tobacco, and cacao are its chief agricultural productions; while on the coast large quantities of salt are made from sea-water. Rich iron deposits have recently been found here. The chief town is Colima, about 6 miles S. of the volcano, and containing about 20,000 inhabitants. Manzanillo, the port of Colima, is about 17 leagues W. of the capital, and a place of some trade.

Cohahuila

Cohahuila.—Adjoining to New Leon and Tamaulipas is Cohahuila, which is generally elevated, and being well sheltered from the N.W. winds, possesses a healthy climate. A considerable mountain chain stretches across the state in a north-westerly direction, and its surface is most luxuriantly irrigated by the numberless springs and streams which, bursting from these ridges, become tributaries to the Rio del Norté. Its pastures are clothed with rich natural grasses, and are admirably calculated for breeding, rearing, and fattening cattle; whilst its forests furnish abundance of wood, which is well calculated for every kind of construction. There are mines of saltpetre, copperas, alum, lead, tin, and copper, besides some silver in Santa Rosa, and gold in Sacramento. These mineral treasures, for want of population and of capital, have been rather ascertained than explored. The inhabitants are almost wholly of the white race, or with such slight mixture of the Indian blood as to make no distinction in colour worthy of notice. The native tribes within the province have been extinguished; but on the borders towards the N. and W. are several warlike tribes of Indians. In these parts also there are droves of wild cattle and horses, and herds of buffaloes. The capital of the state is Leona Vicario, or Saltillo, a large town containing about 20,000 inhabitants. It is situated upon the side of a hill branching off from the Sierra Madré, which in this quarter presents nothing but barren rocks; whilst the intervening valleys or plains are all nearly destitute of vegetation. The inhabitants are chiefly occupied in agriculture, and produce excellent wheat and barley, and great variety of fruits. The vines cultivated here make wine of very excellent flavour, and considerable strength.

Lower California.—The territory of Lower California comprehends that long narrow strip of land which extends from the northern boundary of the republic southward to Cape St Lucas, having on the E. the Gulf of Mexico and on the W. the Pacific. It is about 700 miles in length, and varies in breadth from 30 to 100 miles. The surface consists of an irregular chain of rocks, hills, and mountains, which run through its entire length, and which attain a height of nearly 5000 feet. Amid these ridges there are occasionally found a few sheltered spots of productive land; but it is for the most part a barren, dreary waste, and is one of the most unattractive countries in the warm or temperate regions. There are few streams or springs, few trees of any size; and the heavy rains, falling on the central ridges, carry down the sloping sides of the peninsula almost all the cultivable soil. Valuable mines of gold, silver, copper, and lead are known to exist in the peninsula, but only a few of these are worked, and that in a rude manner. The salt mines on the island of Carmen, in the Gulf of Mexico, are very productive. Among the islands of the gulf immense numbers of seals are constantly found, and the whaling grounds on the Pacific coast are of great value. During the sixteenth century the pearl fishery in the gulf produced a valuable revenue, but it has now dwindled into insignificance. The coasts of Lower California are flat, sandy, and irregular, frequently indented by coves, inlets, and bays; while many islands lie near and border them in the gulf. The climate is regarded as not unhealthy; the winter is short, and frost and ice are unknown. The heat of summer, however, is intense, parching the thin soil, and rendering life almost insupportable in the most exposed regions, or in the narrow and confined glens. The principal ports on the W. coast are San Quentin, which is said to afford a secure anchorage for the largest vessels, and Magdalena, which is much resorted to by whalers during the winter season. The only towns of importance in the peninsula are Loreto and La Paz; the latter the capital and seat of government. The population is almost entirely Indian or of a mixed race.

MEXICO, New, one of the territorial governments of the United States of America, is situated between Lat. 31. 20. and 38. N., and Long. 103. and 117. W., and has a length from E. to W. of 700 miles, and an average breadth of 400. It is immediately S. of the territories of Utah and Kansas, W. of Texas and the Indian territories, and has the Mexican States to the S., and California to the W., separating it from the Pacific Ocean. Its area, including a late addition, is 234,507 square miles, being five times the extent of the state of New York.

The Rocky Mountains cross the New Mexican territory from N. to S. The mountains of Guadalupe, Sacramento, Organ, Sierra Blanca, &c., are diverging ranges from the main chain of the Rocky Mountains. Among the Sierra Madre Mountains a height of 10,000 feet is reached above the high table-lands of the Rio Grande. This river, formerly called Rio Bravo del Norte, is the largest in the territory, draining the great valleys of the Sierra Madre and the Jumanes, &c. The Pecos River drains the eastern slope of these mountains; the Gila runs directly westward to the Colorado from its source on the Sierra Madre. The other rivers are,—the Puerco, the Canadian, Salinas, San Pedro, San Francisco, Colorado; none possessing much importance for navigation, except, perhaps, the Colorado. The Rio Grande, after it enters Texas, may be navigated many hundred miles by steamers. From the great elevation of New Mexico, it has a temperate climate. Some of the mountain-peaks are crowned with perpetual snow. Rains fall between July and October; but the country is too much parched, with the exception of a few favoured valleys, to hope for much agricultural development. More thorough explorations are, however, needed to pronounce absolutely in regard to it. In 1846 a military reconnoissance was made of it by Major Emory of the United States army, which is published among the official reports of the government. The notes are very full and interesting, and the following is a digest from them:—

"The country to-day is rolling, almost mountainous. Grass begins to show itself; the soil is good enough apparently, but vegetation is stunted. Our eyes for the first time are greeted with waving corn; all the intermediate country is broken and covered with a dense growth of pine, piñon, and cedar. The hills rise 1000 feet above the road. Found excellent grass on the Rio Pecos. Mountains rise from 1000 to 2000 feet above the road. Scenery wild; granitic sands and rocks in abundance on the road to Santa Fé. Cedar and pines are crowded together. Halted in a valley covered with some grama and the native potato in full bloom. On leaving the narrow valley of the Santa Fé, the country presents nothing but barren hills, utterly incapable, both from soil and climate, of producing anything useful." Referring to the Rio del Norte:—"The river impinges close to the hills below La Joya; two sand-hill spurs, overlaid with fragments of lava and trap, close the valley, just leaving space in the river to pass between. On either side is excellent grass, shaded by large cotton woods. The whole prairie is the loveliest I have seen in New Mexico. The valley of the Del Norte, as we advance, loses what little capacity for agriculture it possessed. The plants of New Mexico are,—Cacti of endless abundance and gigantic size, the disagreeable *Larrea mexicana*, *Obine canescens*, *Tessaria borealis*, *Diotis lanata*, *Franseria acanthocarpa*, varieties of mezquite, a species of *Malva Convolvulus*, an unknown shrub found in the bed of all deserted rivers, large grama nearly equal to oats, and *Dalea formosa*, a branched shrub, 3 feet high, with beautiful purple flowers. The table-lands to the west are covered with sand and large round pebbles. The soil of New Mexico is in general barren, but in many places adapted to the culture of the grape. On the whole, however, this territory may be regarded as an important military possession of the United States. Wherever the eye wanders huge mountains are seen, of black volcanic formation, of very compact argillaceous limestone, tinged at times with scarlet from the quantities of red felspar. Through these the Gila has cut its way with infinite labour, assisted by the influx of the Prieto, the Azul, and San Carlos rivers. The Prieto is said to flow down from the mountains freighted with gold, its sands being impregnated with the precious metal. The Gila now presents an inhospitable look; the mountains of trap, granite, and red sandstone cluster together in irregular and confused strata. The valley, not more than 300 feet from base to base of these perpendicular mountains, is deep and well grown with willow, cotton-wood, and mezquite. The Gila and San Pedro meet in a deep bottom overgrown with cotton-wood, mezquite, chamiza, willow, and black willow. There is little or no grass; and the formation along the river is a conglomerate of sandstone, lime, and pebbles, with deep caverns. The precipices are of granite and limestone, with seams of basalt and trap; vast boulders of pure quartz at times obstruct the way. The whole of North Mexico, embracing New Mexico, Sonora, &c., as far north as the Sacramento, is the same in physical character, and differs little in climate or products. Nowhere can fertilizing showers be relied upon to any extent for the cultivation of the soil. The earth is destitute of trees, and in great part of any vegetation. A few feeble streams flow in different directions from the great mountains that traverse this region. These streams are separated by mountains, or by plains without water or vegetation, and, so far as they are useful to man, may be called deserts. Culture is therefore confined to those narrow stripes of land which are capable of irrigation, and is conducted only on the sternest principles of coercion."

The whole of the New Mexican territory probably abounds in mineral wealth, which will doubtless be rapidly developed. Gold is found frequently on the Rio Grande and the Colorado, and mines have been worked in different localities. Copper, iron, and gypsum are found, and also coal and lead. A mining company in New Mexico (1857) reports as follows:—

"We are progressing well in our explorations and operations. The Aravaca rancho lately purchased for the company contains many silver mines of rich ores, besides some gold placers and copper and lead mines. We have lately discovered and occupied ten veins of silver ore near the Ceno Colorado, between Sopiri and La Aravaca, of promising richness. The principal vein, named in honour of our old friend and president 'The Heintzleman Mine,' yields upon assay thirty marcos to the carga of 300 lb., or nearly L.20 in silver to the 100 lb. ore. The ore is abundant, and we have a force of Mexican miners employed in its extraction, but have no bellows or means of smelting and refining."

When the census of 1850 was taken, it appeared that there were 3750 farming interests in New Mexico, containing 166,201 acres of improved, and 124,370 acres of unimproved land; the farms were valued at L.350,000, and the implements at L.16,200; the average value of these interests being but L.96, or $\frac{1}{12}$th the value of those in New Jersey, and $\frac{1}{15}$th the value of those in Louisiana. The following were the leading agricultural products:—Horses, asses, and mules, 13,733; neat cattle, 32,977; sheep, 377,271; bushels wheat, 196,516; Indian corn, 365,411 bushels; hay, 373 tons; 15,688 bushels peas and beans; 4236 gallons molasses; 8467 lb. tobacco; 32,901 lb. wool; 2363 gallons wine. Total value of property in the territory, L.1,000,000.

The capital invested in manufactures in 1850 was L.13,000; raw material used, L.23,000; product, L.52,000. The particulars are not published.

The commerce of New Mexico amounts to very little, and the annual imports for the United States were said to reach in 1846, L.100,000. This commerce constituted what was called the Santa Fé trade, and was conducted overland from Missouri in waggons. The most of the waggons, however, continued on their way to the Mexican provinces of Sonora and Chihuahua; and the whole extent of the commerce reached several millions of dollars. Much of it is now conducted by the way of Texas and the Rio Grande. Santa Fé, the chief town, had in 1850 a population of 4846, and San Miguel, 2008. Major Emory considered the inhabitants as the poorest in the territory, and says that the houses are built of mud or bricks, and in the Spanish style, generally of one storey, but very comfortable within. The thick walls make them warm in winter and cool in summer. The city is dependent upon the distant hills for wood. Every description of produce is dear.

In 1850 there were 73 churches in the territory, all Roman Catholic, possessing property to nearly the value of L.20,000, and having accommodation for 28,160 persons. The number receiving education was 466; and 25,089 persons over twenty years of age, or 61 per cent. of persons of that age in the territory, could neither read nor write. Two newspapers were published, circulating annually 38,800 copies. Pop. (1850) exclusive of Indians,—whites, 61,525; free coloured, 22; total, 61,547. The number of dwellings was 13,453. Of the total population, 58,415 were born in the territory, 772 in other parts of the United States, about 370 in Great Britain, and 215 in Germany; total foreign, 2063. The Indian population was 45,000 or 50,000.

The government of New Mexico consists of a governor appointed by the president of the United States, who is also superintendent of Indian affairs; a council of 13 members, elected every two years; and an assembly of 26 members, elected annually. The judiciary are appointed by the president.

Scattered throughout this extensive territory are many curious and extensive ruins, the relics of an advanced population of Indian or Aztec origin long since passed away. It constituted a Mexican province until conquered and purchased by the United States. In 1850 the territorial government was created; and in four years afterwards its dimensions were increased by the purchase of what is called the Wessilla Valley, embracing about 27,000 square miles. The territory has been making but small advances in population or wealth, and it will be long before it can take an important place in the affairs of the nation.

MEYER, FELIX, a landscape painter, was born in 1653 at Winterthur, canton of Zürich, Switzerland. After receiving lessons in his art from a painter at Nuremberg, he studied under Ermels, whose style he adopted. He then visited Italy for a short time, but finding that the climate did not agree with his health, he returned to Switzerland, and found free scope for the exercise of his genius in depicting the sublime scenery of his native country. He was remarkable for the ease and rapidity with which he executed his designs; and these qualities on one occasion were the means of extending his fame beyond the limits of his own country. Having arrived in the course of his travels at the Abbey of St Florian in Austria, he was requested by the abbot to give his advice about two large rooms which he wished to have painted in fresco; a work which the artist he had employed seemed unable to perform. Meyer immediately began to describe the designs he would recommend; and as he went on, with a piece of charcoal in his hand, rapidly sketching the various objects of the landscape, he excited the admiration of the abbot to such a degree that he engaged him to paint the whole. Although the landscapes of this artist are deservedly famous, he was not so successful in painting figures; and in some of his pictures those parts have been done by Melchior, Roos, and Philip Rugendas. Meyer died in 1713.

MEYER, *Johann Heinrich*, a German artist, was born in 1759 at Stäfa, on the Lake of Zürich, in Switzerland. He studied at Zürich under Füssly for some time; and in 1784 went to Italy. At Rome he met Goethe, with whom he formed a friendship so close, that the artist generally went by the name of "Goethe-Meyer." He also visited Naples, Venice, and other places, and returned to Switzerland in 1787. In 1792 he went to Goethe at Weimar, where he was made professor in the School of Design; and in 1795 he visited Italy again, and lived in Naples and Florence till 1797, when he returned through Switzerland to Weimar. Here he lived for many years in close and familiar intercourse with Goethe, whom he assisted in many of his works on art. Meyer was appointed in 1807 director of the academy of Weimar; and died at Jena in 1832. His paintings are few. The most important are an allegorical frieze in the palace of Weimar, and some drawings and water-colour sketches of ancient remains and the works of the old masters. He is chiefly famous as a writer on art, and his principal work is entitled *Geschichte der Bildenden Künste bei den Griechen*, Dresden, 2 vols., 1824. A third and a posthumous volume, in continuation of the history of art, especially in Rome, was edited by Reimer, and published at Dresden in 1836. He also edited the works of Winckelmann in 8 volumes.

MEYER, *Jacques*, a historian, was born in 1491 at Vleteren, near Bailleul in Flanders. After receiving his education at Paris he entered the church, and subsequently established a school at Ypres, by which he acquired considerable renown, and which he afterwards removed to Bruges when appointed to the church of St Donatien there. This school he finally gave up when he became curate of Blankenburg, where he died in 1552. His principal works are,—*Flandricarum Rerum Decas*, Bruges, 1531; and *Annales Rerum Flandricarum*, Antwerp, 1561.

MEYRICK, SIR SAMUEL RUSH, K.H., an eminent antiquary, descended from the ancient family of the Meyricks of Bodorgan in Anglesea, was born on the 26th August 1783. After taking his bachelor's degree at Queen's College, Oxford, at the age of twenty he made what his father considered an imprudent marriage, which led to his being disinherited. Meyrick practised law for many years in connexion with the Ecclesiastical and Admiralty courts. In 1810 he published his first work, the *History and Antiquities of the County of Cardigan*, when he was chosen a fellow of the Society of Antiquaries; and in 1814 he produced, in conjunction with Captain C. H. Smith, a work on the *Costume of the Original Inhabitants of the British Islands*. But the great work on which his fame as an antiquary particularly rests is his Arms and Armour, published in 3 vols. 4to, 1824, under the title of *A Critical Inquiry into Ancient Armour as it existed in Europe, but more particularly in England from the Norman Conquest to the reign of King Charles II.; with a Glossary of Military Terms of the Middle Ages.* After having rendered material assistance in 1826 in arranging the arms and armour of the Tower, and of the collection at Windsor, Meyrick had the honour of receiving from William IV. in 1832 the Hanoverian order, and was shortly afterwards made a knight-bachelor. In 1828 he built Goodrich Court on the Wye, arranged specially for the display of his collection of ancient armour, of which Joseph Skelton in 1830 gave an account in his *Engraved Illustrations of Ancient Armour*. Meyrick's last work of any importance was *Lewis Dwnne's Heraldic Visitation of Wales*, completed in 1846. Besides assisting in the compilation of Fosbroke's *Encyclopædia of Antiquities*, and writing the descriptive matter of Shaw's *Specimens of Ancient Furniture*, Sir Samuel R. Meyrick was a frequent contributor to the *Archæologia*, the *Gentleman's Magazine*, the *Analyst*, the *Cambridge Quarterly Magazine*, and the *Cambrian Archæological Journal*. He died on the 2d April 1848, in his sixty-fifth year.

MEYWAR. See OODEYPORE.

MÈZE, a seaport-town of France, in the department of Herault, is situated on the lagoon of Thau, 19 miles S.E. of Montpellier, and 5 N.W. of Cette. The harbour, which is protected by moles, is capable of receiving vessels of 60 tons. The inhabitants are employed to a considerable extent in the manufacture of brandy and salt; and the trade in these and in corn, wine, &c., is of some importance. In the neighbourhood of Mèze is the old abbey of Vallemagne, of which the church and cloisters, built in the thirteenth century, are still in perfect preservation, and are considered equal to any similar edifice in France. Pop. 4986.

MÉZERAI, FRANÇOIS EUDES DE, an eminent French historian, the son of Isaac Eudes, a surgeon, was born at Rye in Lower Normandy in 1610, and took the surname of *Mézerai* from a hamlet near Rye. After completing his studies at Caen he proceeded to Paris, where he procured the place of commissary at war, which he held during two campaigns. He then shut himself up in the college of St Barbe, in the midst of books and manuscripts; and in 1643 published the first volume of the *Histoire de France*, which he completed in 1651. This work surpassed all previous histories of France, and its author was rewarded by the king with a pension of four thousand livres. In 1668 he published an abridgment of his History of France in 3 vols. quarto, which was well received by the public; but he inserted in that work the origin of most of the taxes, with very free reflections, which led to the withdrawal of his pension. Annoyed at this treatment, he resolved to write on subjects which could not expose him to such disappointments; and accordingly he composed his treatise on the origin of the French, which added greatly to his fame. He was elected perpetual secretary to the French Academy; and died in the year 1683. He is said to have been so extremely negligent of his person, that one morning he was actually seized by the *archers des pauvres*, or parish officers, a mistake at which he was highly diverted. He used to study and write by candle-light at noonday in summer; and even lighted his visitors to the door. Having during his life affected a sort of religious scepticism, he recanted on his deathbed, and told his friends to "remember that Mézerai dying was more to be believed than Mézerai living." His merits as a writer are not of the highest order; but his works, whilst often coarse in style, are generally clear, direct, and forcible. In addition to the works already referred to, Mézerai published,—*Une Traduction de l'Histoire des Turcs de Chalcondyle*, Paris, 1662; *Une Traduction Francaise du Traité de Jean de Salisbury, intitule "La Vanité de la Cour,"* Paris, 1640; *Traité de la Verité de la Religion Chrétienne*, translated from the Latin of Grotius, Paris, 1644; *Histoire de la Mère et du Fils*, that is, of Mary of Medicis and Louis XIII., Amsterdam, 1730.

MEZIÈRES, a town of France, capital of the department of Ardennes, is situated on the Meuse, which here, making a bend in its course, nearly surrounds the town; 120 miles N.E. of Paris, and 80 N.W. of Metz. The town is ill built. Its chief importance is derived from the strength of its position and fortifications, which consist of walls, a citadel, and other defences, by Vauban. The principal building is a Gothic church of the fifteenth century, remarkable for its handsome portals and curious bas-reliefs. There are also several other churches, an hospital, town-hall, theatre, arsenal, and other buildings. The manufactures consist of leather and cutlery; and the trade, which is inconsiderable, is chiefly in linen and woollen stuffs, and leather. Mezières was besieged in 1521 by Charles V. with 20,000 men, and was about to be abandoned and destroyed by Francis I. when the Chevalier Bayard offered to take the command, and to hold the town against the emperor. His offer having been accepted, with only 2000 men he successfully resisted for six weeks the army of Charles. Bombs are said to have been first used in this siege. In 1815 Mezières held out for two months against the Prussians, but was at length obliged to capitulate. Pop. (1851) 3970.

MEZO-BERENY, a town of Hungary, in the county of Bekes, and 7 miles N.W. of the town of that name. The inhabitants are chiefly employed in the cultivation of the vine and olive, and in the rearing of cattle. Pop. 7900.

MEZO-HEGYES, a village of Hungary, in the county of Csanad, 33 miles E. of Szegedin. This village is only remarkable for the large stud of 3000 horses established here by Joseph II. in 1785. The horses are of great excellence, and the stables are large and handsome buildings. This establishment annually furnishes, in time of peace, 1000 horses to the Austrian army. Pop. 149.

MEZO-KOVESD, a market-town of Hungary, in the county of Borsod, 7 miles E. of Erlau. The town contains two churches, a school, and barracks for cavalry. Four fairs are held here annually. Pop. 6570.

MEZO-TUR, a market-town of Hungary, in the county of Heves, on the right bank of the Beretyo, 24 miles S.E. of Szolnok. It has three churches, considerable manufactures of pottery, an annual fair, and some trade. Pop. 15,673.

MEZZOFANTI, JOSEPH CASPAR, *Cardinal*, son of Francis Mezzofanti and Gesualda dall' Olmo, was born at Bologna, September 17, 1774. His father, who was a carpenter, and who designed him for the same handicraft, placed him, while a mere child, at a dame's school, from which he was soon removed to one of the free schools of the city under the care of the brethren of the Oratory. Father Respighi, a learned and benevolent priest of that congregation, perceiving the extraordinary talents of the boy, prevailed upon his father to place him at a school of a higher class conducted by the Abate Cicotti, and eventually at one of the celebrated "Scuole Pie," from which so many eminent Italian scholars have been produced. Several of the teachers in this school were foreign ex-Jesuits,—Spanish, Portuguese, Mexican, German, and Swedish; and it was from this early opportunity of intercourse with foreigners, and of familiarity with foreign languages, that Mezzofanti's love of linguistic studies received its first impulse. He early evinced a disposition to embrace the ecclesiastical state; and though his father at first opposed this resolution, he consented in the end, and the youth entered the pontifical seminary of Bologna, probably in the year 1786. An illness, however, with which he was seized about his fifteenth year, caused a considerable interruption of his studies, and his theological course was not completed till the year 1797. Of his scholastic and collegiate studies few details, beyond the names of his preceptors, are preserved; and the only notable indication of his future eminence that has been recorded is the prodigious quickness and tenacity of his memory. On one occasion he repeated verbatim a folio page of Chrysostom after a single reading; and (although little is known of the circumstances under which some of them are acquired) it is ascertained that, before he completed his collegiate studies, he had mastered not only the Latin, Greek, and Hebrew languages, but also Arabic and Coptic, together with Spanish, French, German, and Swedish.

In September 1795 Mezzofanti was promoted to priest's orders, having just completed his twenty-third year. A few weeks previously he had been appointed professor of Arabic in the university, and he commenced his lectures in the following December. This office, however. he held but a short time. On the annexation of Bologna to the Cisalpine Republic, an oath of adhesion to the new government was tendered to all officials, civil as well as military. Mezzofanti declined to take this oath; and although an offer was made to him to dispense with the oath, provided he would but present himself at one of the semi-public reunions in the Palazzo del Governo, he persisted in his refusal, and was in consequence deprived of his chair. For many years from this time his circumstances were exceedingly straitened, as his parents, now advanced in years, and his only sister and her numerous family, depended almost entirely upon him for support, and his only resource was the precarious income derived from private tuition, chiefly in languages. In the beginning of 1803, however, he was appointed assistant librarian of the Institute of Bologna; and in the November of the same year he was reinstated in his former professorship; or rather was reappointed, with the more comprehensive title, "professor of oriental languages and of Greek;" but, in the manifold political vicissitudes of the period, he was again doomed to a disappointment similar to that which had before befallen him. The professorship of oriental languages was suppressed by a decree of the viceroy of the kingdom of Italy in the year 1808; and Mezzofanti was once more thrown upon the precarious occupation of a private teacher for support until the year 1812, when he was appointed assistant librarian of the university. On the restoration of Pius VII. in 1814, he was again installed in his professorship; and in the following year was named chief librarian of the university,—an office which he continued to hold in conjunction with his professorship as long as he remained in Bologna.

Meanwhile, his progress in languages during these years had been rapid and untiring. His sacred duties as volunteer chaplain in the hospitals, which at this time were constantly crowded with wounded or invalid soldiers of the various armies which the revolutionary war brought together in Northern Italy, placed him in communication with natives of almost every country of Europe,—French, Spaniards, Germans, Poles, Hungarians, Bohemians, Croats, Russians, Swedes, &c. Religious zeal and charity, therefore, no less than the love of learning, became for him a motive of study; and in an incredibly short space of time he was able to master all the leading peculiarities of each new language that presented itself. In 1804 he sent to the celebrated orientalist John Bernard de Rossi of Parma a series of compositions in twelve languages; and as these were most probably learned languages, it may be fairly supposed that this number by no means represented the full extent of his acquirements at that date. He himself relates that his pastime was to turn every opportunity of study to account. The hotel-keepers used to give him notice of the arrival of all strangers at Bologna, and whenever the new arrival promised to bring a new language, or any special opportunity of improvement in an old one, within his reach, he "made no scruple about calling on them, interrogating them, making notes of their communications, asking instruction in the pronunciation of their respective languages." His study of books kept pace with his cultivation of living instructors. He made it a rule to learn every new grammar, and to apply himself to the vocabulary of every strange dictionary, which came in his way. And, as his memory was not only singularly quick, but tenacious almost to a miracle, and as his faculty of analyzing and appropriating the grammatical structure of languages was all but intuitive,—an instinct rather than an intellectual effort,—it will easily be understood that, even with the scanty opportunities of practice which an inland city like Bologna afforded, his power of acquiring foreign languages was quickened or developed in the very exercise.

Accordingly, when the peace of 1815 again opened Italy to travellers, visitors from the various countries of Europe were amazed, as they arrived in Bologna, to find a provincial abbate, who had never quitted his native province, speak indiscriminately not only English, French, German, Russian, Polish, and all the leading European languages, but Turkish, Arabic, Hebrew, Greek, Persian, and the other languages of the East. When Mr Stewart Rose visited him, in 1817, he "never once, during long and repeated conversations in English, misapplied the sign of a tense—that fearful stumbling-block to Scotch and Irish." A Smyrniote servant who accompanied Mr Rose "declared that he might have passed for a Greek or Turk in the dominions of the Grand Seignior." With Baron Zach, the celebrated astronomer and editor of the *Correspondance Astronomique*, in 1820, he spoke in German, "first in good Saxon (the *crusea* of the German), and afterwards in the Austrian and Swabian dialects, with a correctness of accent that amazed him to the last degree." In the same interview he spoke to the baron in Hungarian "with a compliment so well turned, and in such excellent Magyar, that he was taken completely by surprise." He spoke Polish and Russian with equal fluency to one of the baron's companions, Prince Volkonski; and at a subsequent meeting he added two much more uncommon languages, Wallachian and Zingari. Captain (now Admiral) Smyth, who was also of the party, still survives to confirm the literal truth of these statements. Lord Byron, Lady Morgan, the Countess of Blessington, and several other English tourists, who followed in the track of Mr Stewart Rose, speak of Mezzofanti in terms equally extraordinary. With M. Molbech, a Danish traveller (still librarian of the Royal Library of Copenhagen), he conversed during a long visit in Danish, which he "spoke with almost entire correctness." With Dr Tholuck, the celebrated orientalist of Halle, he spoke in Arabic and in Persian, "slowly, but with great propriety and exactness;" and he even wrote impromptu for him a Persian distich after the manner of Hafiz, which Dr Tholuck praises for the elegance of its sentiment and the propriety of its language and rhythmical structure.

A reputation so extraordinary procured for him the offer of many eligible appointments in several of the capitals of Europe. He was invited to Paris in 1805, to Naples about 1810, to Rome in 1814, to Vienna in 1815, to Florence on several occasions; but he declined all these flattering and advantageous offers, and remained in comparative poverty at Bologna till 1831, when having been sent to Rome as one of a deputation to the newly-elected Pope Gregory XVI., after the suppression of the Bolognese revolution, he at last yielded to the earnest solicitation of that pontiff, and transferred his residence to the papal capital. He was appointed a domestic prelate of the pope and canon of the church of St Mary Major on his arrival; and in 1833, when Angelo Mai was transferred from the Vatican Library to the post of secretary of the Propaganda, Mezzofanti was installed chief keeper of the Vatican. He was at this time in his sixtieth year, but his energy had not yet undergone the slightest diminution. Soon after he reached Rome he made a journey to Naples, expressly for the purpose of studying Chinese in the Chinese college of that city; and though his health broke down during this visit, he subsequently resumed the study at Rome with such success as not only to compose and speak in this most difficult language, but even to preach to the young Chinese ecclesiastics in the college of the Propaganda! Among the students of this vast missionary establishment, too, he found many new fields of language open to him; and it is ascertained beyond all doubt, that, advanced as was his age when he settled in Rome, he subsequently acquired many additional languages, of which he had known nothing whatever during his residence at Bologna. Of these, besides Chinese already alluded to, may be mentioned several North American Indian languages, Californian, Maltese, Angolese, Amariñña (an Abyssinian language), and above all, Basque, in both dialects of which (Labourdain and Souletin) he learned to converse when he was nearly seventy years old!

In the year 1838 he was advanced to the cardinalate, conjointly with his friend, the distinguished scholar Angelo Mai. He was appointed head of several ecclesiastical congregations; but never held any office connected with the government. His elevation, however, brought no change in his literary occupations. He continued to pursue his favourite study with the same assiduity; he was still, as before, accessible at all times to strangers who sought his acquaintance; and to the last he never failed to pay a daily visit to the students of the Propaganda, with whom he loved to speak in their respective languages, and to whom he freely acted as instructor in any language which they desired to cultivate.

One of the most remarkable characteristics of his wonderful gift was the power which he possessed of passing suddenly in conversation from one language to another, without the slightest hesitation or the smallest trace of intermixture or confusion. One of his friends compares the completeness of the transition to a man's "passing from one room into another;" so utterly did he leave the first language aside from the moment he began to speak in the second. Another, describing its rapidity, says it was "like a bird flitting from spray to spray." The cardinal himself declared that from the moment he began to speak in a language, he thought, reasoned, saw, in that medium only, as though he possessed no other beside.

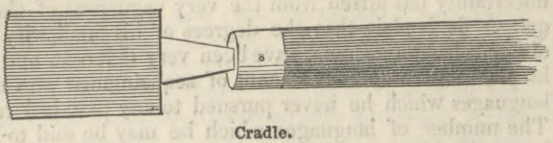
Visitors were amazed, too, to find him not alone perfectly master of the classical language of their respective countries, but often conversant with the various dialects of each to a degree really marvellous. To a German he would speak in the Swabian or Austrian dialects; to a Hungarian in any of the three dialects of Magyar; to a Spaniard in Castilian, Andalusian, or Catalan. He was familiar with several of the provincial dialects of English, and often amused English visitors by imitations of Yorkshire or Somersetshire provincialisms, or of the cockneyisms of a London cabman. Scotch, too, he was more conversant with than are ninety-nine out of every hundred Englishmen. He was even acquainted with these provincial subdivisions of several languages which are themselves but minor members of the European family; as, for example, the Dutch or Flemish. The secret lay in his prodigious memory. He often declared that he never forgot a word which he had once learned; and his memory was as ready as it was tenacious. His power of composing in these various languages was no less wonderful. He would write, quite impromptu, couplets or quatrains in any required language, according to the nation of his visitor; often, it is true, commonplace in sentiment, and exhibiting but little poetic talent; but displaying, nevertheless, singular command of words and extraordinary mastery of the rhythmical structure of the language, as well as of its principles of metrical versification. Many such little impromptus, in every language of Europe, are in existence. The same power he often exhibited on a larger scale, in the preparation or revision of the metrical pieces in various languages recited at the yearly academies of the Propaganda.

Nor was his knowledge confined to the languages of these various countries. All those who conversed with him attest that his familiarity with their several literatures was very great, and this not merely with the authors of the highest name in each, but with writers comparatively little read, and least of all likely to attract the notice of a foreigner. Of this fact, incredible as it may appear, there is the clearest evidence from travellers of all the principal nations—English, French, Germans, Spaniards, Russians, Poles, Hungarians, Bohemians, Danes, Swedes, Flemings, Dutch, and even Greeks, Armenians, Persians, Turks, and other orientals.

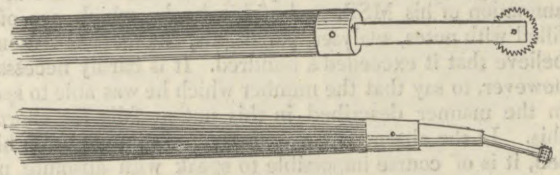
A good deal of uncertainty has existed as to the number of languages known by Mezzofanti, and considerable variety of statement has prevailed on the subject. Much of this uncertainty has arisen from the very vagueness of the inquiry. It is plain that the degrees of his familiarity with different languages must have been very different, and that he possessed a certain amount of acquaintance with many languages which he never pursued to any practical result. The number of languages which he may be said to have known in this way was indeed very great. From a report drawn up by one of his family, and founded on a careful examination of his MSS. and of his books, which are often filled with notes, analyses, paradigms, &c, there is reason to believe that it exceeded a hundred. It is hardly necessary, however, to say that the number which he was able to speak in the manner described in this notice falls far short of this. In the absence of any distinct statement from himself, it is of course impossible to speak with absolute precision; but from a detailed inquiry recently instituted both at Rome and in almost all the other European capitals, and even in the East, there is distinct evidence (marvellous as it may be deemed) of his having *spoken* (with various degrees of excellence, but yet sufficiently for the purposes of intercourse) between fifty and sixty languages, and of his having *known, less perfectly*, probably twenty others, in some of which he could converse less fluently, or at least initiate a conversation.

It will easily be supposed that Cardinal Mezzofanti's success as a general scholar must have, in great measure, been sacrificed to this one absorbing pursuit. But he nevertheless enjoyed a respectable reputation. In the sacred learning of his own profession he was well read. He was an earnest though not a very eloquent preacher. That he possessed considerable knowledge of mathematics is attested by an interesting conversation of his with M. Libri, the distinguished historian of mathematical science in Italy; and his visitors, from whatever country they came, generally found him familiar with the history of their respective nations. He was one of the most amiable of men, and his charity, even when his resources were most limited, was active and unceasing. He died at Rome during the absence of the papal court at Gaeta, March 15, 1849. His only published work is a panegyrical oration in memory of his first Greek master Father Emanuel da Ponte, printed at Bologna in 1820. (C. W. R.)

MEZZOTINTO, a word of Italian origin, signifying *half-painted*, is applied to a particular style of engraving from its near resemblance to painting. Its invention has been ascribed to Prince Rupert; but it is much more probable that the real originator of the art was Ludwig von Siegan, an officer in the service of the landgrave of Hesse. This art has reached its highest perfection among English engravers, whose portraits after Reynolds, Raeburn, Lawrence, &c., are worthy of the highest commendation for the elegance of their execution. The mezzotint process possesses the additional merit of enabling the artist to give transcripts of his pictures at a cost exceedingly moderate when compared with the great expense of line engraving. The process has been very much improved since the beginning of the present century, by the introduction of clever etching of the outline and shades along with the mezzotinto, which at once gives character, charm, texture, and consistency to the subjects represented. While the mode of laying the ground is so well known, that plates of every description can be procured by every preparer of copper or steel, it may nevertheless be requisite to give a brief description of the process, especially as the laying of the ground forms part of the work of artists. The instruments employed for this purpose are called *cradles*, from their rocking motion, and may be made by any blacksmith. They consist of pieces of properly tempered steel, prepared with teeth, and fitted into handles, as shown in the accompanying cut, and are of all dimensions adapted to be used by the hand. The teeth, which are of all degrees of fineness, are applied to the surface of the plate fixed upon the table, to which a rocking motion is applied in all directions, until a perfectly black ground is given to the plate by raising a barb or burr upon it which holds the printing-ink for the impression. Other instruments, such as scrapers and burnishers, are employed, and may be readily procured. Rulettos are also sometimes used for darkening or deepening any particular object or space, and can easily be obtained. The difficulty of the process, which can only be overcome by practice, consists in the laying of the ground, some portions of the work requiring coarser and others finer grounding. No special rules can be given for the rest of the process, which consists partly in scraping and partly in burnishing off, first the middle tints, and then the lights.



Cradle.



Rulettos.

It has been customary to give Le Blon of Frankfort's method of printing in colours in treating of mezzotinto, which is performed by various plates; but such modes of procuring coloured engravings may be better seen and understood by consulting Baxter's oil-colour painting from wood blocks, or Hullmandel's lithographic printing in colours, known by the name of "Cromo-Lithography," methods which have in great measure superseded the former.

MGLIN, a town of Russia, government of Czernigov, and 130 miles N.E. of the town of that name. It contains four churches; and has some trade in the agricultural produce of the neighbouring country, which is not very fertile. Pop. 6327.

MIAKO, Miaco, or Meaco, a city of Japan, and the ecclesiastical capital of the empire, is situated near the S. coast of the island of Niphon, about 240 miles W.S.W. of Yeddo; Lat. 35. 24. N., Long. 153. 30. E. The town stands in a wide plain, bounded in all directions by hills covered with trees and gardens, and is 4 miles in length by 3 in breadth. The houses are built for the most part of wood, and are two storeys in height; the streets are regular but narrow. The principal buildings of Miako are palaces and temples, both of which are very numerous, there being, it is said, 130 of the former, and not less than 6000 of the latter. Of the temples, the most remarkable are the *Fokosi*, an edifice of white marble, with numerous pillars of cedar wood in the interior, and a large statue of Buddha; and the temple of Kwanwon, which has an image of that deity even larger than that of Buddha. The Mikado, or ecclesiastical emperor of Japan, resides, with his attendants the *Dairi*, in a part of the town divided from the rest by walls and ditches. The court of this emperor, which is composed of all the most learned men in Japan, is in fact the principal college in the empire; and the greater part of the books published in Japan come from the Dairi and other learned men in Miako. The town is also remarkable as the chief seat of the manufacturing industry of Japan; the principal articles being carved ornaments and japanned wares. Pop. believed to be between 500,000 and 1,000,000.

MIAVA, a town of Hungary, in the county of Neutra, is situated on a river of the same name, falling into the March, 48 miles N.N.E. of Presburg. The inhabitants are of the Sclavonian race, and in religion they are for the most part Lutherans. There are two churches and a synagogue; manufactories of woollen stuffs, distilleries, saw-mills, &c. Miava has also some trade in hemp and flax. Pop. 9800.

MICAH, one of the twelve minor prophets of Scripture, was born in Moresheth of Gath, and, according to the inscription of the book, prophesied during the reigns of Jotham, Ahaz, and Hezekiah (B.C. 757–696), and was consequently contemporary with Isaiah. The genuineness and authenticity of the prophecy of Micah is unquestionable; although it is a matter of dispute whether the passage in chap. iv. 1–3 is borrowed from Isaiah ii. 2, 4, or that in Isaiah borrowed from Micah, or whether both be not derived from a common and more ancient source. Hengstenberg (*Christology*) strongly maintains Micah's originality; while De Wette (*Einleitung*) observes that we have the best reason for regarding the last years of Ahaz as the period of Micah's prophetic glory. The period of Micah's predictions, however, is fully attested by Jeremiah (chap. xxvi. 18, 19), where Micah is said to have foretold the destruction of Jerusalem in the reign of Hezekiah.

The most remarkable predictions contained in this prophet have been pointed out by Jahn, and are as follows:—1. The destruction of the kingdoms of Israel and Judah (iii. 12; vii. 13). 2. The Babylonian captivity, delivered 150 years before the event (iv. 10, 11; vii. 7, 8, 13). 3. The return from the captivity, and the tranquillity of the Jews under the Persian and Grecian monarchies, referring to events from 200 to 500 years distant (iv. 18; vii. 11; xiv. 12). 4. The heroic exploits of the Maccabees (iv. 13). 5. The establishment of the royal residence in Zion (iv. 8). 6. The birth and reign of the Messiah (v. 2). The style of Micah is remarkable for sublimity and vehemence, besides abounding in rapid transitions, elegant tropes, and piquant plays upon words. There are also several specimens of animated dialogue in this prophecy, especially in the second part, where the Lord is represented as conversing with his people, reproving their morals, threatening chastisement, and offering consolation by the promise of a return from their exile.

Micah is the third of the minor prophets, according to the arrangement of the Septuagint; the sixth according to the Hebrew; and the fifth according to the date of his prophecies. (See De Wette's *Einleitung*; Pocock's *Commentary on Micah*; Groseschopr's *Micah Uebersetzt*; and the *Introductions* of Jahn and of Eichhorn.)

MICHAEL I., Rhangabe, Emperor of Constantinople, was the son of Theophylactus, and grandson of Rhangabe, from whom he derived his surname. The Emperor Nicephorus honoured him with the hand of his daughter Procopia, and the office of master of the palace; but after the battle with the Bulgarians, in which that monarch was slain, and his son Stauracius was mortally wounded, the latter, while sensible that he could not long retain the purple, was opposed to Michael as his successor. Michael, however, was in 811 named emperor even before the death of Stauracius, and made an ineffectual attempt against his life; but he was unable to retain the throne against the opposition of the army, although the people were well disposed towards him. He retired to a convent after a reign of two years, and died in the year 845

Michael II., *Babbus*, or the Stammerer, Emperor of Constantinople, was born at Amorium in Phrygia, and was one of the principal officers of Bardanes. He assisted Leo V., his companion in arms, to obtain the throne, but afterwards conspired against him; and being convicted of treason, was condemned to be thrown into a fiery furnace. Before the sentence was executed, however, Leo was murdered by the other conspirators, and Michael was removed from his dungeon to the throne, even before his irons could be struck off. Michael was opposed by Thomas, another of the officers of Bardanes, who led 80,000 Asiatics against Constantinople, but was defeated and taken captive by the emperor, and treated with great cruelty. Michael died in 829, after a reign of nine years.

Michael III., Emperor of Constantinople, grandson of the preceding, succeeded his father Theophilus in 842 at the age of three, and was for some time under the guardianship of his mother Theodora. This emperor rivalled Nero in vice and cruelty; and neglected the loss of provinces for the sake of a victory in the chariot race. These excesses, along with the profane insults which he offered to the religion of his people, made him an object of universal hatred and contempt; and he was at last murdered by Basil the Macedonian in 867, after a reign of twenty-five years.

Michael IV., *The Paphlagonian*, Emperor of Constantinople, was raised to the throne in 1034 by Zoe, daughter of Constantine IX., the last of the Macedonian dynasty. This princess was married to Romanus III.; but becoming enamoured of Michael, her chamberlain, she poisoned her husband, and married her attendant. He, however, being of a weak character, and subject to epileptic fits, possessed the supreme power only in name, and was a mere instrument in the hands of his brother John. During his reign the Bulgarians made an incursion into Thrace and Macedonia, and Constantinople itself was in no small danger; but the indolent and infirm emperor, much to the surprise of friends and foes, put himself at the head of the army, and gained a victory, which compelled the invaders to retire. Michael returned in triumph to Constantinople, and shortly after died in 1041, after a reign of seven years.

Michael V., *Calaphates*, Emperor of Constantinople, and nephew and successor of the preceding, was the son of a caulker of ships, from whom he derived his surname, and was invested with the purple in 1041 by the influence of his uncle John. No sooner was he established on the throne than he banished his uncle and the empress Zoe, an act which raised a tumult against Michael, and put an end in 1042 to his short reign of four months. The dethroned emperor lived for some time afterwards in a monastery.

Michael VI., *Stratioticus*, Emperor of Constantinople, succeeded the Empress Theodora in 1056, being, as his surname indicates, of the military profession. His government was feeble in the extreme; and he was at last compelled to abdicate by Isaac Comnenus, who had defeated his army in Phrygia. Thus, after an inglorious reign of one year, Michael retired to a convent where he spent the rest of his life.

Michael VII., *Parapinaces*, Emperor of Constantinople, was the son of Constantine XI., and was appointed by his father in 1067 joint emperor along with his brothers Andronicus and Constantine. Michael, however, was in reality sole emperor, as his brothers were contented with mere empty titles and honours; but he was by no means fitted for the duties of his station, being a man of narrow mind, and a dabbler in philosophy and rhetoric. At length two generals of the name of Nicephorus, surnamed Bryennius and Botaniates, simultaneously rebelled against him, when Michael in 1078 resigned the purple, and retired into a monastery. He was afterwards made Archbishop of Ephesus.

Michael VIII., *Palæologus*, Emperor of Constantinople, was born, as his name indicates, of the ancient and noble race of the Palæologi, in the year 1234; and at an early age was so distinguished as a soldier and statesman as to be raised to the dignity of constable or commander of the French mercenaries. Although by his generosity and affability he gained the affections of the army and populace, his ambition rendered him an object of fear and suspicion to the court, and involved him in dangers from which it required all his courage and prudence to effect his escape. On the death of Theodore II., who had more than once unjustly attempted his life, Michael took part in the conspiracy by which Muzalon, one of the guardians of the young successor to the throne, was murdered; and succeeded in getting himself appointed regent in his stead. Shortly afterwards Michael was crowned emperor at Nice; and his reign was rendered illustrious by the recovery of Constantinople in 1261. This emperor died in 1282, after a troubled reign of twenty-two years, during the course of which, though stained with many cruelties and crimes, he restored by his vigour and ability the decayed fortunes of the Greek empire. (For further information respecting these emperors, see Constantinopolitan History).

MICHAEL'S MOUNT, St, a granite rock in Mount's Bay, county of Cornwall, England, about three-quarters of a mile S. of Marazion; N. Lat. 50. 7., W. Long. 5. 28. It is of a pyramidal form, 250 feet in height, and about a mile in circuit, and is joined to the land by a causeway, which is covered by the sea at high water. This has been supposed by some to be the place called by the Greeks *Ictis*, from whence they obtained tin; but this opinion is by no means certain. As early as the fifth century a chapel was founded here, which was an object of pilgrimage; and remains of a Benedictine priory, founded by Edward the Confessor, are yet to be seen. It was fortified, and a place of some importance in former times; and was taken by John de Vere, a follower of the House of Lancaster, in 1471; by the Cornish rebels in 1548; and by Colonel Hammond, in the civil war in 1646. The Mount is still fortified, having 3 batteries and 18 guns. There is a small village on the lower part of the peninsula, with a population of 163.

Michael, *St.* See Azores.

MICHAELIS, Johann David, a celebrated biblical critic of Germany, was the eldest son of the distinguished Hebrew scholar Dr Christian Benedict Michäelis, professor in the university of Halle, and was born at that place on the 27th of February 1717. His father devoted him at an early age to an academical life; and with that view he received his elementary education in a celebrated Prussian seminary called the Orphan-house, at Glanche, in the neighbourhood of his native place. He commenced his academical career at Halle in 1733, and took his master's degree in the faculty of philosophy in 1739. In 1741 he visited England, where his superior knowledge of the oriental languages, which was considerably increased by his indefatigable researches in the Bodleian Library at Oxford, introduced him to the acquaintance, and gained him the esteem, of the first literary men of the day, with several of whom, particularly Bishop Lowth, he afterwards kept up a regular correspondence. On his return to Halle, after an absence of fifteen months, he began to read lectures on the historical books of the Old Testament, which he continued after his removal to Göttingen in 1745. On the death of the chancellor Ludwig, whose lectures on German history laid the foundation of that peculiar knowledge of social law so admirably displayed in the *Mosaisches Recht*, Michäelis was appointed to catalogue the immense library of his former master. The result of his labours was published in 1745, and is considered an excellent specimen of such works. In 1746 he was appointed professor extraordinary, and soon afterwards professor of philosophy, in the university of Göttingen, where he afterwards, in the capacity of professor of theology and oriental languages, rendered the highest services to this institution. The next year he obtained the place of secretary to the Royal Society there, of which he was director in 1761, and he was subsequently made aulic councillor by the court of Hanover. In 1764 his distinguished talents, and a publication relative to his plan for an expedition to Arabia, procured him the honour of being chosen a corresponding, and afterwards a foreign, member of the Academy of Inscriptions at Paris, of which class the institution admitted only eight; and in the same year he became a member of the society of Häerlem. In 1775 Count Hopkin, who eighteen years before had prohibited the use of his writings at Upsal, when he was chancellor of that university, prevailed upon the King of Sweden to confer upon him the order of the Polar Star as a national compensation. In 1786 he was raised to the distinguished rank of privy councillor of justice by the court of Hanover; and in 1788 he received his last literary honour by being unanimously elected a fellow of the Royal Society of London. His great critical knowledge of the Hebrew language, which he displayed in a new translation of the Bible and in other works, raised him to a degree of eminence almost unknown before in Germany; and his indefatigable labours were only equalled by his desire of communicating the knowledge he had acquired to the numerous students of all countries who frequented his admirable lectures, which he continued to deliver in half-yearly courses on various parts of the sacred writings, and on the Hebrew, Arabic, and Syriac languages, to the last year of his life. He was forty-five years professor in the university of Göttingen, and during that long period he filled the chair with dignity, credit, and usefulness. He died on the 22d of October 1791, in the seventy-fourth year of his age.

The principal works of J. D. Michäelis are, in oriental literature, grammars of the Hebrew, Chaldee, Syriac, and Arabic languages, *Oriental u. exeget. Bibliothek*, 1781–85, 23 vols.; *Supplementa et emendationes ad Lexica-Hebraica*, Gött. 1784. In history, geography, and chronology, *Spicilegium Geographiæ Hæbrorum exteræ post Bochartum;* several discourses on Jewish law and antiquities, mainly embodied in his masterpiece the *Mosaisches Recht*, 1770-5, 6 vols., and translated into English in 1814 by Dr Alex. Smith, and entitled *Commentaries on the Laws of Moses.* His *Introduction to the New Testament* is familiar to the English reader through the well-known translation of Bishop Marsh.

MICHAELMAS, the feast of the archangel St Michael on the 29th of September, was instituted, according to Brady (*Clavis Calendaria*, vol. ii.), in A.D. 487. On Michaelmas-day, which is a stated rent-day in this country, there is an old custom, still kept up in certain districts, of having a roast goose to dinner, probably on account of the fact alluded to by an amusing writer in *The World*, No. 10, that "stubble geese are in the highest perfection" at that period. There are also a few quaint lines bearing on this point in Poor Robin's Almanack for 1695, beginning, "Geese now in their prime season are;" and there is a common saying that "if you eat goose on Michaelmas-day, you will never want money all the year round."

There was another custom on this day of which few traces, if any, now remain, viz., the baking and eating of *St Michael's cake* or *bannock.* Martin, in his *Description of the Western Islands of Scotland*, says that the inhabitants of Skye, and especially those of Kilbar village, have on this day a "general cavalcade, and several families bake the cake called St Michael's bannock, . . . and all strangers, together with those of each family, must eat the bread that night." Macauley, in his *History of St Kilda*, alludes to the same observance in that island, and adds, that all who ate the cake "had, of course, some title to the friendship and protection of Michael." (See Brand's *Popular Antiquities*, Bohn, vol. i., pp. 353, 367, 372.)

MICHAUX, ANDRÉ, a botanist, was born in 1746 at Sartory, near Versailles, and studied under Lemonnier the astronomer and Jussieu the botanist. In 1779 he travelled in England, from which country he introduced into France several new varieties of trees and shrubs; and in 1780 he explored the hills of Auvergne and the Pyrenees, and brought from Spain several sorts of grain, which were sent to the Jardin des Plantes at Paris. In 1782 he was sent by the Count of Provence, afterwards Louis XVIII., to Persia; but arriving there during a period of civil war, he was plundered by the Arabs of all but his books. Having obtained from the British consul at Bassora the means to continue his journey, he proceeded to Ispahan, where he cured the Persian monarch of a dangerous disease; and after spending two years in different parts of Persia, he was recalled, and returned to France with a fine herbarium and many valuable kinds of seed. In 1785 he was sent by the government to North America, where he travelled through a great part of the country, from Hudson's Bay to Florida, and from the Atlantic to the Mississippi. The French revolution, however, deprived him of the funds he had formerly received from the government; and his own means were soon exhausted, so that he was obliged to return to France. On his homeward voyage he was shipwrecked, and only escaped with his life and four boxes of specimens. He arrived in Paris in 1796; and notwithstanding the justice of his claims, the Directory gave him but a small indemnification for his losses, and that not till after three years of anxious expectation. But Michaux was able to bear the privations of poverty and neglect with the same patience and perseverance with which he had endured the hardships of his former adventurous life. He lived on the same coarse fare, and slept on the same bear-skin, in the midst of the luxury of Paris, as in the deserts and ruins of the East, or in the prairies and forests of the West. In 1800 he went to Madagascar, where he died in 1802. Michaux was the author of several books, of which the principal are,—*Histoire des Chênes de l'Amérique Septentrionale*, Paris, 1801; and *Flora Borealis Americana*, Paris, 1803.

MICHEL ANGELO BUONARROTI, perhaps the greatest master of the arts of design who has ever appeared, was born in the castle of Caprese in Tuscany, on the 6th of March 1474. His father, Ludovico di Leonardo Buonarroti Simone, was a descendant of the noble and illustrious family of the Counts of Canossa, and allied to the imperial blood. This circumstance had nearly occasioned the world the loss of the great artist; for when the strong bias of his mind became apparent, which occurred at a very early age, his father and uncles discouraged his pursuits, and treated him with harshness, conceiving that their family would be degraded should a scion of their race adopt the profession of artist. But objection, prejudice, and even persecution, proved useless when opposed to devoted attachment and irresistible genius. Michel Angelo received the rudiments of his education at Florence, the nursing-mother of the arts, and here he enjoyed ample facilities of gratifying his taste for drawing. Ludovico finding it hopeless to attempt to frustrate the intentions of nature, yielded at last to the advice of friends and the wishes of his son, who was accordingly placed under Domenico Ghirlandajo, a distinguished professor of the arts of painting and design. The youth was articled to serve three years; but, contrary to custom, instead of paying, he received a premium; an indubitable proof of his great merits, even at the age of fourteen. The original document by which he was engaged bears date April 1488. His earliest effort in oil showed that he was born to grapple with difficulties from which other men shrink, whilst his success proved that he was also destined to overcome them. The subject was "St Anthony beaten by Devils." In this little picture, besides the figure of the saint, there were crowded wild and grotesque forms and monsters, to which he was so intent upon giving an aspect of reality, that he painted no part without referring to some natural object. But painting did not engross the whole of his time and attention. The great patron of the arts at this period was Lorenzo de' Medici, who, for the purpose of elevating sculpture to a level with painting, opened a garden in Florence, which he amply supplied with antique statues, bas-reliefs, busts, and the like. Thither the youth of the city repaired to study the classic creations of antiquity; and it is scarcely necessary to say that it became the favourite haunt of Michel Angelo.

From copying the drawings and paintings of others, his attention was turned to the modelling of figures in clay, in imitation of the monuments of ancient art; and the transition from this, the initiatory step in sculpture, to the moulding of the marble into symmetrical forms, was natural, and speedily withdrew his mind from every other study. The vigilant and practised eye of Lorenzo soon discovered the genius of the youthful sculptor in the execution of a mask representing a laughing faun. His father was sent for, and requested to resign Michel to the care of the family; and this being complied with, apartments were allotted to him in the ducal palace. Here he received every indulgence and attention, being treated with parental affection, and allowed to pursue the bent of his genius, not only without interruption, but cheered and encouraged by the cordial approbation of his munificent patron. Amongst the works which he executed under these favourable auspices was a bas-relief representing the "Battle of the Centaurs;" on viewing which at a future period of his life, he lamented that he had not confined himself to a branch of art wherein he had so soon attained such excellence. This is the strongest evidence which could be produced of the rare merits of the sculpture; for artists almost uniformly speak disparagingly of their early efforts.

On the death of Lorenzo, which happened about two years after he had entered his service, Michel Angelo with a heavy heart returned to the paternal mansion. Nothing belonging to Lorenzo was inherited by his son Pietro except the territorial possessions of the family; and although the young artist continued to pursue his studies with unabated zeal, little patronage or encouragement was to be expected or obtained from a frivolous debauchee. The pusillanimity of this person soon distracted the councils of Florence; and Michel, to escape the storm which he saw impending over that city, retired to Bologna, but returned in about a year afterwards, when tranquillity had been restored. About this period there prevailed a sort of mania for the antique. Whilst the discoveries of antiquity created a new era in art and literature, the importance of which can never be too highly estimated, many ignorant individuals, smitten with the enthusiasm of the time, betrayed their want of judgment by the indiscriminate manner in which they lavished their praise on these remains; and Michel Angelo resolved to take advantage of the popular excitement. He executed a "Sleeping Cupid;" and having stained the marble in such a way as to give it the appearance of a genuine antique, it was transmitted to a proper person in Rome, who, after burying it in his vineyard, dug it up, and then reported the discovery. The pardonable trick completely succeeded for a time, and the statue was bought by a cardinal for a considerable sum; but of this Michel Angelo received only a small portion. Such deceptions, however, seldom remain long concealed; the officious zeal of friends, or the vanity of authorship, usually brings about the exposure of a successful imposition. After the mask was laid aside, and the real artist became known, he received a flattering invitation to visit Rome. Thither he accordingly repaired: and whilst there he executed a statue of "Bacchus," another of a "Cupid," and a group of the "Virgin weeping over the dead body of Christ" for St Peter's church, together with a cartoon representing St Francis receiving the *stigmata*.

The celebrated gonfaloniere Pietro Soderini, well known as a patron of genius, having been elected to guard the peace and protect the liberties of Florence, Michel Angelo returned to that city. With the sanction of the new chief magistrate, he was allowed to appropriate to his use a huge block of marble, which, after having been much injured by Simone des Fiesole in attempting to shape it into a colossal statue, had for many years lain neglected in the court of the Palazzo Vecchio in Florence. Out of this he executed a gigantic statue of David, which gave great satisfaction. He also cast a figure in bronze of the size of nature, and a group of "David and Goliath;" but, that his hand might not "lose its cunning" in the sister art, he painted a "Holy Family." This picture is preserved in the Florence gallery; and it is the only painting in oil by Michel Angelo now remaining the authenticity of which is not disputed. Having been commissioned to ornament the hall of the ducal palace with a cartoon, he chose for the subject an event connected with the war between the Florentines and Pisans. The work represents the Florentine soldiers, who, alarmed by an unexpected assault whilst bathing in the Arno, are getting out of the water with the utmost expedition, and preparing for action; and although only outlined in charcoal, chalk, and the like, it was considered as the most extraordinary production which had appeared since the revival of the arts in Italy. In the meantime, Julius II. having been raised to the pontifical throne, Michel Angelo was invited to the Vatican, whither he repaired without finishing the cartoon; but being disgusted with Rome, he returned to Florence, and completed the design. The painting of the picture itself, however, was never begun. Political events, and a second invitation from Julius II., again attracted him to the Eternal City, and he was employed by his holiness to construct a magnificent mausoleum, which, although immediately commenced, was interrupted during its progress, first on account of a misunderstanding between the artist and the pope, and afterwards from other causes. The artist repaired to Bologna, and political events having brought the pope to this city, a reconciliation took place. In a few days Julius II. ordered a colossal statue of himself to be executed in bronze, which Michel Angelo finished in sixteen months, and returned to Rome at the end of June 1508. This statue was the personification of severe majesty, with one hand raised in the attitude of benediction; but being somewhat at a loss how to dispose of the left, he asked the pope whether he would like a book to be placed in it, when the warlike pontiff promptly replied,—"A sword rather; I was never given to letters." He was, however, disappointed in his hopes of being allowed to proceed with his great architectural undertaking; for the pope had changed his mind, it is alleged through the jealousy of Bramante, and the artist was requested to decorate with pictures the ceiling and walls of the Sistine chapel. But his previous disappointment was forgotten in his subsequent triumph. This stupendous work of genius excited the highest admiration, which contemporary opinion and the judgment of after ages have confirmed; yet only eighteen or twenty months were spent in its execution.

After the death of Julius II. in 1513, the papal throne was filled by Leo X., whose magnificent reign forms an era in the intellectual history of modern times. Yet, strange as the fact may appear, the life of Michel Angelo during his pontificate is nearly an entire blank. He was employed in extracting marble from a quarry which was

Michel Angelo.

wrought with difficulty, and in constructing a road over intricate swamps and through mountainous ridges, for the purpose of conveying it to the sea. Leo X. died in 1521, and under his successor Adrian VI. Michel Angelo employed himself upon the monument of Julius. The reign of Adrian was short; and on his death Clement VII. was raised to the papal throne. The confusion with which the civil affairs of Rome were soon overwhelmed drove the artist to Florence, where he continued his architectural and other works for the chapel and library of S. Lorenzo, and executed a statue of Christ. His talents as an engineer were likewise put in requisition for the defence of the city. Before commencing the works he visited Ferrara, then the best fortified town in Italy, and was received with the utmost courtesy by the Duke Alphonso, who showed him every part of the works, and at the same time requested a specimen of the artist's abilities either in sculpture or in painting. A picture of "Jupiter and Leda" was the result; but this great production is generally supposed to have been lost. Michel Angelo was enabled to complete the fortifications of Florence before the siege of the city commenced; and, as in the case of Syracuse, the genius of one individual for a considerable time proved more than a match for thousands of armed men and the mightiest engines of war. By treachery the city passed into the hands of the enemy; but the great artist, although he had shown the dexterity of Archimedes in frustrating the designs of the besiegers, did not share the fate of the great geometrician. The finishing of two monuments for the Medici family was the price of his liberty.

Tranquillity being restored to Italy, Buonarroti returned to Rome; and although frequently interrupted, both by Clement VII. and by his successor Paul III., he at last completed the monument to Julius II. It consists of seven statues, amongst which is the celebrated one of Moses, a production evincing, in a higher degree than any of his other sculptures, that character of majesty and sublimity which more or less pervades them all. His next work was the painting of the "Last Judgment" in the Sistine chapel, which was finished in 1541; and so great was the admiration excited by this mighty effort of genius, that many persons came from distant parts of Italy to see it. He subsequently painted the "Martyrdom of St Peter" and the "Conversion of St Paul," which cost him great fatigue, as age was beginning to impair his physical energies. But that his intellectual powers still retained their pristine vigour, the church of St Peter's, the most splendid monument of his genius and success as an architect, affords ample evidence. This fabric was begun by Julius II. in 1506, and being successively intrusted to Bramante and Antonio de San Gallo, by this transference from hand to hand it was in danger of becoming a huge incongruity. On the death of Antonio de San Gallo in 1546 Michel Angelo was appointed architect; and notwithstanding the jarring and complexity of the original designs, he succeeded in simplifying and harmonizing the whole. The work proceeded for a time with considerable rapidity. But he was occasionally withdrawn from it to other things, such as the building of bridges, the superintendence of which might have been safely intrusted to some inferior person. During the latter years of his life the papal chair was filled by several pontiffs, some of whom forwarded, and others retarded, his great undertaking, employing him in the construction of chapels and other buildings. Nor did he live to witness the completion of this splendid edifice, the greatest and most magnificent Christian temple on earth. He was carried off by a slow fever on the 17th of February 1563. His obsequies were celebrated as became the memory of so unrivalled a genius.

Michel Angelo was of the middle stature, bony in his make, and rather spare, but broad over the shoulders. His complexion was good; his forehead was square, and somewhat projecting; his eyes were of a hazel colour, but rather small; and the general effect of his countenance was impaired by a blow which he had received in youth.

The character of Michel Angelo as an artist has already been delineated in this work by a masterly hand. (See the article Arts, *Fine.*) Grandeur of conception is the quality which distinguishes his works from those of all other artists who have appeared in modern times. Whether he excelled most in painting, in sculpture, or in architecture, it would not be easy to determine. He has left the noblest specimens of human genius in each department of art. He is the Milton of artists. Things beyond the visible diurnal sphere were within the range of his imagination; and when he stoops to earth, he invests nature with an ideal grandeur and majesty. His boys are men, his men are a race of giants: his demons are the evil spirits of Dante and Milton made visible; and his angels are the offspring of the sky. The Sistine chapel is allowed to be the most finished work of art in the world; and its perfection is owing chiefly to Michel Angelo's divine paintings. The whole wall behind the altar is covered by his picture of the "Last Judgment;" the vaulted ceiling represents the creation of the world, and around it are prophets and sibyls. In the sublime painting of the "Last Judgment," terrible power is the predominating feature. The good and the bad, angels and devils, crowd the scene, and Christ is represented in the act of judging, or rather of condemning. His complete knowledge of anatomy, which he constantly studied, enabled him to represent in the most perfect manner the human figure in every possible attitude, and to express pain and despair through all their gradations. His other pictures exhibit the same daring sublimity of conception and power of execution. The church of St Peter's at Rome is the most splendid triumph of his architectural talents. His style in architecture is distinguished by grandeur and boldness; and in his ornaments the untamed character of his imagination is frequently apparent, in his preference of the uncommon to the simple and elegant. In sculpture his statue of Moses is universally acknowledged to be the noblest monument of his genius, displaying, more than any other of his numerous works in this department of art, all the great qualities of his mind.

Michel Angelo was likewise an author, and excelled both in verse and prose. His poetry, like his art, was powerfully influenced by the Platonic philosophy to which he seems to have formed an early attachment through his connection with the Platonic Academy of Florence. His poetical pieces consist of sixty-two small poems, named madrigals, and sixty-four sonnets, besides a few pieces of greater length, of which the most touching is an elegy on the death of a brother. Some of these poems are the light, airy creations of gay fancy; but the greater part—particularly his sonnets, which comprehend his most beautiful effusions—are of a much graver cast, and are characterized by lofty thought and noble sentiment, expressed in strong, energetic, and elegant language. His sonnets are generally of a highly abstract nature, and are not unfrequently rendered painfully obscure by the subtle allegorical style which Dante had so popularized in Italy. (See an elegant essay by E. Taylor, on *Michel Angelo considered as a Philosophic Poet*, and accompanied by various translations, London, 1846.)

Lives of Michel Angelo were published during the artist's lifetime by Condivi and Vasari. The most recent, and in many respects the most valuable, biography of Michel Angelo is that entitled *The Life of Michel Angelo Buonarroti, with Translations of many of his Poems and Letters; also Memoirs of Savonarola, Raphael, and Vittoria Colonna*, by John S. Harford, Esq., D.C.L., 2 vols., London, 1857.

Michelozzi.

MICHELOZZI, Michelozzo, a Florentine sculptor and architect, was born about the year 1396. He was in his youth a pupil of Donatello, and soon displayed great genius and skill in executing marble and bronze statues. He was much attached to the service of Cosmo de' Medici, for whom he built a palace in Florence, now known by the name of the Palazzo Riccardi. This building is remarkable as being the earliest in Florence built after the modern rules; and as combining convenience as a dwelling with simplicity and beauty of architecture. When Cosmo was banished in 1433 Michelozzi followed him to Venice, where he erected the library of the convent of San Giorgio Maggiore, and designed several other edifices. In 1434 he returned with his patron to Florence, where he continued to exercise his art with such success, that he was appointed a member of the Florentine magistracy. After the death of Cosmo, Michelozzi continued to enjoy the favour of his son Pietro, for whom also he planned many buildings. He died at the age of sixty-eight, about the year 1470; but neither the date of his birth nor that of his death is exactly known.

MICHIGAN, one of the United States of North America, is bounded on the N. by Lake Superior; E. by Lake Huron, the Strait and Lake of St Clair, the Strait of Detroit, and Lake Erie, all of which separate it from Canada; S. by the states of Ohio and Indiana; and W. by Lake Michigan and the state of Wisconsin. It lies between 41.40. and 47.30. N. Lat., and between 82. 12. and 90. 30. W. Long., and has a total land area of 56,243 square miles. This state consists of two large peninsulas, separated from each other by the Straits of Mackinaw, and known respectively as the Northern and Southern; the former, formed by Lakes Superior and Michigan, is about 320 miles in length and 130 in extreme breadth; while the latter, formed by Lakes Michigan and Huron, has a length of 283 miles and an extreme breadth of 210 miles. These two peninsulas are very different from each other both in aspect and nature. The Northern is mountainous in its western part, some of the heights having an elevation of 2000 feet. The Wisconsin or Porcupine Mountains, which form the watershed between Lakes Michigan and Superior, attain an elevation of about 2000 feet in the N.W. portion of this peninsula. Towards the centre of this division there is a high table-land, broken by numerous hills, and extending E. as far as the Pictured Rocks, on the coast of Lake Superior. These rocks consist of masses of sandstone, formed by the continued action of the wind and waves into fantastic shapes, resembling ruined temples, castles, &c. The E. part of the peninsula from this point to its extremity consists of an undulating tract of country, sloping gradually down to the coasts on either side, which consist on the N. of sandstone rocks, and on the S. of limestone. The rivers of this part of the state are not of great size or importance; and those that flow to the N. have generally a rapid descent, and abound in picturesque falls and rapids. The principal of those which flow N. are,—the Montreal, the Ontonagon, the Huron, the St John's, and the Chocolate; and of those flowing S., the Menomonee and the Manistee. The Montreal and the Menomonee partly form the boundary between this state and that of Wisconsin. The southern peninsula consists of a varied surface of hill and dale, not rising in any part to a great elevation, but everywhere considerably above the level of the lakes, and having in many places steep coasts, from 100 to 300 feet in height. A ridge of hills traverses the country from S. to N., somewhat to the E. of the centre, and separates the waters of the rivers flowing E. to Lake Huron from those flowing W. to Lake Michigan.

In the southern part of this peninsula there are extensive plains or openings, as they are generally called by the inhabitants, covered more or less thickly with scattered oaks of different kinds, with here and there clusters of hickory. The numerous knolls which rise in all directions, the rivers, which are fringed with belts of wood, and the extensive and luxuriant meadows which occur in many places, combine to render this country one of the richest and most beautiful in scenery of any in the United States. Further to the N. there are dense forests, interrupted now and then by small prairies occupied by farms. Across the middle of the peninsula, from Saginaw Bay westward, a stripe of land extends, which is entirely covered with pine forests. This region is about 25 miles in breadth; and the unbroken forests of pines give to the country a dark and gloomy appearance. To the N. of this region beech and maple trees again become predominant, and the pines are only scattered here and there among them. The principal rivers of this peninsula are,—the St Joseph's, the Kalamazoa, the Grand, the Maskegon, and the Manistee, which flow into Lake Michigan; the Au Sable, and the Saginaw, flowing into Lake Huron; and the Raisin, flowing into Lake Erie. The geological character of the rocks of the northern peninsula of Michigan is principally primitive; those parts, however, near Lake Michigan exhibit a more recent formation; and the southern peninsula is chiefly secondary, being similar in its nature to the western part of the state of New York; while there are numerous boulders of primitive rock scattered over every part of this state. The northern peninsula is very rich in minerals, and possesses copper mines, which are in all probability among the richest and most extensive deposits of that mineral in the world. It is chiefly found in the Kewenaw peninsula, a piece of land jutting out into Lake Superior, from which the state of Michigan sent to Washington a block of copper several tons in weight, and nearly pure. This block is now to be seen built into the wall of the National Monument, bearing the arms of Michigan and this inscription,—"From Michigan: an emblem of her trust in the Union." Iron is also found in great abundance to the S.W. of the copper region; and the state has also lead, gypsum, peat, limestone, marl, and coal; but these have not yet been worked to any great extent. The soil of the southern peninsula is rich and fertile; and although the northern peninsula is in general barren, yet even here there are some tracts of great fertility. The climate of the northern part is severe, and the cold in winter intense; while in the S. it is much milder and more temperate than those parts of the eastern states which lie in the same degree of latitude. Cultivation, however, has not extended beyond the southern part of the lower peninsula, since the tide of emigration has rather passed through Michigan on its way to the countries farther W. than made any permanent settlements there. The quantity of cultivated land in the state amounted in 1850 to 1,929,110 acres; and the produce in the same year consisted of 5,641,420 bushels of Indian corn, 4,925,889 of wheat, 2,886,056 of oats, 2,359,897 of potatoes, and 472,917 of buckwheat; besides 2,043,283 lbs. of wool, 7,065,878 of butter, 1,011,492 of cheese, 2,439,794 of maple sugar, 404,934 tons of hay; live stock worth L.1,668,486; market produce, L.3,070; fruit, L.27,635; and butcher meat, L.276,735. The manufactures of the state of Michigan have not as yet made much progress, owing to the recent period at which this country has been settled; but in 1850 there were in Michigan 1979 establishments of various sorts. Among these there were 15 woollen factories, employing 129 hands and L.19,583 capital, and producing annually 141,570 yards, valued at L.18,800; 64 forges, furnaces, &c., employing 362 hands, and producing 5430 tons, to the value of L.62,645; several breweries and distilleries, employing 98 hands and L.29,047 capital, and producing 901,220 gallons; 6 tanneries, with L.59,583 capital, and producing leather to the worth of L.75,828; besides many other establishments.

The state of Michigan has been considerably improved by railways, two of which were begun by the state, but afterwards sold to private companies. The Michigan Central Railway extends from Detroit westward through the centre of the state to New Buffalo, and has a total length of 284 miles; the Michigan Southern, which, in connection with the Indiana Northern, extends from Monroe to Chicago, a distance of 243 miles. There are, besides, several smaller lines and branches. The position of Michigan, nearly surrounded by the largest fresh-water lakes in the world, is extremely favourable for its commercial prosperity; and this is further increased by the number and excellence of its harbours all along the coast, which surpass in both of these respects those of any other lake state. The number of vessels built in the state in the year ending June 30, 1855, was 27; and their tonnage, 7844. The value of the exports from Michigan in the same year was L.118,436; and that of the imports was L.58,620. The government of the state is elected by general suffrage every second year; and consists of a governor, with a salary of L.208 a-year, and a lieutenant-governor, who presides in the Senate, and receives 12s. 6d. a-day during the sitting of the legislative body. This body consists of a Senate and House of Representatives; the former containing 32, and the latter 66 members; and both popularly elected for two years. Michigan sends four members to the National House of Representatives; and has six votes in the election of a president of the United States. The judiciary consists of a supreme court, circuit courts, probate courts, and justices' courts. The franchise extends to every white man or civilized Indian, not a member of a tribe, above the age of twenty-one, and who has resided for a certain time in the state. The present constitution received the sanction of the people in 1850. The question of a general revision of the constitution is to be submitted to the people every sixteen years; but any change may be made on receiving the approval of two-thirds of each branch of the legislature, and being afterwards ratified by a majority of the electors.

The public debt of the state, November 30, 1855, was L.497,908; and on the 1st November 1856 it was L.489,056. The receipts for the year ending November 30, 1855, amounted to L.122,583, which, together with a balance of L.115,178, makes up a total of L.237,761; and the expenditure for the same year was L.130,162; leaving a balance of L.107,599. The state contained in December 1855, 4 banks, with an aggregate capital of L.152,174, and a circulation of L.119,638. According to the census of 1850 there were in the state 362 places of worship, of which 103 belong to the Methodists, 67 to the Presbyterians, 58 to the Baptists, 42 to the Roman Catholics, 29 to the Congregationalists, 25 to the Episcopalians, 12 to the Lutherans, 7 to the Quakers, 6 each to the Dutch Reformed Church and the Universalists, and 7 to minor sects. The total amount of church accommodation was 118,892 sittings, and the value of the whole church property, L.150,667. The government of Michigan pays considerable attention to the subject of education; and there is a fund set apart for the support of the schools in the state, which amounted in 1852 to L.119,935, and in 1854 to L.288,393. Besides this fund, which is obtained by the sale of public lands, there was raised by taxation in 1854 for the schools of the state L.73,266. The number of schools supported by these means was, in 1850, 2714, with 3231 teachers and 110,455 scholars. Besides these, Michigan had 37 schools, with 71 teachers and 1619 scholars, not supported by the state.

The university fund belonging to the state amounted in 1854 to L.94,255; and L.14,508 was raised by taxation in that year for the support of the school and township libraries, which then contained in all 121,201 volumes. The state contains 3 colleges, with 22 professors and 308 students; and a normal school opened in 1853. The principal of the other institutions are,—the asylum for the deaf, dumb, and blind, opened in 1854; the asylum for the insane, opened in the same year; the house of correction for juvenile offenders, opened in 1856; and the state prison at Jackson, which contained, November 30, 1854, 246 convicts. Capital punishment has been abolished in this state since 1848; and criminals convicted of murder are now imprisoned for life, with hard labour, in the state prison. Michigan is divided into 64 organized and 21 unorganized counties: and the capital of the state is Lansing.

The country now occupied by the state of Michigan received its first European settlement from the hands of the French soon after the middle of the seventeenth century. At the peace of 1763 it came, with the other French possessions in North America, into the hands of the British. On the expulsion of the French, the celebrated Indian chief Pontiac seized the opportunity to rid the country of the whites, and accordingly instigated a simultaneous rising among the Indians, who surprised and took all the forts in the country, massacring the inhabitants, with the exception of Detroit, which held out until relieved by British troops, who subdued the Indians, and freed the colonists from farther danger. The American revolution followed soon after; and the country now forming the state of Michigan came into the possession of the Union in 1796, and was made a territorial government in 1805, with Detroit for its capital. In 1812 it became the theatre of the war between Britain and the United States. Detroit was surrendered to the British in that year by General Hull, and the whole country was overrun by the British and Indians; but not long after they were finally expelled by General Harrison. Previous to 1830 the inhabitants of this country were chiefly Canadian French, but at that time it began to be occupied by emigrants from the other states, especially those of New England. Thus, while formerly little had been done to improve the culture or products of the land,—the French being contented idly and ignorantly to follow the customs of their fathers,—now that a more enterprising and energetic race of settlers had succeeded them, the country made rapid advancement in wealth and prosperity. In 1837 Michigan was admitted as one of the United States, having then a population of nearly 100,000. According to the census of 1850, the state contained,—whites, 395,071; free persons of colour, 2583: total, 397,654.

Michigan, *Lake*, one of the five great lakes of North America, is situated between 41. 30. and 46. N. Lat., and between 85. 50. and 88. W. Long.; having a length of 330, and a breadth of 90 miles, with an area of 20,000 square miles. The lake is fed by a number of rivers from the adjoining country, the principal of which are,—the Grand, Maskegon, St Joseph, and Kalamazoo, from Michigan; the Calumet from Indiana; the Chicago from Illinois; and the Milwaukee and Sheboygan from Wisconsin; and it discharges its waters through the Straits of Mackinaw into Lake Huron. Michigan has not many large bays, the largest being Green Bay, on the W. shore, chiefly in Wisconsin, more than 100 miles in length, and varying in breadth from 15 to 35 miles. On the E. coast the principal indentations are Little Traverse Bay and Grand Haven. Lake Michigan has few islands, and these are situated chiefly near the N.E. extremity. The shores are generally low; and the water seems to be gradually retiring from the eastern shore, and making encroachments on the western. The depth of the lake is between 900 and 1000 feet; and the surface is about 600 feet above the level of the sea. Though inferior in size to Lake Superior, this lake is in some respects second to none of the great American lakes. It extends farther to the S. than Lake Superior, and its shores thus enjoy a climate more mild and a soil more fertile than is found farther north. Its position is also highly favourable for commerce, being connected at once with the Mississippi and with the eastern coast of America; with the former by the Fox River, Lake Winnebago, and the Wisconsin River, as well as by a railway from Chicago to Galena; and with the latter by the railways through the state of Michigan and along the coast of the lakes. The commerce of the lake is accordingly very great, and continually increasing. The principal harbours on its shores are,—Green Bay, whose imports in 1851 amounted in value to L.400,000, and exports to L.200,000: Two Rivers, imports in the same year, L.23,958; exports, L.23,500: Grand River, imports, L.45,822; exports, L.55,223: St Joseph's, imports, L.111,720; exports, L.173,316: Manitowoc, imports, L.22,234; exports, L.16,067: Port Washington, imports, L.188,417; exports, L.29,052: Sheboygan, imports, L.271,855; exports, L.25,355: Milwaukie, imports estimated at L.3,035,702; exports at L.542,880: Racine, imports, L.306,884; exports, L.215,530: Kenosha, imports, L.272,262; exports, L.137,756: Waukegan, imports, L.129,132; exports, L.40,587: Chicago, imports, L.5,085,500; exports, L.1,168,056.

MICIPSA, King of Numidia, was the son of Masinissa, and succeeded his father in 148 B.C., along with his two brothers Gulussa and Mastanabal,—the kingdom being divided by Scipio between the three, in such a way that Micipsa possessed Cirta, the capital, in his portion of the inheritance. Soon afterwards, by the death of his brothers, Micipsa became sole monarch, in which position he continued till his death in 118 B.C., when he left his crown to his two sons Adherbal and Hiempsal, along with his nephew Jugurtha.

MICKIEWICZ, Adam, the most illustrious poet of Poland, was born at Nowogrodek in Lithuania in 1798, of a noble but poor family. From the district school of his native village he passed to the gymnasium of Minsk, and in 1815 to the university of Wilna, where his uncle was one of the professors, and where our own poet Campbell was once a candidate for the office of regent. This university, since suppressed by the Russian government, was then celebrated as a school of mathematics and natural science; and Mickiewicz early showed a strong inclination for chemistry and natural history, but gave no indication at that time to his friends of being possessed of any talent for verse. His first collection of poems appeared in two slim volumes at Wilna in 1822, after he had received the appointment of professor of classical literature at Kowno. They were received with extraordinary enthusiasm by the public; and the general voice of his country, and of all Sclavonic nations, assigned him the name of the "Polish Byron," and pronounced him the greatest poet of Poland. The larger portion of these poems, however, which consist mainly of ballads, remind the reader rather of Monk Lewis than of Byron. They are founded on the wild heathen superstitions and old pagan ballads of the Lithuanian peasantry, which the poet in his boyhood had gathered up out the obscure and neglected remnants of a dialect presenting the closest affinities with the Sanscrit. Besides the ballads these early volumes contain two longer poems of superior value. One of them, *Grazyna, a Lithuanian Tale*,—said to have inspired the unfortunate heroine Emilia Plater, who fought so bravely in the Polish ranks against Russia in 1830,—is the story of a Lithuanian princess who fell fighting in her husband's armour at the head of his retainers, rather than permit him, through private jealousy, to join his forces to the enemies of his country. The other, *Dziady* (*The Ancestors*), is a wild and irregular drama, full of powerful but revolting poetry, inspired by loathsome superstition and dark horror. He was assailed by Dmochowski, the Polish translator of Homer, among other critics, for his "romantic" innovations; but, despite this critical hostility, a company of young poets rapidly sprung up in and around Wilna, and formed themselves into the "School of Mickiewicz." But he was not destined long to enjoy in peace the honours of the poetical chief. His friend Zan had formed a society at Wilna for the cultivation of the Polish language and literature, of which the enthusiastic poet and a number of the alumni of the university were members. The jealousy of Russia was excited, and the society was dissolved. The indefatigable Zan, after repeated attempts to reorganize his cherished association, was condemned in 1824 to perpetual imprisonment; while his friend Mickiewicz and others escaped with a sentence of perpetual banishment in the Russian interior. The Polish poet was conveyed to St Petersburg whither his fame had already travelled, and he was received in the literary circles of that capital with great marks of respect. Here in 1824, while Byron was dying at Missolonghi, the Polish Byron, Adam Mickiewicz, and the Russian Byron, Alexander Pushkin, first met; and a keen sympathy soon sprung up between the illustrious Polish exile and the leading men of letters of the Russian capital. But genial literary intercourse and a spirit of revolution seemed to the watchful mind of despotism to be all but synonymous terms; and Mickiewicz got prompt orders to leave St Petersburg for Odessa. A tour in the Crimea resulted in a collection of *Crimean Sonnets*, which met with great success,—the author little dreaming that he should live to witness far other materials for moralizing on the "Steppe of Eupatoria," and the "old castle of Balaclava," than he found in the records left by the cultivated Greek, the enterprising Genoese, and the relentless Turk, on that memorable peninsula. Mickiewicz was invited to form one of the household of Prince Galitzin, governor of Moscow; and was subsequently permitted to return to the capital, where he published his *Conrad Wallenrod* in 1828, a romantic tale of great power, founded on a real historical character of Lithuania. The book, though breathing a deep spirit of freedom, escaped the political censorship of St Petersburg, though not of Warsaw and Wilna, by a dexterous preface, which informed the reader that the subject was chosen because it belonged entirely to the past, and because it could have no relation to the interests of the present. Having obtained permission to travel, Mickiewicz visited Goethe at Weimar, and had just made the acquaintance of Fenimore Cooper at Rome when news of the insurrection of Warsaw of 1830 reached him. He was too late to join his countrymen in their unsuccessful struggle, and he resolved to retire to Dresden, where he composed another part of his dramatic poem of *Dziady*. He makes himself the hero, and introduces more than one of his fellow-exiles by their real names. The first scene, which is placed in the corridor of the Basilian convent on the night of Christmas, is written with such immense power that it was said by an able critic to place the author on a level with Goethe. It was published at Paris in 1832, where his last long poem, and some say his finest, of *Pan Tadeusz* (*Sir Thaddeus*), appeared two years afterwards.

The star of Mickiewicz had now reached its zenith. On the establishment of a chair for the Sclavonic languages and literature in the College of France in 1840, the choice of Mickiewicz as professor was considered a peculiarly happy one. Unfortunately it turned out the very opposite. He had fallen under the influence of a religious charlatan, named Tomianski, some years before, who persuaded him that he had cured Madame Mickiewicz of a serious illness by means of mesmerism. The daring imagination of the poet, by long brooding over the dark mysteries accompanying such phenomena, plunged him into a sea of the wildest fanaticism. After a few brilliant lectures on Sclavonic literature, he addressed his audience on "the worship of Napoleon," and the "Messiahship" of some mysterious Pole, who, in 1844, proved to be the quack mesmerist. The deluded poet had to leave Paris; but he was permitted to retain the nominal professorship till 1851, when he was made sub-librarian at the Arsenal. He was sent on a mission to the East by the French emperor in 1855; and died at Constantinople on the 27th of November of the same year. His remains were removed to France, and interred at Montmorency, near Paris. No poet of Europe, during the last quarter of a century, had achieved so much as Mickiewicz, and his name stands unquestionably first in the literature of his country. His prose works, however (one of which, *The Polish Pilgrimage*, has been translated into English), do not occupy a high position. An edition of his works was published in 4 vols., Paris, 1856, entitled *Pisma Adama Mickiewicza, na nowo przejrzane, dopelnione*, &c.

MICKLE, William Julius, the translator of the *Lusiad*, was the son of Mr Alexander Mickle, a Scottish clergyman, who had formerly been an assistant to Dr Watts in London, and one of the translators of Bayle's Dictionary. He was born at Langholm in Dumfriesshire in 1734; and after his father's death he came to Edinburgh to reside with his uncle, who was a brewer there, and who admitted him to a share of his business. Not being qualified to succeed in this calling, however, he went to London about the conclusion of the war of 1755, to procure a commission in the marine service. In this he was disappointed; but he introduced himself to the first Lord Lyttelton, who encouraged him to persevere in his poetical studies.

From the time of Mickle's arrival in London till the year 1765 it is not known how he employed his time. In that year, however, he engaged himself as corrector to the Clarendon press. From this time till 1770 he published several small pieces in prose and verse, which brought him into some notice, the principal of which were *Pollio*, an elegiac ode (1765), and *The Coneubine*, written in imitation of Spenser (1767), and afterwards published, with alterations, under the title of *Sir Martyn*. He also wrote against Arianism and Deism in his Letter to Dr Harwood, and in his *Voltaire in the Shades*. His tragedy of the *Siege of Marseilles* proved a failure, and was never produced. When not more than seventeen years of age, he had read the *Lusiad* of Camoens in French, and projected the design of giving an English version of that poem. Accordingly, in 1771, he published the first book as a specimen; and quitting his residence at Oxford, he went to a farm-house at Forest Hill, where he pursued his design with unremitting assiduity till the year 1775, when the work was completed. It met with severe censure for the diffuseness of the translation, and for the unwarrantable liberties taken with the original. During the time that Mr Mickle was engaged in this work he supported himself entirely as a corrector of the press; and on his quitting that employment he had only the subscriptions which he received for his translation to support him.

A second edition of the *Lusiad* was prepared in 1778; and whilst he was meditating a publication of all his poems, he was appointed secretary to Governor Johnstone, who had obtained the command of the Romney. In November 1779 he arrived at Lisbon, and was appointed by his patron joint agent for the prizes which were taken. Mickle received much honour from the Portuguese, and was admitted a member of their Royal Academy. On his return to England he fixed his residence at Wheatley in Oxfordshire, and after writing several pieces in prose and verse, the last of which was a ballad called *Eskdale Braes*, he died on the 25th of October 1788. His poems possess but little general merit. The best of his ballads perhaps is *Cumnor Hall*, which suggested Scott's *Kenilworth*.

MICON, an Athenian artist and sculptor, was the son of Phanochus, and flourished in the fifth century B.C. He assisted in the painting of the Pœcile at Athens; and, according to some authors, had a hand in the famous picture of the "Battle of Marathon." He was assisted in some of his works by Polygnotus. He executed several statues; but he was especially famous for his representations of horses.

MICROMETER.

Micrometer, from *μικρος*, *small*, and *μετρον*, *a measure*, is the name of an instrument, generally applied to telescopes and microscopes, for measuring small angular distances within the field of the former, or the size of small objects within that of the latter.

Previously to the invention of the telescope astronomers experienced great difficulty in measuring small angles in the heavens; but we may safely infer from the observations of Hipparchus, that he had succeeded, either by the actual division of his instruments or by estimation, in determining celestial arcs to *one-third* of a degree.

When the telescope was applied by Galileo and our countryman Harriot to the examination of the solar spots, it does not appear that they executed their drawings from any other than estimated measures. This indeed seems quite certain in the case of Harriot, whose original sketches we have had an opportunity of inspecting. The elaborate solar observations of Scheiner, made in 1611, with a telescope on a polar axis, and published in 1630 in his *Rosa Ursina*, though minutely laid down and performed with great care, were certainly made without any instrument for subdividing the field of view.

Gascoigne. A.D. 1640.

As telescopic observations, however, multiplied, astronomers felt the necessity of having something more accurate than their eye for ascertaining minute distances in the heavens; and there can be no doubt that a micrometer was invented by our countryman Mr Gascoigne previous to 1640, not long after the publication of the *Rosa Ursina*. According to the description of it which he addressed in a letter to Mr Oughtred, and to the account of one of Gascoigne's own instruments which Dr Hooke examined, its construction was as follows:—A small cylinder, stretching across the eye-tube of the telescope, is cut into a fine screw throughout one-third of its length, the other two-thirds being formed into a coarser screw, with threads at twice the distance. This compound screw is confined at both ends to its place, the fine part of it passing through a female screw in one bar, and the coarse part through a female screw in another bar, these two bars being grooved into each other, as in a sliding rule. Hence, if a nicely ground edge is fixed to one bar and another to the other bar, so that these edges are accurately parallel, a motion of the screw round its axis will separate these two edges, and each edge will move with a different velocity. The parts of a revolution are measured by an index and divided face at the coarse end of the screw, while the number of whole revolutions is measured by a graduated bar moved by the coarse screw. The fine screw serves the purpose of keeping the middle part of this variable field (or the opening between the edges) in the axis or line of collimation of the telescope; for while the coarse screw moves the edge which it carries from the other edge considered as fixed, the fine screw moves both the edges, and indeed the whole frame, in an opposite direction, with one-half of the velocity; an effect which is produced by fixing its bar to the tube of the telescope.[1] As Mr Gascoigne fell in the civil wars, near York, in 1644, before he had given any full account of his invention and its application to astronomy, we are indebted to Mr Richard Townley, into whose hands one of the instruments came, for the preservation of so valuable a relic. Mr Townley informs us that Mr Gascoigne had made use of his micrometer for some years before the civil wars, and had measured distances on the earth, determined the diameters of the planets, and endeavoured to find the moon's distance from two observations of her horizontal and meridional diameters. Mr Townley's instrument was of the size and weight of "an ordinary pocket-watch." It marked 40,000 divisions in a foot, $2\frac{1}{2}$ divisions corresponding to a second of space. Mr Townley had it improved by a common watchmaker. Flamsteed was presented with one of the instruments in 1670 by Sir Jonas Moore; but though he left three guineas with Mr Collins to get proper glasses made for it, he could not procure them till autumn 1671, when he began his observations with it at Derby, and continued them with it in 1671, 1672, 1673, and 1674.[1] He informs us that Townley's improvement consisted in substituting one screw for two. He mentions also that Gascoigne had, in August 1640, measured with his micrometer the diameters of the sun and moon; and the relative distances of the stars in the Pleiades.

Hooke.

Dr Hooke made an important improvement in this micrometer by substituting parallel *hairs* for the parallel edges of the brass plates;[2] and Dr Pearson conjectures that he had adopted this construction in his zenith sector, by which he proposed, in his dispute with Hevelius, to measure *single seconds.*

Malvasia. 1622.

It would appear, from the Ephemerides of the Marquis of Malvasia, published in the year 1662, that he had measured the distances of the stars, and the diameters of the planets, and projected the lunar spots, by means of a *reticle* of silver wire fixed in the focus of the eye-glass of his telescope. In order to determine the distances of the wires which composed this network, he turned it round till a star moved along one of the wires, and having counted the number of seconds which the star took to pass over the different distances between the wires, he obtained a very accurate scale for all micrometrical purposes.

Auzout. 1666.

About the year 1666 MM. Auzout and Picard, unacquainted with what had been done by Gascoigne, published an account of a micrometer.[3] Auzout's micrometer is said to have divided a foot into 24,000 or 30,000 parts. It resembled the Marquis of Malvasia's, with this difference, that the divisions were measured by a screw, and he sometimes employed fibres of silk in place of silver wires.

Huygens.

The celebrated Christian Huygens was also an early inventor of micrometrical methods; and the subject has been prosecuted with great diligence and success by Cassini, Röemer, Bradley, Savary, Bouguer, Dollond, Maskelyne, Ramsden, Sir W. Herschel, Rochon, Troughton, Wollaston, Arago, Fraunhofer, Pearson, Amici, Porro, and Secchi.

In giving an account of the inventions and methods of these various authors, we shall adopt the following arrangement:—

1. Description of wire-micrometers in which the wires are moved by one or more screws.
2. Description of wire-micrometers in which the angular distance of the wires is varied optically by changing the magnifying power of the telescope.
3. Description of double-image micrometers in which two singly-refracting lenses, semi-lenses, or prisms, are separated by screws.
4. Description of double-image micrometers in which the two images formed by two singly-refracting lenses, semi-lenses, or prisms, are separated optically.
5. Description of double-image micrometers in which the two images are formed by double refraction.
6. Description of position-micrometers.
7. Description of the lamp-micrometer and the lucid-disc micrometer.
8. Description of fixed micrometers with an invariable scale.
9. Description of micrometers for microscopes.

CHAP I.—DESCRIPTION OF WIRE-MICROMETERS IN WHICH THE WIRES ARE MOVED BY MEANS OF ONE OR MORE SCREWS.

Troughton's wire-micrometer.

The micrometer of Gascoigne, when furnished with hairs, as suggested by Dr Hooke, embodies the principle of the best and most recent micrometers. Instruments on this construction have been made by all our eminent opticians; but we have no hesitation in saying, that the micrometer constructed by the late celebrated artist Mr Troughton exhibits all the ingenuity which has been displayed in this delicate and useful apparatus. This eye-piece, and micrometer attached to it, are shown in figs. 1, 2, and 3, where fig. 1 is a horizontal section in the direction of the axis of the telescope. The eye-piece *ab* consists of two plano-convex lenses *a*, *b*, of nearly the same focal length, and the two convex sides facing each other. They are placed at a distance less than the focal length of *a*, so that the wires of the micrometer, which must be distinctly seen, are beyond *b*. This arrangement gives a *flat field*, and prevents any distortion of the object. This eye-piece slides into the tube *cd*, which screws into the brass ring *ef*, through two openings, in which the oblong frame *mn* passes. A brass circle *gh*, fixed to the telescope by the screw *i*, has rack-teeth on its circumference that receive the teeth of an endless screw *w* (fig. 3), which, being fixed by the arms *xx* to the oblong box *mn*, gives the latter and the eye-piece a motion of rotation round the axis of the telescope; and an index upon this box points out on the graduated circle *gh* (fig. 3) the angular motion of the eye-piece. The micrometer properly so called is shown in fig. 2, where *k*, *l* are two forks, each connected with a screw *o* and *p*, turned by the milled heads *m* and *n*. These forks are so fitted as to have no lateral shake. Two pins *q*, *r*, with spiral springs coiled round them, pass loosely through holes in the forks *k*, *l*, so that when the forks are pressed by their screws towards *q* and *r*, the spiral springs resist them, and consequently push them back when the screws are turned in the opposite direction.

[3] *Phil. Trans.,* No. 21, p. 373, January 1666.

Wire-Micrometers.

Two fine hairs, or wires, or spiders' lines, *s*, *t*, are stretched across the forks, the one being fixed to the inner fork *k*, and the other to the outer fork *l*, so as to be perfectly parallel, and not to come in contact when they pass or eclipse one another, in which case they will appear as one line. A wire *st* is stretched across the centre of the field, perpendicular to the parallel wires.

The most difficult part of this instrument in the execution, as well as the most important, is the screw or screws which move the forks. The threads must not only be at the same distance, but have their inclination equal all round. In the screw used by Troughton, there are about 103·6 threads in an inch. On the right hand of the line *st* (fig. 2) is a scale, not seen in the figure, which indicates a complete revolution of either screw, the small round hole being the zero. This hole is bisected when the two lines appear as one.

In using this instrument we separate the wires by their respective screws till the object to be measured is exactly included between them. The number of revolutions and parts of a revolution necessary to bring the two wires into the position of zero will then be a measure of the angle required, provided the value of a revolution has been previously ascertained with accuracy.

Methods of finding the value of a revolution of the screw.

The easiest method of ascertaining the value of a revolution of the screw, according to the late Dr Pearson, who devoted much attention to this subject, is to ascertain how many revolutions and parts of a revolution measure exactly the sun's vertical diameter in summer, when his altitude is such that the refraction of both limbs is almost the same. The sun's diameter in seconds being divided by that number, the quotient will be the value of a single revolution, the sun's diameter having been corrected by the difference between the refraction of his two limbs. The ordinary method of ascertaining the value of a revolution is, to observe accurately the time taken by an equatorial star, or a star of known declination, reduced to the equator, to pass over the space between the wires when at a distance, and to convert this time into degrees, at the rate of 15° per hour. The number of degrees, minutes, and seconds, divided by the revolutions and parts of a revolution which are necessary to bring both wires into zero, will give the value of one revolution of the screw. The same thing may be done by measuring a base with great accuracy, and observing the space comprehended between the wires at that distance. The angular magnitude of this space, divided by the number of revolutions of the screws which bring the wires to zero, will be the value of each.

New method.

A most elegant and accurate method has been recently employed, we believe, by Professor Gauss of Göttingen, for measuring the value of the revolutions of micrometer-screws. He employs for this purpose a standard telescope with a micrometer, the value of whose scale has been accurately determined. Since the wires of a telescope-micrometer adjusted to distinct vision of the stars or planets are accurately in the focus of parallel rays falling on the object-glass, it follows that rays issuing from the wires, and falling on the inside of the object-glass, will emerge from it perfectly parallel. Now, if we place the object-glass of the standard telescope close or near to that of the first telescope, the parallel rays formed by those issuing from its wires will be refracted to the focus of the standard telescope, and a distinct image of the wires will be there formed. The observer, therefore, when he looks into the standard telescope, will see distinctly the wires of the first telescope, and, by means of his micrometer, he will be able to measure exactly the angular distance of these wires, at whatever distance they happen to be placed. This angular distance, divided by the revolutions and parts of a revolution which are necessary to bring the wires of the first telescope to the zero of their scale, will give the value of one revolution of the screw, or of one unit of the scale on the right hand of the long wire *st* (fig. 2).

Wire-Micrometers.

Fibres for micrometers.

The most essential parts of a micrometer are the parallel fibres, which require not only to be extremely fine, but of a uniform diameter throughout. Gascoigne, as we have seen, employed the edges of brass plates, Dr Hooke hairs, and subsequent astronomers wires and fibres of silk. Fontana in 1775 recommended the spider's line as a substitute for wires, and he is said (we think erroneously) to have obtained them so fine as the 8000th part of a line. Mr Troughton[1] had the merit of introducing the spider's line, which he found to be so fine, opaque, and elastic, as to answer all the purposes of practical astronomy. This distinguished artist, however, informed the writer of this article that it was only the stretcher, or the long line which sustains the web, which possesses these useful properties.[2] Sir David Brewster has employed the fibres of spun glass, which are bisected longitudinally with a fine transparent line about the $\frac{1}{3000}$th of an inch in diameter. This central line increases with the diameter of the fibre, and diminishes with the refractive power of the glass. In cases of emergency, the fibres of melted sealing-wax may be advantageously employed, or, as recommended by Professor Wallace, the fibres of asbestos. We have found crystals of *mesolite* so minute and regular as to be well adapted for the same purpose.

Wollaston's fine platinum wires.

The art of forming wire of extreme minuteness has been perfected by Dr Wollaston. Having placed a small platinum wire in the axis of a cylindrical mould, he poured melted silver into the mould, so that the platinum wire formed the axis of the silver cylinder. The silver was now drawn out in the usual way till its diameter was about the 300th of an inch, so that if the platinum wire was at first $\frac{1}{10}$th of the diameter of the silver cylinder, it will now be reduced to the 3000th part of an inch. The silver wire is now bent into the form of the letter U, and a hook being made at each of its ends, it is suspended by a gold wire in hot nitric acid. The silver is speedily dissolved by the acid, excepting at its ends, and the fine platinum wire which formed its axis remains untouched. In this way Dr Wollaston succeeded in forming wires $\frac{1}{4000}$th, $\frac{1}{5000}$th, and even $\frac{1}{18000}$th of an inch in diameter. When the fibres are prepared, their ends are placed in parallel scratches or grooves drawn on the forks, or, in other cases, on the diaphragm or field bar, and fixed by a layer of bees' wax or varnish, or, what is more secure, by pinching them with a small screw near their extremities.

Illumination of the wires.

In astronomical observations it is necessary to illuminate the wires of micrometers. In the transit instrument this is generally effected by means of a lamp, which throws its light along the horizontal axis of the telescope to a small speculum which reflects it upon the wire, although it may be done, as in other cases, by a small speculum placed outside of the object-glass. A very ingenious method has been more recently suggested and used, viz., of making the wires self-luminous by bringing them to a red heat by electricity. This idea seems to have presented itself to several astronomers,—to Arago, Savart, and Capocci of Naples; but it is to Arago that we are indebted for the earliest invention, construction, and use of it. The wire or wires, attached to suitable springs, pass from incandescence to absolute darkness, and reciprocally through all intermediate intensities. He had reason to fear that the images of objects beyond and apparently near to the heated wire would be sensibly undulating; but in an experiment which he made with a small power he found that there was no perceptible deviation to the extent of a second. This method of illumination has, we understand, been employed by Mr Johnson of Oxford in illuminating the wires of the microscopic micrometers for reading off the separation of the semi-lenses of the object-glass in his heliometer, without the observer leaving the telescopic eye-piece. He has used, we hear, the same process for illuminating the wires of his telescope micrometer. M. Arago has also employed galvanic electricity for bringing to a red heat a wire which is employed to illuminate the telescopic wires on their sides turned towards the observer, the useless rays which the wires do not stop, escaping by the object-glass, or being absorbed by the black varnish within the tube. The method of doing this in the best manner has been briefly described by M. Breguet in the *Comptes Rendus*, &c., 1847, vol. xxiv., p. 322. It consists in making a transverse slit in the tube which contains the eye-glass, and placing the illuminating wire without the tube, and in a plane between the eye-glass and the wires to be illuminated.

---

[1] Mr Quekett ascribes the introduction of the cob-web micrometer to Ramsden. (*Treatise on Miscroscope*, p. 196.)

[2] Captain Maury, superintendent of the National Observatory in the United States, informs us that when in search of spider lines for the diaphragm of his telescopes, he procured the finest and best threads from a cocoon of a mud-red colour; but he adds, the threads of this cocoon, as seen singly in the diaphragm, were of a golden colour. (*Physical Geography of the Sea*, p. 121.)

M. Porro's method of illumination. Another method of illuminating the wires has been imagined by M. Porro. It consists in substituting plates of glass instead of the metallic plates which carry the wires. These plates of glass are ground and polished on their edge into suitable curves, so as to introduce, perpendicularly to the axis of the telescope, a thin vein of light, which will illuminate the wires without reaching the eye of the observer. Hence it happens that the wires appear of a silvery white in a dark field.[1]

Images of wires proposed. Many years ago Sir David Brewster communicated to the Chevalier Burg, the distinguished author of the Lunar Tables, a new method of obtaining micrometer lines by placing in the field of view the reflected images of a fixed or moveable system of wires, or of lucid discs attached to the side of the eye-piece. This is effected by placing in the field of view a plate of parallel glass inclined to the axis of the eye-piece. The wires being illuminated, their images will be distinctly seen in the field of view, and while they have all the properties of real wires, they have the additional advantage of being transparent, so that a star or small planet or satellite may be seen moving along the axis of the wire, in place of being eclipsed by it. The motions of the wires in real micrometers are accurately repeated in its reflected image, and consequently the position and distance of the image-wires are measured with the same accuracy as if they were real.

Photographic micrometers. A new method of constructing microscopical scales or systems of delicate lines, opaque or transparent, and fitted both for astronomical and microscopical observations, has been recently proposed by Sir David Brewster. Mr Dancer of Manchester has succeeded in making photographic portraits upon collodion so small that they are wholly invisible to the eye, and that *ten thousand* portraits may be introduced into a square inch. The film of collodion upon which these photographs are taken is so thin and transparent that it is invisible, and allows objects to be seen through it as distinctly as if it were the thinnest glass. If a system of opaque or transparent lines therefore is impressed upon it photographically, when reduced to the minutest size from a system of large and sharply defined lines, we shall have the most perfect micrometrical scale that can be conceived, the portion of the collodion that contains no nitrate of silver being as transparent as if the dark spaces were solid wires or metallic plates placed in the focus of the eye-glass. (See chapters vi., p. 118, and viii., p. 121, for an account of other applications of this method.)

For a great deal of valuable practical information respecting the construction and use of the wire-micrometer, the reader is referred to Dr Pearson's *Introduction to Practical Astronomy* (vol. ii., pp. 99, 110, 115, &c.), where valuable tables will be found for facilitating the application of the micrometer both to celestial and terrestrial purposes. See also Sir John Herschel and Sir James South's *Observations of* 380 *Double and Triple Stars* (p. 22, 23), containing tables of the values of Troughton's screws.

CHAP. II.—DESCRIPTION OF WIRE-MICROMETERS IN WHICH THE ANGULAR DISTANCE OF THE WIRES IS VARIED OPTICALLY BY CHANGING THE MAGNIFYING POWER OF THE TELESCOPE.

Röemer. MM. Röemer and De la Hire first conceived the idea of varying the angular magnitude of the meshes of a net of silver wire fixed in the focus of the eye-glass of a telescope, for the purpose of measuring the digits of eclipses. This was done by a second lens moving between the wires and the object-glass. The late Mr Watt informed the writer of this article that he had used a similar principle, but had never published any account of it.

The plan of opening and shutting a *pair of parallel wires* optically instead of mechanically, and of using it as a general principle in micrometers, was first adopted by Sir David Brewster, and has been applied to a variety of methods of varying the magnifying power of the telescope.

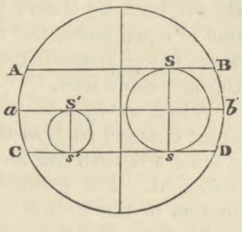

Fig. 4.

The general principle will be readily understood from fig. 4, where AB, CD are two wires or lines of any kind permanently fixed in the focus of the eye-glass of a telescope. If the sun S′s′ is in contact with the lower wire CD, it is obvious, that if we increase the magnifying power of the telescope by any optical means anterior to the wires, we may magnify or expand the sun's disc S′s′ till it becomes Ss, when its north or upper limb will exactly touch the upper wire AB. Now if the sun's diameter happens to be 31′ when its disc Ss just fills the space between the wires AB, CD, the distance of the wires must have been 62′ when, as at S′s′, it fills only half that space. Hence the wires have been moved optically, so to speak, and have subtended all angles between 31′ and 62′.

The methods of varying the magnifying power of the telescope used by Sir David Brewster consist in varying the distance of the two parts of the achromatic eye-piece; or in varying the focal length of the principal object-glass by means of another object-glass, either convex or concave, moving between it and its principal focus.

Eye-glass micrometer. The first of these methods is shown in fig. 5, where AB

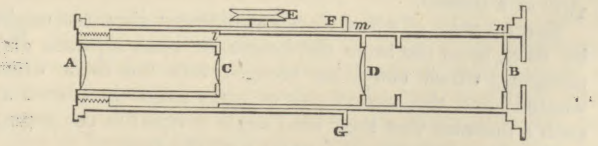

Fig. 5.

is the eye-piece with its four lenses, A, C, D, B, in their natural position. The part AFG, with the two lenses A, C, is fixed to the telescope, and a space is left between the tube AC and the outer tube AFG, to allow the moveable part DB of the eye-piece to get sufficiently near the lens C. The tube DB is moved out and in by a rack and pinion E. A scale is formed on the upper surface *mn*, and subdivided in the usual manner with a lens and vernier, which it is unnecessary to represent in the figure. The value of the divisions of the scale are determined by direct experiment. A motion of DB through a space of 4 inches will, generally speaking, double the magnifying power of the telescope.

---

[1] *Comptes Rendus*, &c., 1851, vol. xxxii., p. 677.

Object-glass micrometer.

The best method, however, of varying the magnifying power of the telescope is the second, which is shown in fig. 6, where O is the object-glass, f its principal focus, and L the second lens, which is moveable between O and f. Parallel rays R, R, after being refracted by O, so that they would converge to f, are intercepted by L, which converges them to F, the focus of the combined lenses. The effect of the lens L is therefore to diminish the focal length of the object-glass, and consequently the magnifying power of the telescope, which will obviously be a *minimum* when the lens L is at l, and a *maximum* when it is at l'. The angle subtended by a pair of fixed wires will suffer an opposite change to that on the magnifying power, being a maximum when the lens L is at l, and a minimum when it is at l'. Hence the scale for measuring the variable angle of these wires may always be equal to the *focal length* of the object-glass O; and the inventor of the instrument has shown, both by theory and by experiment, that the scale is one of equal parts, the variations in the angle of the fixed wires being proportional to the variations in the position of the moveable lens.

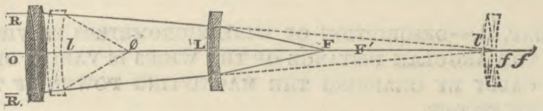

Fig. 6.

When we wish to measure angles that do not suffer a great change, such as the diameters of the sun and moon, a scale less than the focal length of the object-glass will be sufficient. For example, if we take a lens L, which by a motion of ten inches varies the magnifying power from 40 to 35, then, if the angle of the wires is 29′ when the lens L is at l', it will be 39′ 9″ when the lens is ten inches from l', or the magnifying power 35. We have therefore a scale of *ten* inches to measure a change of angle of 4′ 9″, so that every 10th of an inch will correspond to 3″·3, and every 100th of an inch to ⅓d of a second. Such a micrometer will serve to measure the diameters of the sun and moon at their various distances from the earth.

If we wish to measure the distances of some double stars, or the diameters of some of the smaller planets, with a telescope whose magnifying power varies from 300 to 240, by the motion of a lens over *ten inches*, place the parallel wires at a distance of 40″, which will be increased to 50″ by the motion of the lens. Hence we have a scale of *ten inches* to measure *ten seconds*, or the *tenth* of an inch to measure *one* second, or the 100th of an inch to measure $\frac{1}{10}$th of a second.

Several pairs of wires, placed at different distances, might be fixed upon the same diaphragm, or upon separate diaphragms, which could be brought into the focus when wanted; and the second pair of wires might be placed at such a distance that their least angle is equal to the largest angle of the first pair, and so on with the rest.

A wire-micrometer thus constructed is certainly free from almost all the sources of error which affect the common moveable wire-micrometer. The errors arising from the imperfection of the screw, the uncertainty of zero, and other causes, are avoided; and the wires are always equidistant from the centre of the field, so as to be equally affected by any optical imperfection in the telescope. The scale indeed may be formed by direct experiment, and the results will be as free from error as the experiments by which the scale is made.

When this micrometer is applied to a portable telescope it becomes of great use in naval, military, or geodetical operations, and is employed in measuring distances, either by taking the angle subtended by a body of known dimensions, or by measuring the two angles subtended by a body of unknown dimensions from the two extremities of a known or measured base. For these purposes the telescope is fitted up without a stand, as shown in fig. 7.

The principle of separating a pair of wires optically is singularly applicable to the Gregorian and Cassegrainian telescopes, where no additional lens or mirror is required. As the magnifying power of both these telescopes may be increased merely by increasing the distance of the eye-piece from the great speculum, and then readjusting the small speculum to distinct vision, we can thus vary the angle of a pair of fixed wires by making the eye-piece moveable. This will be easily comprehended from Figure 8, where SS is the great speculum of a Gregorian reflector, AA the tube, M the small speculum, whose focus is G, and centre of curvature H. It is fixed to an arm MQ, moveable to and from SS in the usual way. The image $R'r'$ is that formed by the speculum SS, and $r''R''$ that formed by the small speculum. This last image being in the focus of the eye-glass E, will be seen distinct and magnified. If the eye-glass E is pulled out to E′, then, in order that the object may be seen distinctly, the image $r''R''$ must be brought into the position $r'''R'''$, FF′ being equal to EE′; but this can be done only by advancing the small speculum M to M′, f and F′ being now the conjugate foci of M. But by this process the magnifying power has been considerably increased, because the part of the whole magnifying power produced by M was equal to $\frac{MF}{Mf}$, whereas it is now $\frac{M'F'}{M'f}$, a much larger quantity. The angle subtended by the wires has therefore been diminished in the same proportion as the magnifying power has been increased. The scale in this case is not one of equal parts, but after the extreme points of it have been determined experimentally, the rest may be filled up either by calculation or direct experiment.

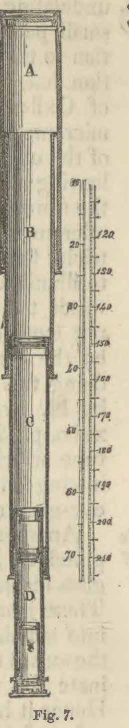

Fig. 7.

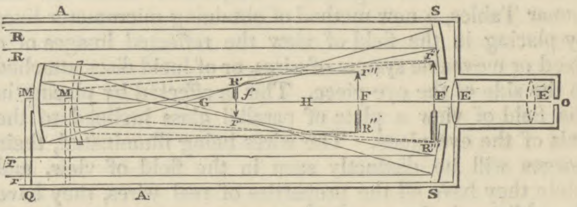

Fig. 8.

Dr Pearson[1] has inadvertently stated that Sir David Brewster's "patent micrometer is not competent to measure very small angles, even if it had sufficient magnifying power." If he means the patent micrometer as made by Mr Harris, as a naval and military telescope for measuring distances, or as a coming-up glass, he is quite right, because the power of measuring small angles is not required for these practical purposes. But it is quite evident that the *smallest* angles can be measured by the micrometer when fitted up for astronomical purposes. We have only to use a pair of wires placed at a very small distance, or a pair of semi-lenses whose centres are placed at a very small distance, and then vary their angle till it becomes equal to the very small angle which we wish to measure.

---

[1] *Introduction to Practical Astronomy*, vol. ii.

CHAP. III.—DESCRIPTION OF DOUBLE-IMAGE MICROMETERS IN WHICH TWO SINGLY-REFRACTING LENSES, SEMI-LENSES, OR PRISMS, ARE SEPARATED BY SCREWS.

Röemer, 1678.

M. Röemer, the celebrated Danish astronomer, is said to have been the first who suggested the use of a double-image micrometer. He did this about 1678, but the idea does not seem to have been carried into effect, or known to his successors. Nearly seventy years afterwards, viz., in 1743, Mr Servington Savary of Exeter communicated to the Royal Society an account of a double-image micrometer; and five years afterwards, in 1748, the celebrated Bouguer proposed the very same construction, which he called a heliometer. This instrument consisted of two lenses, which could be separated and made to approach each other by a screw or other mechanical means. These lenses gave double images of every object; and when the two images of any object, such as the sun or moon, were separated till they exactly touched one another, the distance of the object-glasses afforded a measure of the solar or lunar diameter, after an experimental value of the divisions of the scale had been obtained.

Savary. 1743.

Bouguer. 1748.

Dollond. 1753.

As two complete lenses, however, must always have their least distance equal to the diameter of either, this instrument was incapable of measuring the diameters of small bodies. This obvious defect no doubt led John Dollond, in 1753, to the happy idea of the divided object-glass micrometer, in which the two halves of an object-glass are made to recede from the position in which they form a complete object-glass. When the centres of the two halves coincide, they obviously form one lens, and give only one image. When the centres are slightly separated, the images will be slightly separated; and small objects may be brought into contact and have the angles which they subtend accurately measured. The scale will therefore have a zero corresponding to the coincidence of the centres of the semi-lenses. The principle of this instrument will be understood from fig. 9, where H, E are two semi-lenses, whose centres are at H, E, and F their focus. If PQ be a circular object whose diameter is to be measured, or P, Q two points whose angular distance is to be determined, the lenses are to be separated till the two images x, z are in contact at F. As the rays QHF, PEF pass unrefracted through the centres H, E of the semi-lenses, the angle subtended by QP will be equal to the angle HFE, or that which the distance of the centres of the semi-lenses subtends at F. Since the angles, therefore, are very small, they will vary as HE; and when the angles corresponding to any one distance of the centres is determined, those for any other distance will be ascertained by simple proportion.

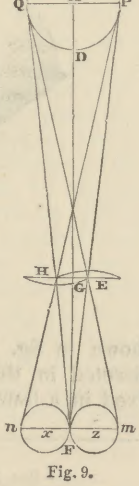

Fig. 9.

Mr Dollond, who had not at this time invented the achromatic telescope, applied his micrometer to the object end of a reflecting telescope, as shown in fig. 10, which represents the micrometer as seen from beyond the object end of the reflector. A piece of tube B, carrying the micrometer, slides into or over the tube A of the telescope, and is fastened to it by a screw. The tube B carries a wheel (not seen in the figure) formed of a ring racked at the outer edge, and fixed to the brass plate CC, so that a pinion moved by the handle D may turn it into any position. Two plates F, G are kept close to the plate CC by the rabbeted bars H, H, but with so much play that they can move in contrary directions by turning the handle E, which drives a concealed pinion that works in the two racks seen in the highest part of the figure. As the two semi-lenses are fixed to the plates F, G, their centres will be separated by the action of the handle E, and their degree of separation is measured by a scale of 5 inches subdivided into 20ths of an inch, and read off by a vernier on the plate F, divided into 25 parts, corresponding to 24 of the scale, so that we can measure the separation of the semi-lenses to the $\frac{1}{500}$th of an inch. The vernier is to the right of H, and may be adjusted to the zero of the scale, or the position of the lenses when they give only one image, by means of the thumb-screw I, a motion of the vernier being permitted by the screws which fix it to the plate F passing through oblong holes.[1]

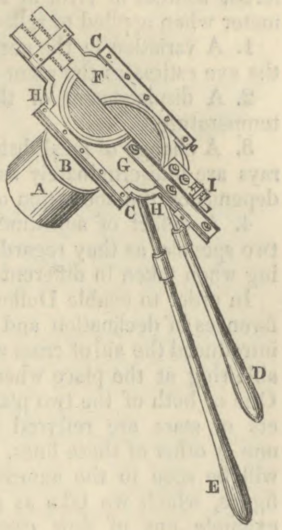

Fig. 10.

Mosotti.

In this construction the micrometer is too far from the observer, and destroys the equilibrium of the telescope. The instrument itself, however, has more serious defects, as it has been found that the measures of the sun's diameter, taken by different observers with the same instrument and at the same time, differ so much as 12 or 15 seconds. This defect has been ascribed to the different states of the observers' eyes, according as they have a tendency to give distinct vision within or beyond the focal point, where the image is most perfect; in the former case the limbs being somewhat separated, and in the latter overlapping. M. Mosotti, in the *Effemeride* of Milan for 1821, has discovered the true cause of this defect by a series of accurate experiments, which he made with this micrometer attached to a Gregorian reflector of two feet in focal length. The focal length of the divided object-glass was 511·3357 inches, or 42 feet 7½ inches. M. Mosotti has shown that a diversity of measures will be obtained by the same observer, if, for the purpose of obtaining distinct vision, he gives a slight displacement to the small speculum by the adjusting screw. If the position of this speculum which gives distinct vision were a point, it would be easy to find that point; but as distinct vision can be obtained only within a space of 10 or 12 thousandths of an inch, owing to aberration, every different observer will place the mirror at a different point within that range, and consequently obtain a measure corresponding to the image which he views. M. Mosotti recommends that the axis of the adjusting screw, which carries the small speculum, should carry a vernier connected with a scale on the outer surface of the tube A. By means of this vernier the observer is able to give a fixed position to the small speculum, so that he always views the same image, and is thus sure of obtaining the same measure of the same object, so far as the observation is concerned. M. Mosotti found also that the measures were affected by a change of temperature, which, by changing the length of the tube, displaced the small speculum. In his instrument this displacement amounted to 0·0075 of an inch, which, he has shown, corresponds to a change of focal length from 511·3357 to 514·84 inches; and that the error from this cause, upon a length of 30′, will be 13″ in excess.

---

[1] *Phil. Trans.*, vol. xlviii.

Pearson. The following is Dr Pearson's enumeration of the different sources of error in the divided object-glass micrometer when applied to reflectors:—

1. A variation in the position of the small mirror when the eye estimates the point of distinct vision.

2. A displacement of the small mirror by change of temperature.

3. A change of focal distance when central and extreme rays are indiscriminately used. The amount of this error depends on the aberration of the semi-lenses.

4. A defect of adjustment, or of perfect figure, in the two specula, as they regard each other, the measures varying when taken in different directions.

Maskelyne. In order to enable Dollond's micrometer to measure differences of declination and right ascension, Dr Maskelyne introduced the aid of cross wires, which he fixed in a moveable ring at the place where the double image is formed. One or both of the two planets or stars are referred to one or other of these lines, as will be seen in the annexed figure, which we take as an example out of four cases. Let ENWS be the field of view, NS the meridian, and EW the line of east and west; then, in order to obtain the difference of right ascension and declination of two stars, he opened the semi-lenses till he obtained double images of each star. He then turned round the micrometer till the two images of the first star passed over the vertical wire NS at the same instant, and having counted the time that elapsed till the two images of the other star passed over the same line, he had the difference of right ascension in time. By means of the screw which elevated his telescope, and partly by opening the semi-lenses, he made the north image of one star, and the south image of the other, as at A, B, describe in their motion the horizontal wire EW, and at that position of the semi-lenses the scale indicated the difference of declination.

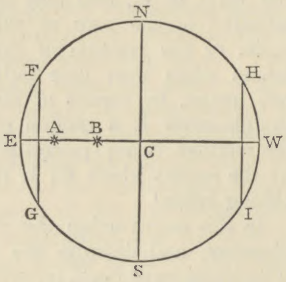

Fig. 11.

Mr Dollond junior's improvement. A very important improvement upon the divided object-glass micrometer was made by Mr Dollond's son, who adapted it to a refracting telescope, and removed the different sources of error to which it had been found liable. This improvement consists both in the *nature, form,* and *position* of the semi-lenses. The semi-lenses are made concave, and consist of crown and flint glass, so as to give an achromatic image along with the object-glass of the telescope to which they are applied. These concave semi-lenses, of course, lengthen the focal distance of that object-glass. When a *circular* lens was bisected, as in the old construction, the metallic parts which held the semi-lenses obstructed the light in proportion to their separation; a defect of a serious nature in an instrument. In order to correct this evil, Mr J. Dollond substituted two long slices of glass cut from the diametral portion of a lens nearly six inches in diameter. Hence, in every position of these oblong semi-lenses, none of the metallic setting comes before the object-glass, and consequently the light is never obstructed, and is always of the same amount, whatever be the separation of the lenses. In the old construction, where the diameters of each lens slid along each other in contact, a part of the central portions having been removed by grinding the diameters smooth, the two images of an object never could coincide so as to give an accurate *zero;* but in the new construction, the space equal to what was removed by grinding is filled up with a brass scale and vernier; and the only evil of this is the loss of light corresponding to the thickness of this scale; but this trifling defect is amply compensated by the perfect coincidence of the images at *zero.*

This important instrument is shown in fig. 12, where the same letters are used as in fig. 10 to denote the analogous parts of the two instruments. The end of the telescope is shown at A, and B is the rim of brass, which, by sliding upon A, fixes the micrometer to the telescope. The frame CC, moved by teeth on its outer edge, carries one of the halves G of the lens, and a similar frame with teeth carries the other half F. A scale six inches long is fastened like an edge-bar to CC, and each inch is subdivided into 20 parts, which are read off with a vernier of 25 parts, which is fastened as an edge-bar to the moveable frame that carries F. The two moveable frames are imbedded in a fixed plate HH, screwed to the tube B of the micrometer, and having a circular hole in its middle equal to the diameter of the object-glass. The two semi-lenses are separated by turning the milled head to the right of A, which moves the frame CC, and then the other frame F through the medium of a concealed wheel and a concealed pinion. The mechanism for giving the rotatory motion is also concealed. The adjustment of the vernier to zero is effected by the screw I.

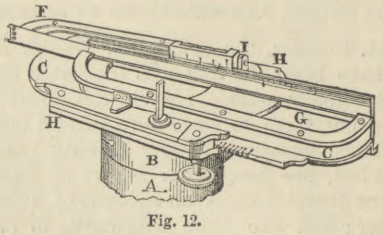

Fig. 12.

Ramsden's dioptric micrometer. 1777. The property which the double-image micrometer possesses of measuring angles in all directions, directed to it the attention of Ramsden and other eminent opticians. Ramsden accordingly communicated to the Royal Society of London in 1777[1] an account of two instruments of this kind, under the name of the *Dioptric* and *Catoptric* Micrometers. In order to avoid the effects of aberration, Ramsden proposed, in his dioptric micrometer, to place two semi-lenses in the conjugate focus of the innermost lens of the erect eye-tube of a refracting telescope. In place of the imperfections of the lenses being magnified by the whole power of the telescope, they are magnified only about five or six times, and the size of the micrometer glass does not require to be $\frac{1}{100}$th part of the area which is necessary in Dollond's instrument. This instrument is shown in fig. 13, where A is a convex or concave lens, bisected in the usual way. One of the semi-lenses is fixed in a frame B, and the other in a similar frame E,

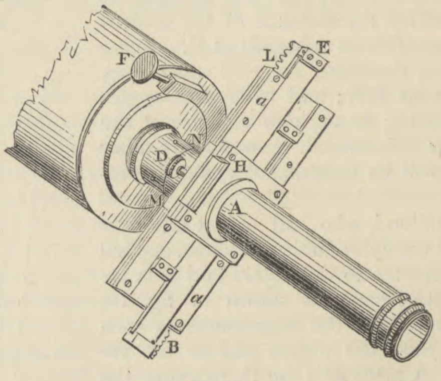

Fig. 13.

Double-Image Micrometers.

both of which slide upon a plate H, against which they are pressed by thin plates *a*, *a*. The milled button D, by means of a pinion and rack, moves these frames in opposite directions; and the separation of the semi-lenses thus effected is measured by a scale of equal parts L on the frame B, the zero being in the middle, and the divisions read off by two verniers at M and N, carried by the frame E; the vernier M showing the relative motion of the two frames when the frame B moves to the right, and N when the frame B is moved to the left. An endless screw F gives the whole micrometer a motion round the axis of vision. This instrument being only the divided object-glass micrometer in miniature, and differently placed, the reader will have no difficulty in understanding its construction and use, from the details already given in the preceding pages.

Dr Pearson informs us, on the authority of Mr Troughton, that a Captain Countess, R.N., having accidentally broken the third lens of a terrestrial eye-piece of his telescope, observed the double images which it produced; and that this observation led to the contrivance of the coming-up glass that was first made by Nairne, with a double screw for separating the halves of the amplifying lens. Hence it is *conjectured* that Ramsden derived his idea of using a bisected lens for his dioptric micrometer and dynameter. The above facts may be quite true; but Ramsden certainly did not require any such hint, as it was a very natural transition from a bisected object-glass to a bisected eye-glass.

Dr Pearson also states that Mr George Dollond had constructed a dioptric micrometer almost the same as Ramsden's, without knowing anything of what Ramsden had proposed. We have no doubt that both these ingenious opticians were quite original in their ideas, for it will not be supposed that Captain Countess's broken lens furnished Mr Dollond with the idea of his contrivance. Dr Pearson has given a drawing and description of Mr Dollond's construction of the micrometer as made for Mr Davies Gilbert and himself.[1] It does not appear that Mr Ramsden ever constructed it. The weight of this micrometer was found by Dr Pearson too great for an ordinary achromatic telescope.

Ramsden's catoptric micrometer.

Mr Ramsden likewise proposed a catoptric double-image micrometer, which, from being founded on the principle of reflection, is not disturbed by the heterogeneity of light, while he considered it as "avoiding every defect of other micrometers," having "no aberration, nor any defect which arises from the imperfection of materials or of execution, as the extreme simplicity of its construction requires no additional mirrors or glasses to those required for the telescope." "It has also peculiar to itself the advantages of an adjustment to make the images coincide in a direction perpendicular to that of their motion. In order to effect these objects, Mr Ramsden divided the small speculum of a Cassegrainian reflector into two equal halves, and by inclining each half on an axis at right angles to the plane that separated them he obtained two distinct images; but as their angular separation was only half the inclination of the specula, which would give only a small scale, he rejected this first idea, and separated the semi-specula by making them turn on their centre of curvature, any extent of scale being obtained by fixing the centre of motion at a proportional distance from the common centre of curvature. The mechanism necessary to effect this is shown in fig. 14, where A is the bisected speculum, one of the semi-specula being fixed on the inner end of the arm B, its outer end being fixed on a steel axis *x* extending across the mouth of the tube C. The other semi-speculum is fixed on the inner end of the arm D, its outer end terminating in a socket *y*, which turns upon the steel axis *x*. These arms are braced by the bars *a*, *a*. A compound screw G, having its upper part cut into double the number of threads in an inch, viz., 100, to the lower part *g*, which has only 50, works with the handle in a nut F in the side of the tube, while the part *g* turns in a nut H fixed to the arm B. The point of the compound screw separates the ends of the arms B and D, and pressing against the stud *h* fixed to the arm D, turns in the nut H on the arm B. A spiral spring within the part *n* presses the two arms B, D against the direction of the double screw *e g*, so as to prevent all shake or play in the nut H. The progressive motion of the screw through the nut will be half the distance of the semi-specula, so that these specula will be moved equally in opposite directions from the axis of the telescope.

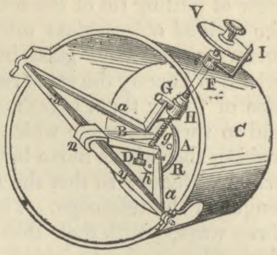

Fig. 14.

A graduated circle V, divided into 100 parts on its cylindrical surface, is fixed on the upper end of the screw G so as to cause it to separate the semi-specula. The fixed index I shows the parts of a revolution performed by the screw, while the number of whole revolutions of the screw is shown by the divisions of the same index. A steel screw R, moveable by a key, inclines the small speculum at right angles to the direction of its motion. Distinct vision is procured in the usual manner, and the telescope has a motion about its axis, in order to measure the diameter of a planet in any direction; and the angle of rotation in reference to the horizon is shown by a level, graduated circle, and vernier, at the eye end of the large tube.

Catoptric micrometer for a Newtonian telescope.

A catoptric double-image micrometer has been suggested by Sir David Brewster as applicable to the Newtonian telescope. The plane mirror is bisected, and is made to form two images, either by giving each semi-speculum a motion round their common line of junction, or round a line perpendicular to that common line. The mechanism by which this may be effected does not require any description. If the micrometer is required for the sun or any luminous body, the small mirror may be made of parallel glass, which would have the advantage of not obstructing any of the light which enters the telescope, while it reflects enough for the purposes of distinct vision. We shall again have occasion to refer more particularly to this idea in the next section.

Amici's micrometer.

Professor Amici has described, in the Memoirs of the Italian Society, a new micrometer, which gives double images by means of semi-lenses separated by mechanical means; but as we have not access to this work, we shall draw our description of the instrument from one given by Dr Pearson, which is very far from being distinct, in so far, at least, as the construction of the semi-lenses, or *bars of glass*, as they are called, are concerned. The semi-lenses seem to be portions of a large concave lens, separated in the usual manner, so as to give two distinct images of objects; but the peculiarity of the invention seems to consist in the lenses being placed between the object-glass of a telescope and its principal focus, the cone of rays being divided at a point about six inches before the place where the focal image is formed. Dr Pearson, who made experiments with one of these instruments, has hinted at the inconveniences which he experienced in using it.

CHAP. IV.—DESCRIPTION OF DOUBLE-IMAGE MICROMETERS IN WHICH THE TWO IMAGES FORMED BY TWO SINGLY-REFRACTING LENSES, SEMI-LENSES, OR PRISMS, ARE SEPARATED OPTICALLY.

In the year 1776 Dr Maskelyne constructed and used

Double-Image Micrometers.

Maskelyne's prismatic micrometer.

his prismatic micrometer, which he had contrived with the view of getting rid of the sources of error to which he found the divided object-glass micrometer liable. Having cut a prism or wedge of glass into two parts, so as to form two prisms of exactly the same refracting angle, he conceived the idea of fixing them together, so as to produce two images, and to vary the angle which these two images formed by making the prisms move between the object-glass and its principal focus; so that the scale is equal to the whole focal length of the telescope. The two prisms may be placed in three ways,—with their thin edges joined, with their square thick edges or backs joined, or with their sides or triangular edges joined. In the first position the double images will have only one-half of the light which is incident on the object-lens when the prisms are close to it, and their degree of illumination will diminish as they approach the focus. In the second position they will, as before, have only one-half of the incident light when close to the object-glass, but the illumination will gradually increase as the prisms advance to the focus. In the third case, the prisms being in a reverse position, the light will be the same in every part of the scale, each of them receiving half the rays which fall upon the object-glass. On this account Dr Maskelyne preferred this last arrangement.

In the instrument which Dr Maskelyne constructed, and which seemed to have had only a thirty-inch object-glass, the prisms were not achromatic, and consequently the touching limbs of a luminous body were affected with the prismatic colours. In the case of the sun, where all the rays might have been absorbed but the red, this was of little consequence; but in other cases it was a serious defect, which could be removed only by making the prisms achromatic; or it might have been diminished by making the prisms of fluor spar, in which the dispersion is very small. One of the Dollonds accordingly executed for Dr Maskelyne an achromatic prism, which performed well. It does not appear that Dr Maskelyne made any observations of value with this instrument.

New divided object-glass micrometer.

A new divided object-glass micrometer has been constructed by Sir David Brewster, and described in his Treatise on New Philosophical Instruments. It consists of an achromatic object-glass LL (fig. 15), between which and its principal focus *f* two achromatic semi-lenses, fixed at a given distance, are made to move. These lenses are shown in fig. 16, and are fixed on a piece of tube, which screws into a tube, by pulling out and pushing in which they are made to recede from or approach to the object-glass LL. By this motion the angle subtended by the two images varies in the same manner as the angle subtended by a pair of fixed wires was made to vary by the motion of a second object-glass. When the semi-lenses are close to LL, as shown at A, B (fig. 15), the two images which they form are much separated, and their centres subtend a large angle; but as the lenses approach to *f*, the centres of the images gradually approach each other, and consequently the angle which they subtend continually increases. Hence, if we determine by experiment the angular distance of their centres when the lenses are close to LL, and likewise the angle when they are at *f*, the other end of the scale, and if we fill up the intermediate points of the scale either from theory or direct experiment, we shall have an instrument which will measure with the greatest accuracy all angles between the two extreme ones. Another or several pairs of semi-lenses may be applied to the same telescope, and placed at smaller or greater distances, so that, by means of other scales adapted to them, we may obtain all angles that may be required. The lenses A, B may be concave or convex; and when a large scale is required, with a tenth of an inch to a second, or even greater, we have only to use semi-lenses of long foci, and the scale may be confined to the part of the tube nearest the focal point.

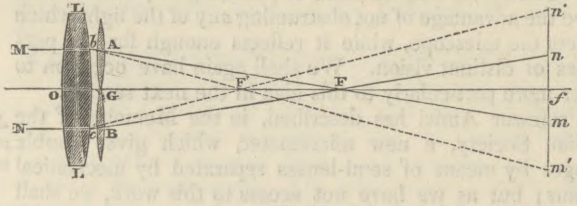

Fig. 15.

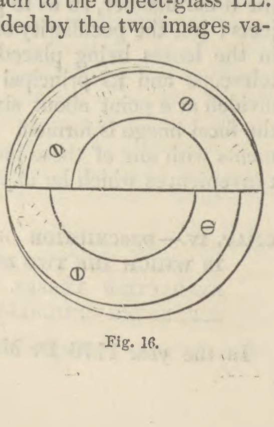

Fig. 16.

Sir David Brewster has proved, both from theory and experiment, that the scale is one of equal parts; so that, after having ascertained experimentally the two extreme angles, the whole scales may be completed by dividing the interval into any number of equal parts, and these subdivided, if necessary, by a vernier scale.

When the semi-lenses are placed without the object-glass LL, and this object-glass moved towards *f*, as in the annexed figure, the angular distance of the images is invariable.

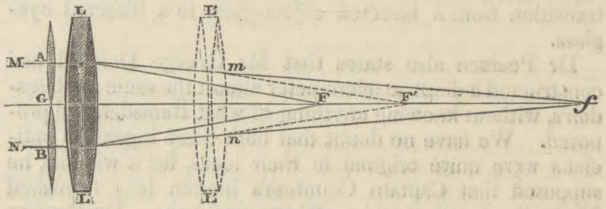

Fig. 17.

This instrument has been constructed for measuring distances, and as a coming-up glass for ascertaining whether a ship is approaching to or receding from the observer. In this form it constitutes part of fig. 7, the semi-lenses being made to screw into the same place as the second object-glass, and having a separate scale for themselves. In this form many of the instruments have been constructed by Tulley.

Prismatic micrometer for Newtonian reflectors.

Among the optical micrometers we may describe another invented by Sir David Brewster, and adapted solely to the Newtonian telescope. In order to get rid of the loss of light by the reflection of the small plane speculum, he uses an achromatic prism to reflect the light just as much out of the axis of the telescope as will allow the head of the observer to be applied to the eye-tube, without obstructing any of the light which enters the tube. By using two prisms, as in Maskelyne's instrument, and moving them along the axis of his telescope through a small distance, we shall obtain a good micrometer. The prisms may be separated mechanically, or a doubly-refracting prism may be fixed upon the face of the single or achromatic prism used to turn aside the rays. The achromatism of a single glass prism may be corrected by the doubly-refracting prism, a balance of refraction being left sufficient to turn aside the image to the observer's eye.

CHAP. V.—DESCRIPTION OF DOUBLE-IMAGE MICROMETERS IN WHICH THE TWO IMAGES ARE FORMED BY DOUBLE REFRACTION.

Rochon's first micrometer.

The happy idea of applying the two images formed by double refraction to the construction of a micrometer unquestionably belongs to the Abbé Rochon; and though Dr

Double-Image Micrometers.

Pearson has laboured to show that Dr Maskelyne's prismatic telescope was constructed before Rochon's, yet this does not in the smallest degree take away from the originality and priority of Rochon's invention; for the idea of varying the angle by the motion of the prisms can scarcely be viewed as an essential part of the invention.

Although the double refraction of rock-crystal is small, yet, from its limpidity and hardness, the Abbé Rochon regarded it as superior to any other substance for making doubly-refracting prisms. When he used one prism so cut that its refracting edge coincided with the axis of the prism, in which case its double refraction was the greatest, he found that the separation of the two images was too small to give the angles which he required.[1] He therefore fell upon a most ingenious plan of doubling the amount of the double refraction of one prism, by using two prisms of rock-crystal, so cut out of the solid as to give each the same quantity of double refraction, and yet to double that quantity in the effect produced. The construction of the compound prism was so difficult that M. Rochon informs us that "he knew only one person, M. Narci, who was capable of giving rock-crystal the prismatic form in the proper direction for obtaining the double refractions necessary to the goodness of the micrometer." The method used by Narci seems to have been kept a secret; for in 1819 Dr Wollaston set himself to discover the method of constructing these compound prisms, and has described it in the *Philosophical Transactions*,[2] but not in such a manner as to be very intelligible to those who are not familiar with such subjects. We conceive that the process may be easily understood from the following rule:—Cut a hexagonal prism of quartz into two halves by a plane passing through or parallel to its axis. Grind and polish the two cut faces, and by means of Canada balsam cement the one upon the other, so that any line or edge in the one face may be perpendicular to the same line in the other. Cut and polish a face on each of the united portions, so that the common section of these faces with the cemented planes may be parallel to the axis of the crystal, while they are equally inclined to these planes, and the prism will be completed.

Method of cutting the prisms from the crystal.

We shall now explain, by a diagram, a more simple and economical way of cutting these prisms, though the principle is exactly the same. Let AKGDBLHF be half of a hexagonal prism of quartz, the height of which, DF, is equal to half of its diameter AD. Bisect AD in C, and join CK, CG, and draw CE parallel to AB or DF. This line CE will be the axis of the prism. Grind and polish the section ABFD, and cut off the prisms AKCBLE and DGCFHE, setting aside the intermediate similar prism KGCLHE. The faces ACEB, DCEF are square and equal, so that if we cement these faces together, making the line AB coincide with FE, AC will coincide with FD, CE with DC, and EB with CE. If we wish each prism to have an angle of 60°, we may take either GDFH or GCEH for the refracting face of it; we shall suppose the former. In this case we must grind and polish a face on the other prism ABL, which is accurately parallel to the face GDFH, and the compound prism will be completed. If 60° is too great, we must grind down the face GDFH till it has the desired inclination to DF, and grind and polish a face parallel to it on the other prism. The external faces, in short, to be made upon each prism must be equally inclined to the cemented planes DCEF, ABEC, and have their common section DF parallel to the axis CE of the prism. In place of cutting off the prism AKCBLE, we may cut off only the prism GCDHEF, leaving the intermediate one GKCHLE attached to AKCBLE, and proceed as before. The object of this is to leave enough of solid quartz at KL to give a face of the same breadth as GDFH. If the prisms required are small compared with the quartz-crystal, we may obtain, by the first method, six prisms out of the crystal, or three pair of compound ones. On the other hand, if the required prism is large compared with the crystal of quartz, it may require one-half of the crystal to make one prism, and the other half the other. Nay, it may be necessary to cut each individual prism out of separate crystals, the method of doing which is very obvious from the preceding description.

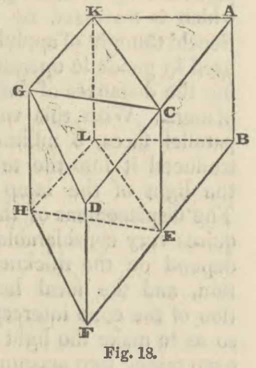

Fig. 18.

Double-Image Micrometers.

When the prism is completed, it is evident that a ray of light incident perpendicularly on the face GHFD will be perpendicular to the axis of the prism CE, and therefore the extraordinary ray will suffer the greatest deviation, viz. 17′: and the same is true of the other prism. But when the ray passes through both, it is found to have a deviation of 34′, which is produced in the following manner: Let AB be a line viewed through one of the prisms, with its refracting angle turned upwards; two images of it will be seen, viz., the extraordinary image at E, and the ordinary one at O. If we now interpose the other prism with its refracting angle downwards, both these images E, O will be refracted downwards. But owing to the transverse cutting of the prisms, the extraordinary image E, which was most raised, now suffers ordinary refraction, and is least depressed, so that in place of being refracted back to AB, it comes only to E′O′. On the other hand, the ordinary image O, which suffered the least refraction, is now extraordinarily refracted, and, in place of reaching AB, is depressed to O′E′; and since the double refraction of each prism, as well as the angles of the prism, are equal, the angular distance of the images E′O′, O′E′ formed by the combined prisms will be double of the distance EO, or 34′.

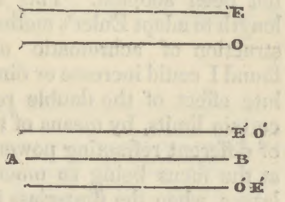

Fig. 19.

The same rule may be followed in cutting the prism out of the limpid and homogeneous topazes of New Holland, the principle axis of which coincides with the axis of the prism. When the crystals are amorphous, the cleavage planes will be a sufficient guide, as the above axis is always perpendicular to them. Such prisms are incomparably superior, as we have practically experienced, to those made of rock-crystal.

When a very large angle is required for any particular purposes, artificial crystals, such as carbonate of potash, &c., may be advantageously employed, the crystals being ground with oil, or any fluid in which they are not soluble. By cementing plates of parallel glass on their outer surfaces they will be as permanent as rock-crystal.

Dr Pearson fitted up with one of Rochon's micrometers an achromatic telescope 33 inches in focal length, and having a magnifying power of 35½. He applied it to two separate compound prisms, one of which had a constant angle of 32′, and the other an angle only of 5′, the vernier in the former case indicating seconds, and in the latter tenths of seconds. A drawing is given of the tube, with

---

[1] In his first experiments Rochon corrected the dispersion of the rock-crystal prism by a similar prism placed in front of it, and having its exterior face perpendicular to the axis of the crystal. This prism, having no effect in doubling the image, gave him a complete correction of the dispersion for the ordinary image.

[2] *Phil. Trans.* 1820, p. 126.

Double-Image Micrometers.

the prisms and scales in figs. 20, 21, as given by Dr Pearson. The tube is graduated from the solar focus into two scales, one being placed on each side of the slit or opening cut along the middle of the tubes, to allow the sliding-piece, shown separately in fig. 21, to move from the object-glass to the solar focus. This sliding-piece holds the prism, the larger prism of 32′ being shown as placed with its sliding-piece in the tube, and the smaller prism of 5′ being shown in the separate sliding-piece (fig 20). The two verniers of the scales are seen on each side of the two screws with milled heads, which pass through the slit, and serve to move the sliding-piece to or from the object-glass when they are not too much tightened.

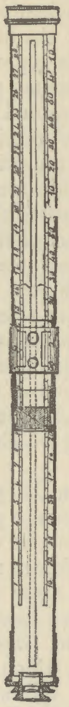

Fig. 20.

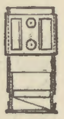

Fig. 21.

In his original memoir on the subject, published in the *Journal de Physique* for 1801,[1] M. Rochon makes the following observations:—"I ought not to omit that in this new construction there are difficulties of execution not easy to surmount, which may have been one reason why these instruments, so useful to navigators, and in certain very nice astronomical observations, have not been adopted. This induced me at length to adopt Euler's method. In the construction of achromatic object-glasses I found I could increase or diminish the absolute effect of the double refraction within certain limits, by means of the interval between the glasses of different refracting powers; the separation of the images at the focus being so much the greater, as the interval is larger, when the flint-glass is the first of the object-glasses, and less when it is the second. Conformably to these new principles, I have had two telescopes with a doubly-refracting medium constructed under my own inspection, which General Gantheaume will employ for determining the position of his ships, and to find whether he be approaching any he may meet with at sea."[2]

Rochon's second micrometer.

In 1812 M. Rochon constructed his doubly-refracting micrometer in another form, from which he anticipated great advantages. He made a parallelopiped of rock-crystal, consisting of two prisms whose refracting angles were each about 30°, so that the angle which they gave was less than 30′, and the two images of the sun of course overlapped each other. The prisms being firmly united by mastic, he ground the parallelopiped into a convex lens, so that when combined with a concave one of flint-glass, it formed an achromatic object-glass with a focal length of about 3 decimetres, or nearly 12 inches. This object-glass separated the centres of the images of the sun about 28 minutes. "He then adapted to this object-glass a common micrometer, which measured angles of 10 minutes, and he had thus three decimetres and 10 minutes to complete the measure of the diameters of the sun or moon."

Arago's doubly-refracting micrometer.

M. Arago, as he himself informs us, employed Rochon's micrometer in taking more than 3000 of the diameters of the planets. He found, however, that he could not make both the images equal in diameter at the same time, and that with high powers this defect was intolerable. When the prism, too, was near the eye-glass, for the determination of the zero of the scale or for the measure of very small angles, the smallest imperfections in the crystal, or in the state of its surfaces, were considerably magnified. In order to remedy this inconvenience he placed the prism without the telescope, between the eye-glass and the eye, at the place where the darkening glasses for observing the sun are fixed. The contact of the two images was then obtained by Sir David Brewster's method of varying the magnifying power of the telescope, as shown in fig. 5, where the two lenses of the eye-piece next the eye are moved to and from the other two lenses. M. Arago, however, having found that this change in the eye-piece was an inconvenience, kept the magnifying power constant, and employed a large number of doubly-refracting prisms in which the angles succeeded one another by variations of 30 and even 15 seconds. By this means he selected the prism which brought the two images nearest into contact. He then took the next, in which the images overlapped, and took the mean of their angles, which he divided by the magnifying power of his telescope. "With prisms," he remarks, "succeeding one another by 15 seconds, and with a magnifying power of 200, each measure will differ from that of the preceding prism by $\frac{15''}{200}$, or $\frac{7}{100}$ths of a second. The uncertainty, therefore, of the mean will be scarcely $\frac{4}{100}$ths, a quantity which may be safely neglected. Previous to the construction of this micrometer, which he describes in the *Comptes Rendus* for 1847,[1] M. Arago seems to have used another form of the instrument, in which, as Dr Pearson informs us,[2] the constant angle was increased by placing the prism in an oblique direction as regards the line of vision; and in which "he determined the respective values of the angles thus increased by means of concentric circles placed vertically at a measured distance from the eye when looking through the prism; for as he knew the diameters of each circle, he could generally find out one of the number which would come into exact contact with its image, and thus give the value of the constant angle."

Micrometers of Porro and Secchi.

A micrometer with double images was executed and used by M. Porro of Paris in 1842, and more recently by M. Secchi, astronomer to the Collegio Romano. M. Porro gives to his micrometer the name of *The Parallel Independent Micrometer*. It consists of a parallel plate of glass placed within the telescope, so that part of the rays from any object pass through it, and another part past it. By a greater or less inclination of the plate, two images of the object may be either superposed or be made to touch alternatively by one side or by another. The change of inclination of the plate gives the measure of the discs or angles required. In order to correct the elongation of the focus of the half pencil which traverses the glass, it is compensated by a fixed glass of the same thickness as that which is traversed by the other half of the pencil. M. Secchi thought of applying this micrometer, which had been used in geodetic operations, to large telescopes for measuring the distances of double stars and the diameters of the planets. With this view he took a plate of glass with parallel faces, 3 millimetres thick and 12 wide, and introduced it into the telescope by the hole through which the light of the lamp passes for illuminating the wires. The displacement of the images, which are very small, requires very considerable inclinations of the plate, and they depend on the thickness of the plate, its index of refraction, and the focal length of the telescope. The position of the cone intercepted by the plate may be regulated so as to make the light of the two images perfectly equal, even taking into account the reflection produced by the surfaces of the plate. M. Secchi applied this micrometer to the telescope of 7 feet of Cauchoix, and one of 14 feet by Merz, and found it to give good results. He remarks, however, that for telescopes of short focus, and perhaps for large ones with high magnifying powers, the displacing plate of parallel glass should be slightly concave, in order to lengthen a little the focus which the displacement shortens. M. Porro disapproves of making the plate concave. He fixes the micrometer on a separate stand, so as to be independent of the position of the telescope, though within it.[1] The displacement d of the image is found by the following formulæ :—

$$d=t\,\frac{\sin \mathrm{I}-\mathrm{R}}{\cos \mathrm{R}},$$

$$\text{and } \sin \mathrm{R}=m \sin \mathrm{I};$$

t being the thickness of the glass, m its index of refraction, I the inclination of the plate or the angle of incidence, and R the angle of refraction. The value of I is given by the instrument to the 100th part of a degree.[2]

Pearson's ocular crystal micrometer.

Dr Pearson has proposed an *ocular crystal micrometer*, and has given a drawing and description of the instrument.[3] It is nothing more than M. Arago's ocular crystal prism, in which the constant angle is varied by Sir David Brewster's variable eye-piece already described. On the same principle, the angle of the prism may be varied by a convex or concave lens moving between the object-glass and its principal focus; but what would be still better, by pulling out or pushing in the eye-piece of a Gregorian or Cassegrainian telescope.

Mr G. Dollond's spherical crystal micrometer.

In 1821 Mr George Dollond communicated to the Royal Society an account of his spherical crystal micrometer, a very ingenious instrument, though, we should think, one difficult to execute; and at the same time, even when well executed, liable to error. Mr Dollond's improvement consists in making a sphere or lens from a piece of rock-crystal, and adapting it to a telescope in place of the usual eye-glass, as shown in fig. 22, where a is the sphere or lens, formed of rock-crystal, and placed in *half holes*, from which is extended the axis bb, with an attached index, the face of which is shown in fig. 23. This index registers the motion of the sphere on the graduated circle. The sphere a is so placed in the half holes that when its natural axis (axis of double refraction, we presume) is parallel to the axis of the telescope, it gives only one image of the object. In a direction perpendicular to that axis it must be so placed that when it is moved the separation of the images may be parallel to that motion. The method of acquiring this adjustment is by turning the sphere a in the half holes parallel to its own axis. A second lens d is introduced between the sphere and the primary image given by the object-glass, and its distance from the sphere should be in proportion to the magnifying power required. The magnifying powers engraven in fig. 23 are suited to an object-glass of 44 inches focal length. The following are the advantages of this construction as stated by its inventor :— 1. It is only necessary to select a piece of perfect crystal, and, without any knowledge of the angle that will give the greatest double refraction, to form the sphere of a proper diameter for the focal length required. 2. The angle may be taken on each side of *zero* without reversing the eye-tube; and intermediate angles may be taken between zero and the greatest separation of the images without exchanging any part of the eye-tube, it being only required to move the axis in which the sphere is placed. 3. It possesses the property of a common eye-tube and lens; for, when the axis of the crystal is parallel to that of the object-glass, only one image will be formed, and that as distinctly as with any lens that does not refract doubly.[1]

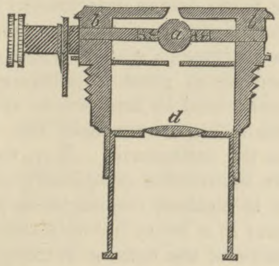

Fig. 22.

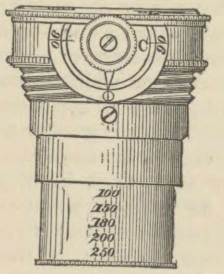

Fig. 23.

Dr Pearson had one of these instruments constructed by Mr Dollond, and applied to an achromatic object-glass 43·6 inches in focal length. He has shown that the scale is not one of equal parts, and has pointed out a method of determining the constant angle of the crystal.

Knowing from experience the imperfect structure of rock-crystal, especially in directions approaching to the axis, we dreaded that a spherical eye-glass of this material would not give perfect vision. Dr Pearson confirms this opinion by actual observation. He attempted to measure the diameter of Mars when about 9″, "but its limits were so imperfectly defined that no satisfactory observation could be made."[2] We would therefore strongly recommend the substitution of limpid topaz from New Holland in place of the rock-crystal.

CHAP. VI.—DESCRIPTION OF POSITION-MICROMETERS.

Position-micrometers.

A position-micrometer is an instrument for measuring angles when a plane passing through the two lines which contain these angles is perpendicular to the axis of vision. Sir W. Herschel first proposed such an instrument for the purpose of verifying a conjecture, that the smaller of the two stars which compose a double star revolves round the larger one. Hence it became necessary to observe if a line joining the centres of any two stars always formed the same angle with the direction of its daily motion. After constructing the instrument which we are about to describe, and making a long series of observations, he verified his conjecture by the important discovery that the double stars formed binary systems, in which the one revolved round the other. The position-micrometer used by Sir William Herschel in his earliest observations, viz., those made in 1779-1783, was made by Nairne, and was constructed as shown in fig. 24, which represents it when inclosed in a turned case of wood, and ready to be screwed into the eye-piece of the telescope. "A is a little box which holds the eye-glass. B is the piece which covers the inside work, and the box A screwed into it. C is the body of the micrometer, containing the brass-work, showing the index-plate a projecting at one side, where the case is cut away to receive it. D is a piece having a screw b at the bottom, by means of which the micrometer is fastened to the telescope. To the piece C is given a circular motion, in the manner the horizontal motion is generally given to Gregorian reflectors, by the lower part going through the piece D, where it is held by the screw E, which keeps the two pieces C and D together, but

Position-Micrometers.

Sir W. Herschel's position-micrometer.

leaves them at liberty to turn on each other. Fig. 25 is a section of the case containing the brass-work, where may be observed the piece B hollowed out to receive the box A, which consists of two parts inclosing the eye-lens. This figure shows how the piece C passes through D, and is held by the ring E. The brass-work, consisting of a hollow cylinder, a wheel and pinion, and index-plate, is there represented in its place. F is the body of the brass-work, being a hollow cylinder with a broad rim C at its upper end; this rim is partly turned away to make a bed for the wheel *d*. The pinion *e* turns the wheel *d*, and carries the index-plate *a*. One of its pivots moves in the arm *f*, screwed on the upper part of *c*, which arm serves also to confine the wheel *d* to its place on *c*. The other pivot is held by the arm *g* fastened to F.

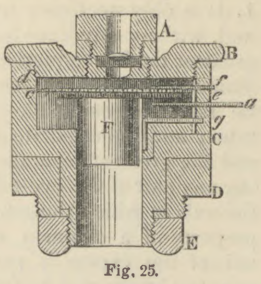

Fig. 25.

A section of the brass-work is shown in fig. 26, where the wheel *d* which is in the form of a ring inlaid on the upper part of F or C, and held by two small arms *f*, *h*, screwed down to *e* with the screws *i*, *i*.

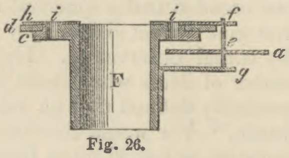

Fig. 26.

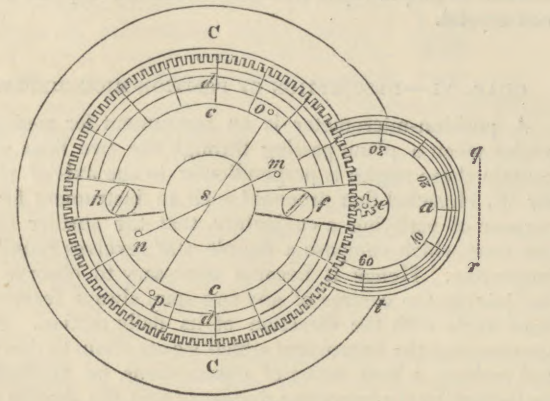

Fig. 27.

A plan of the brass-work is shown in fig. 27, where *dd* is the wheel placed on the bed or socket of the rim of the cylinder *cc*, and is held down by the two pieces *f*, *h*, which are screwed on *cc*. The piece *f* projects over the centre of the index-plate to receive the upper pivot of the pinion, *mn* the fixed wire being fastened to *cc*, and the movable wire *op*, to the annular wheel *dd*. The index-plate *a*, milled on the edge, is divided into sixty parts, each subdivided into two. When the finger is drawn over the milled edge of the index-plate from *q* to *r*, the angle *mso* will open by the rotation of the movable wire *op*, and if drawn from *r* towards *q*, it will shut again. The case CC must have a sharp corner *t*, which serves as an index to point out the divisions on the index-plate.[1] In using this micrometer the movable wire *op* is placed in the direction of the apparent motion of the principal star, and the other wire *mn* made to form such an angle with it that both the stars arrive at this wire at the same time. The inclinations of the wire measured on an index-plate gives the *angle* of position, or that which the line joining the centre of the stars forms with the direction of their daily motion.

We do not know the value of the divisions in the instrument used by Sir William Herschel; but in the position-micrometer of the five-feet equatorial used by Sir John Herschel and Sir James South, in their observations on double stars, the position circle was large enough to show distinctly minutes of a degree by means of its vernier. Since the time of Troughton an important improvement has been made in this micrometer, by separating the position motion from the linear motion. This is done by causing a foot or two of the end of the telescope which carries the wire-micrometer to revolve on the rest of the tube, thus securing a larger circle for the readings, and a firmer motion than could be obtained when all the movements were included in the micrometer itself.

Position-Micrometers.

Troughton's improvement.

The position-micrometer which we have now described has been improved by Sir David Brewster; and the following account of these improvements, which is not susceptible of abridgment, is given in his own words:—

Improved position-micrometer.

In the position-micrometer invented by Sir William Herschel, "the two wires *mn*, *op* always cross each other at the centre of the field *s*, and consequently their angular separation is produced uniformly by the motion of the pinion. This very circumstance, however, though it renders it easy for the observer to read off the angle from the scale, is one of the greatest imperfections of the instrument. The observations must obviously be all made on one side of the centre of the field, as appears from fig. 27; and the use of the instrument is limited to those cases in which the distance of the stars is less than the radius of the field. The greatest disadvantage of the instrument, however, is the shortness of that radius; for the error of observation must always diminish as the length of this radius increases. This disadvantage does not exist in measuring the angle of position of two stars; for the distance remains the same whatever be the radius of the field; but in determining the angle which a line joining two stars forms with a line joining other two stars, or those which compose a double star (an observation which it may often be of great importance to make), and all other angles contained by lines whose apparent length is greater than the radius of the field, this imperfection is inseparable from the instrument. Nay, there are some cases in which the instrument completely fails; as, for instance, when we wish to measure the angles formed by two lines which do not meet in a focus, but only tend to a remote vertex. If the distance of the nearest extremities of these lines is greater than the chord of the angle which they formed measured upon the radius of the field, then it is impossible to measure that angle, for the wires cannot be brought to coincide with the lines by which it is contained. Nay, when the chord of the angle does exceed the distance between the nearest extremities, the portion of the wires which can be brought into coincidence with the lines is so small as to lead to very serious errors in the result.

The new position-micrometer which we propose to substitute for this instrument is free from the defects just noticed, and is founded on a beautiful property of the circle. If any two chords, AB, CD (fig. 28), intersect each other in the point O within the circle, the angle which they form at O will be equal to half the sum of the arches AC, BD; but if these chords do not intersect each other within the circle, but tend to any point O without the circle, where they would intersect each other if continued, as in fig. 30, then the angle which they form is equal to half the difference of the arches AC, BD; that is, calling ϕ the angle required, we have, in the first case, as shown in fig. 28,

$$\phi=\frac{\mathrm{AC}+\mathrm{BD}}{2};$$ and in the second case, as shown in fig. 30,

$$\phi=\frac{\mathrm{AC}-\mathrm{BD}}{2}.$$ Hence, if the two wires AB, CD be placed

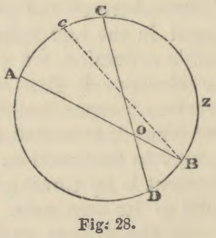

Fig. 28.

---

[1] *Phil. Trans.*, 1781, p. 500.

Position-Micrometers.

in the focus of the first eye-glass of a telescope, the movable one AB may be made to form every possible angle with the fixed one CD, and that angle may be readily found from the arches AB, CD.

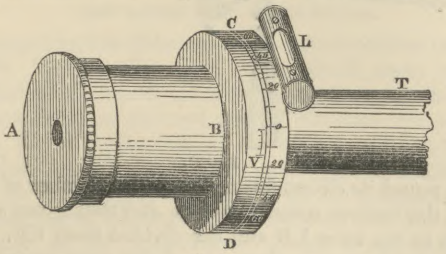

Fig. 29.

The mechanism for measuring these arches is shown in fig. 29, where the graduated circular head CD may be divided only into 180°, in order to save the trouble of halving the sum or the difference of the arches AC, BD; but as it would still be necessary to measure *two* arches before the angle could be ascertained, we have adopted another method, remarkable for its simplicity, and giving no more trouble than if the wires always intersected each other in the centre of the field.

Let AB, for example (fig. 30), be the fixed wire, and CD the movable one, and let it be required to find at one observation the angle AOC or ϕ. Set the index of the vernier to *zero*, when D coincides with B; and as C will be at *c* when D is at B, the arch *c*A will be a constant quantity, which we shall call *b*. Making AC$=m$, and BD$=n$, we have $\phi=\frac{m+n}{2}$. But since the extremity C will move over the space C*c* while D describes the space DB, these arches must be equal, consequently $b=m-n$; hence, adding $2n$ to each side of the equation, we obtain $b+2n=m+n$, or $\frac{1}{2}b+n=\frac{m+n}{2}$, consequently $\phi=\frac{1}{2}b+n$. Hence the angle AOC is equal to half the arch A*c* added to the arch DB; or, since A*c* is invariable, the half of it is a constant quantity, and the angle required is equal to the sum of this constant quantity and the arch DB.

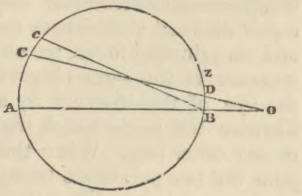

Fig. 30.

When the wires do not intersect each other, as in fig. 30, we have $\phi=\frac{m-n}{2}$, and $b=m+n$; hence, subtracting $2n$ from each side of the equation, we have $b-2n=m-n$, and, dividing by 2, we have $\frac{1}{2}b-n=\frac{m-n}{2}$, consequently $\phi=\frac{1}{2}b-n$. That is, the angle AOC is equal to the difference between half the arch A*c* and the arch DB, or to a constant quantity diminished by the arch DB.

In finding the angle AOC, therefore, we have merely to observe the place of the index when the wires are in their proper position; and as the scale commences at B, or where D and B coincide, and is numbered both ways from B, the degree pointed out on the circular head CD, when increased or diminished by the constant quantity, will give the angle of the wires which is sought. The semicircle on each side of a diameter drawn through B is divided into 180°, the 180th degree being at the opposite end of that diameter.

We may simplify still further the method of reading off the angle AOC, so as to save the trouble even of recollecting the constant quantity, and of adding it to, or subtracting it from, the arch pointed out by the index of the vernier. This advantage is obtained by making the index of the vernier point to the constant quantity upon the part of the scale below B (fig. 28) when the points D, B coincide, or when the wire CD is in the dotted position *c*B; for it is obvious that if *z* marks the zero of the scale, and B*z* is equal to the constant quantity, the arch D*z*, which is pointed out by the index of the vernier, will be equal to $\frac{1}{2}b+n$, or the angle AOC. In like manner, in fig. 30, where the wires do not cross each other within the field, and where B*z* is the constant quantity, the arch D*z* marked out by the index of the vernier is obviously equal to $\frac{1}{2}b-n$, or the angle AOC, which the wires tend to form at O. By means of this adjustment, therefore, we are able to read off the angle AOC with the same facility as if the wires intersected each other in the centre of the field, when the arches are accurate measures of the angles at the centre.

Position-Micrometers.

The end of the eye-tube is represented in fig. 29, where the circular head CD is divided into 360°, and subdivided by the vernier V. L is the level, and AB the part of the eye-piece which contains the diaphragm, with the fixed and movable wires. The head CD and the level L are firmly fixed to the eye-tube T; and from the head CD there rises an annular shoulder, concentric with the tube and containing the diaphragm, across which the fixed wire is stretched. This diaphragm, which is represented in fig. 31, with the wire extended across, projects through the circle of brass EF. All these parts remain immovable, while the outer tube AB, and the other half EF, of the circular head which contains the vernier V, have a rotatory motion upon the shoulder, which rises from CD. The tube AB is merely an outer case, to protect a little tube within it, which contains the eye-glass and the movable diaphragm, with its wire extended across it. The inclosed tube is screwed into the ring EF, and the outer tube is also screwed upon the same ring, so that by moving AB a motion of rotation is communicated to the vernier V, and to the diaphragm and wire belonging to the inner tube, while the rest of the eye-piece, containing the other diaphragm with its wire, remains stationary. By these means the movable wire is made to form every possible angle with the fixed wire, and the angle is determined by the method which we have already explained. The fixed wire is placed a good deal out of the centre of the diaphragm to which it belongs; and the diaphragm itself is placed in a cell, in which it can be turned round so as to adjust the wire to a horizontal line when the level is set. The movable wire is likewise placed at a distance from the centre of its diaphragm, as shown in fig. 32; but by means of screws which pass through the inner tube into the edge of this diaphragm, it can be moved in a plane at right angles to the axis of the eye-piece, so that the movable wire may be placed either in the centre of the field or at different distances from it.

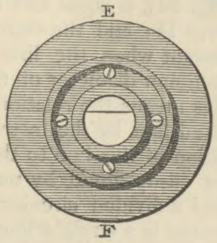

Fig. 31.

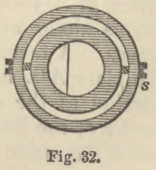

Fig. 32.

Double-image micrometer a position-micrometer.

The double-image micrometer affords a convenient method of measuring angles of position; and we believe this application of it was first made by Sir David Brewster.

In every instrument in which a double image of an object is formed by means of two semi-lenses with their centres at a distance, the one image appears to have a rotatory motion round the other when the telescope is turned about its axis. Thus in fig. 33, if A, B be images of two objects formed by the upper semi-lens when the common

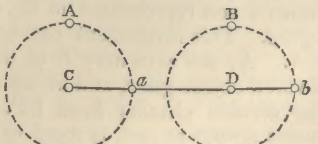

Fig. 33.

Position Micrometers.

diameter of the semi-lenses is perpendicular to the horizon, and C, D the images of the same objects formed by the lower semi-lens; then, by turning the telescope about its axis, or the semi-lenses round in their tube, the image A will appear to move round C in the circle A*a*E, and the image B round D in the circle B*b*F, or in the opposite direction if the telescope or the semi-lenses are turned the other way. When the distance AC is equal to CD, as in fig. 34, the image A will pass over the image D; or if the telescope is turned in the opposite direction, the image B will pass over the image C. In like manner, when AC is greater or less than CD, the images will move as we have represented them in figs. 33 and 35. In all these cases the four images may be brought into one straight line; and when this takes place the line which passes through all the images will uniformly form the same angle with the horizon as the common diameter of the semi-lenses. It is very easy to ascertain with the utmost accuracy when the images form one straight line; but particularly in the case where AC (fig. 34), is equal to CD, for the image of A will then pass over D; and the coincidence of the images will mark the instant when the line which joins them is parallel to the common diameter of the lenses. Hence, as we obtain by this means the relation of the line joining the images to a fixed line in the instrument, the relation of this line to the horizon may be easily found by means of a level and a divided circular head. If the image is a straight line (fig. 35), then the coincidence of the two images, so as to form one straight line, will indicate the parallelism of that line to the diameter of the semi-lenses.

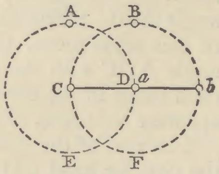

Fig. 34.

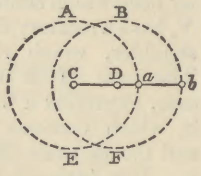

Fig. 35.

In constructing a micrometer of this kind solely for the purpose of measuring angles when the eye is not at their vertex, either the object-glass or the third eye-glass might be made the divided lens. If the object-glass is divided, it should be so constructed that it may have a rotatory motion in its cell, by applying the hand to a milled circumference AB (fig. 36). Connected with the tube TT of the telescope is a circular ring of brass CD divided into 360°; and the divisions upon this scale are pointed out by the index of a vernier *v*, which moves along with the semi-lenses. A level L is fixed to the plate AB, having its axis parallel to the common diameter of the lenses, and being adjusted to a horizontal line when the index points to the zero of the scale. In using the instrument, therefore, the observer turns round the semi-lenses by means of the projecting milled circumference AB, till the coincidence of the two images is distinctly perceived. The index of the vernier will then point out upon the graduated head the inclination of the line which is required.

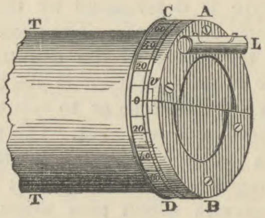

Fig. 36.

When the telescope is long, this form of the instrument, though extremely simple, is not very convenient. The construction represented in fig. 37 is in general to be preferred. This instrument consists of three tubes BL, LC, CA. At the extremity B of the first tube is placed the divided object-glass, and at the other extremity L is fixed the divided circular head EF. The tube CL, which remains always at rest, is fixed to the stand HI by means of the clasp and screw at H. The tube AC, which contains an eye-piece, moves within both the tubes CL and LB. The tube BL extends towards C, the tube CL being within it, and round its circumference are cut a number of teeth, in which the endless screw G works, and thus gives a rotatory motion to the tube LB and the divided head EF. By this means the common diameter of the semi-lenses at B is made to form every possible angle with a horizontal line, which is indicated by a level above L, having its axis parallel to the common diameter of the semi-lenses. The index of the vernier *v*, fixed to the stationary tube CL, points out on the graduated head the angle required. When the instrument is constructed so that the semi-lenses are in the eye-piece, the graduated head must be placed in the eye-tube.

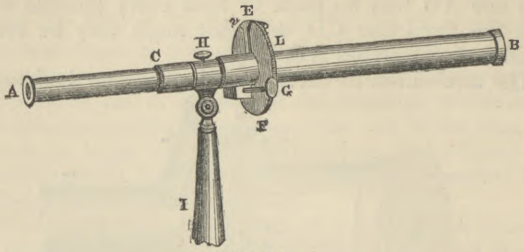

Fig. 37.

If the principle of this micrometer is applied to the double-image micrometer described in chap. iv., in which a pair of fixed semi-lenses moves between the object-glass and its principal focus, we obtain an instrument which will measure at the same observation the angle subtended at the eye of the observer by a line joining two points, and likewise the angle which that line forms with the horizon or any other line. When the two images of the line which joins the two points are brought into contact by the motion of the semi-lenses along the axis of the tube, these images must necessarily be in the same straight line, so that the relation of that line to the horizon, or to any other given line, and the contact of the two images of it which determines its angular magnitude, are obtained simultaneously without any additional observation or adjustment.

Dr Pearson has given some very useful details respecting the use of double-image micrometers in measuring angles of position.[1]

Linear disc micrometer.

When the brightness of the two stars which compose a double star is considerable, their discs may be drawn out into lines of light either by cylindrical refraction or reflection, and the coincidence of these lines will furnish the means of determining the angle of position.

Lucid disc position micrometer.

A position-micrometer upon a new principle has been proposed by Sir David Brewster. He expands the images of the two stars into luminous discs till they overlap each other. The southern limb of the lower disc is then made to move along the fixed wire of the position-micrometer. A line joining the two points where the circumferences of the discs intersect each other is obviously perpendicular to a line joining the centres of the stars, and will therefore form an angle with the fixed wire equal to the complement of the angle of position required. If we therefore make the movable wire pass through the two points where the luminous discs intersect each other, the micrometer scale will give the complement of the angle of position.[2]

Photographic position micrometer.

By the photographic process, already referred to (chap. i.), dark lines may be formed on transparent collodion or albumen at fixed angles, succeeding one another, like Arago's prisms, by angles differing 30″, 15″, or even 5″. These lines may converge to points within or without the field, or even to points at great distances; and in the latter case their inclination may be nicely determined in the large or unreduced copy by a divided circle furnished with a vernier read off by microscopes. A movable photographic line on a plate of collodion upon glass may have a motion close to the plate containing the other lines, and the foci of both made equally distinct by optical means.

[2] *Treatise on New Philosophical Instruments*, p. 45.

CHAP. VII.—DESCRIPTION OF THE LAMP-MICROMETER AND THE LUCID-DISC MICROMETER.

Lamp micrometer.

In measuring the distances and angle of position of double stars Sir William Herschel encountered many practical difficulties which interfered with the accuracy of his results. The uncertainty of the real zero of his scale, the inflexion of light, the imperfections of the screws and divided bars and pinions, and the difficulty of obtaining fibres sufficiently minute for his purpose, but, above all, the disappearance of small stars by the illumination of the wire, led this eminent astronomer to the contrivance of his *lamp-micrometer*, which, while it is exempt from these sources of error, has also the advantage of a large scale.

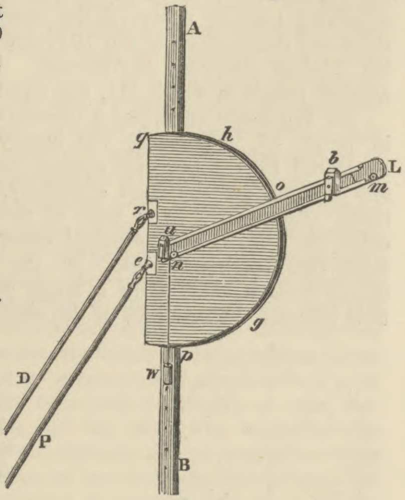

Fig. 38.

The lamp-micrometer is represented in fig. 38, where AB is the upright part of the stand, 9 feet high, upon which a wooden semicircle *qhogp*, 14 inches radius, may be fixed at different heights by a peg *p* put into holes in the stand. An arm L, 30 inches long, moves round a pivot in the centre of the board by means of the handle P, which works a string *eqho* fastened to a hook at the back of L. The arm L is kept at any inclination to the horizon by the weight of the handle P, which is 10 feet long. A small slider *b*, about three inches long, moves along the front of L towards and from the centre at *u*, by means of the handle *r*D, which operates by a string passing over the pulley *m*, and returning by *n* to a barrel at *r*, while a second string *bnw*, with a weight *w*, causes the slider *b* to return to the centre. The end of the arm L is shown on a large scale in fig. 39.

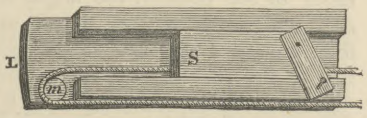

Fig. 39.

Two lamps *a*, *b* (figs. 40 and 41), $1\frac{1}{2}$ inch high and $1\frac{3}{4}$ inch deep, have sliding doors with small apertures made with a fine needle opposite the flame of a single cotton-thread wick, so that when the sliders are shut down, nothing is seen but two fine lucid points like stars of the third or fourth magnitude. The lamp *a* is placed at the centre *u*, so that its lucid point may occupy that centre, while *b* is hung on the slider S, so that its lucid point may be in a line with the lucid point of *a* when the arm L has a horizontal position.

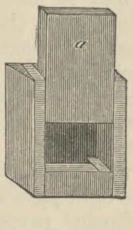

Fig. 40.

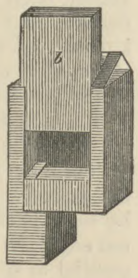

Fig. 41.

A person, therefore, at a distance of 10 feet may govern the two lucid points so as to bring them into any required position by the handle P; and by the handle D he may place them at any distance, from $\frac{6}{10}$ths of an inch to 25 inches.

In using this micrometer Sir W. Herschel placed it 10 feet from his left eye, while with his right he viewed a double star through his Newtonian reflector. By means of his left eye the double star is seen projected upon the micrometer, and he then placed his two lucid points at such a distance that they were exactly covered by the stars. The distance of the lucid points was the tangent of the magnified angles subtended by the stars to a radius of 10 feet. This angle, therefore, being divided by the magnifying power of the telescope, gives the real angular distance of the centres of a double star. With a power of 460 the scale was a quarter of an inch for every second. Sir W. Herschel, in measuring the apparent diameter of *α Lyræ* with this instrument, used a magnifying power of 6450. The magnified angle was 38′ 10″, so that the real angle was $\frac{38' \, 10''}{6450} = 0''\!\cdot\!355$, giving on this occasion a scale of no less than $8\frac{1}{2}$ inches to a second.[1]

Lucid-disc micrometer.

In using high magnifying powers Sir W. Herschel employed another apparatus called the lucid-disc micrometer. A lucid disc made of oiled paper, or any other semi-transparent substance, was placed in the front slider of a lantern, and illuminated by a flame behind it. The lantern was then removed to a distance till the diameter of the disc appeared equal to that of a planet seen in the telescope, so that the angular diameter of the planet became known by dividing the angle subtended by the disc by the magnifying power of the telescope. The result was affected by the colour of the disc and the degree of illumination. The measure was always too small when the illumination was strong, and too great when a black disc was placed on an illuminated ground. Hence Sir William Herschel took a mean of the two as the true measure.

M. Schroeter of Lilienthal, in measuring the diameter of Vesta, Juno, Pallas, and Ceres, used a lucid-disc micrometer, which we presume was not much different from Sir W. Herschel's.

Dr Pearson constructed and used an analogous instrument, in which the left eye looked into a tube containing a system of lines upon a disc of glass, or a spider's line micrometer, so that the object seen with the right eye was projected against these divisions, and its angular diameter ascertained.[2]

CHAP. VIII.—DESCRIPTION OF FIXED MICROMETERS WITH AN INVARIABLE SCALE.

Huygens's micrometer.

The earliest fixed micrometer of which we have a distinct account is that of Huygens, who placed a circular diaphragm in the focus of the eye-glass of his telescope, and found its angular value to be seventeen and a quarter minutes by the time which a star took to pass across it. He then formed two or three long brass plates of different breadths so as to form wedges of different angles. In measuring the diameter of a planet with one of these, he made one of them slide through two slits in the opposite sides of the tube, so that the plane of the brass wedges touched the plane of the circular diaphragm; and having observed in what part of the wedge its breadth just covered the whole planet, he took this breadth in a pair of compasses, and having found what part it was of the whole aperture, he divided seventeen and a quarter minutes by this part, and obtained the diameter required. Sir Isaac Newton has stated that the measures thus taken are always in excess. Had Huygens used long wedge-shaped slips or openings, he would by the same process have obtained measures which erred in defect, and the mean be-

Fixed Micrometers.

tween these two measures would have given the true diameter of the planet.

Cassini's reticle. The reticle (*reticulum*) or fixed micrometer, composed of wires, was invented and used by Cassini. It is shown in the annexed figure, where *ab*, *cd*, *ef*, *gh*, are four hairs or wires intersecting each other at right angles at *i*, in the focus of the eye-glass, *ab*, *cd* being inclined 45° to *ef* and *gh*. In order to find with this apparatus the differences of the right ascension and declination of two stars, direct the telescope so that the first or *preceding* star may appear upon the wire *ab*, and turn round the tube till that star moves along *ab*. The time when this star reaches *i* is carefully noted, and also the time when the *following* star reaches the wire *cd*. The interval between these times, converted into degrees, is the difference of right ascension required. To find the difference of their declinations, mark the time of the second or *following* star's arrival at the points *k* and *l* of the oblique wires *ef*, *gh*. The half of the interval between these times is the time in which the star describes the space *lm* or *mk*, which, converted into degrees, is the angular distance *lm*, which, multiplied by the cosine of the declination of the known or preceding star, gives an approximate difference, which, when applied to the declination of the known star, gives the approximate declination of the unknown or following star. If we now multiply the angular value of *lm* by the cosine of this approximate declination, we shall have the correct difference of declination, which, applied to the declination of the known star, will give the true declination of the unknown star.

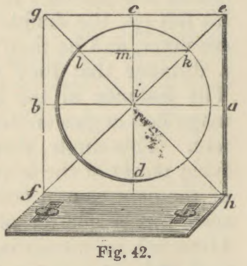

Fig. 42.

Bradley's reticle. In using the above reticle Dr Bradley found his observations embarrassed by the crossing of all the wires at *i*, which hid the preceding star at the very point where it was required to be most distinctly seen.[1] He therefore proposed the construction shown in the annexed figure, where the wires *hg*, *ki* intersect one another perpendicularly at *f*, the centre of the rings. Two slender bars of brass *lg*, *ng* are fixed to the ring *abc*, and inclined each to the diameter *hg* 26° 34′, half the angle of a rhomb whose greater diagonal is double of the lesser. Hence *fk* and *fi* will be each one half of *fg*, $ki = fg$, and $fm = nl - ik$. To avoid the inconvenience of turning the telescope about its axis, Dr Bradley placed the ring *abc*, which carries the wires or brass bars in a groove in the fixed ring ABC, and confining it laterally by three pieces of brass at A, B, and C, he employed an endless screw DEF to work in a toothed rack *de*, fixed to the inner ring *abc*. Let us now suppose the telescope so directed that a star is at *f*, and moving in any line *fq*; then, by turning the milled head D, the wire *fk* will move round *f* till it touches the star at *q*, and will then lie in the direction of the star's motion, while all other stars will move parallel to it. The mode of obtaining accurate results from this apparatus will be understood from the following description of an analogous contrivance described by Lacaille.

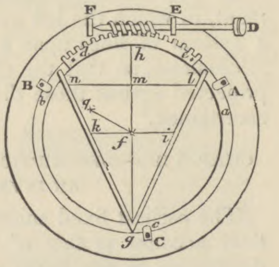

Fig. 43.

Lacaille's reticle. This eminent astronomer used a rhomb FMIL, the diagonals of which, FI, ML, must be exactly perpendicular to one another, and as two to one. The length FI was 15·4 lines, the angle subtended by $ML = 1° 25' 5''$, and consequently $FI = 2° 50' 10''$, as determined by the passage of several of the equatorial stars. Now, as the vertical height of each triangle in the rhomb is equal to the short diagonal, the path of any star passing through the field in a line parallel to that diagonal will always cut off a similar triangle, and the distance of this path from the common apex will have the same ratio to the vertical height of the large triangle, one-half FI, or ML, that the value of the diagonal in time has to the observed time of the passage. Hence the time which any star takes to pass from *m* to *l*, reduced to degrees, and multiplied by the cosine of the declination, is the difference of declination required. The difference of right ascension is obtained as before. With this simple apparatus Lacaille observed the comparative right ascensions and declinations of the 1942 stars which are given in his *Cœlum Australe Stelliferum*. Lacaille constructed another reticle in which ML was one-fourth of FI.

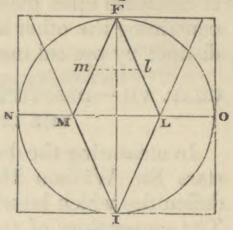

Fig. 44.

Rev. Mr Wollaston's reticle. Mr Wollaston employed a reticule similar to that shown in figure 45, AB being the horary line, and CD the equatorial line. The four squares being within the field, any of them may be used separately, so that observations made successively in a pair of them will check each other as well as the principal observation made in the large right-angled triangle. As the diagonals are equal to one another, they afford a larger passage of a star, and thus increase the accuracy of the observation.

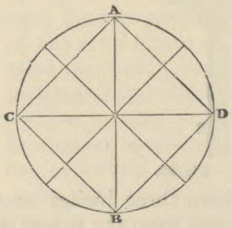

Fig. 45.

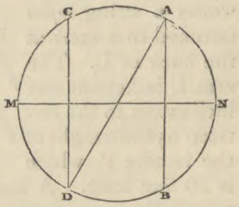

Fig. 46.

M. Valz's reticle. M. Valz[1] of Nismes has proposed the reticle shown in fig. 46 as possessing several advantages over others. It consists of three wires AB, CD, AD, and the equatorial one MN perpendicular to AB, CD. The arches AC, CM, MD, DB, &c., are all 60°. When the stars pass parallel to the equator, the angle formed at the vertex A or B will be 30°, and its cotangent $= \sqrt{3} = 1{\cdot}732$; therefore, calling t the time of passage of one star from the first to the second wire, and t' that of the other star, the difference of declination will be $1{\cdot}732\ (\pm t \pm t')$, and the difference of right ascension will be had from the times of the stars passing the middle of the space between CD and AB, or the means of the times of passing CD and AB. Baron Zach observes that this reticle requires no illumination, that the values of its lines do not require to be known, and that it may be used out of exact adjustment to the parallel of declination, as the corrections for such want of adjustment are easily computed.

Fraunhofer's net-micrometer. The fixed net-micrometer of Fraunhofer is shown in fig. 47. The vertical and oblique lines shown in the figure are cut upon glass with fluoric acid or diamond, and the plate has a circular motion in its cell. These lines are illuminated by light passing through the eye-tube and falling on their cut edges, so that no light passes down the tube. The lines parallel to *ef* are adjusted perpendicular to a circle of declination, and in that position the oblique light of the lamp

---

[1] In the photographic form of this micrometer this evil is completely removed by leaving the point of intersection transparent, so as to form a minute circular space.

[1] Zach's *Correspondance Astronomique*, tom. i., p. 353.

Fixed Micrometers.

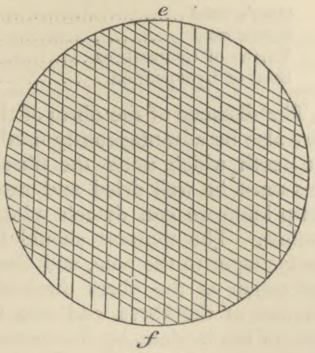

Fig. 47.

illuminates both the vertical and inclined lines. The mutual distances both of the vertical and inclined lines are known from the machine by which they were drawn, and hence the ratio of the times of transit of a star from the vertical to the inclined lines will enable us to determine the position of these in reference to a circle of declination. "The great number of lines," says Dr Pearson, "afford the means of making several observations, which on an average will give right ascensions and declinations equally exact, whether the differences of declination be great or small. When the difference of right ascension is small, as in the case of double stars, the transit of both stars cannot well be observed over the same individual line, but one of them may be observed at the first, and the other at the second line, alternately, till the observe is satisfied with his observation; and should the network experience an alteration of position from any cause, it will in all probability be detected before the computation is commenced. The ingenious artist contrived an engine by which he could cut straight parallel lines at distances so small as $\frac{1}{10000}$ of an inch from each other, and to be crossed by other parallel lines at any given angle of declination; and in the net-micrometer he formed the parallel lines at such a distance from each other, that the inclined intervals bear the same proportion to the vertical intervals that the cosine of the angle of inclination bears to radius, so that about as many transits will take place over the inclined as over the vertical lines. Five lines only are drawn at equal distances from each other, and the sixth line, including the fifth interval, is cut at the distance of one interstice and a half; yet the whole value of any number of intervals may always be known, provided it be noticed how many of the larger kind are included in the whole number. When the cell containing the disc is attached to a revolving graduated circle, the position of a line uniting two stars may also be measured by first adjusting *zero* to the equatorial position of the line *ef*, and then turning the divided disc round till all its parallels successively receive both the stars at the same instant as they pass through the field, which contemporary ingresses may be effected by repeated adjustments and subsequent trials, when the telescope is mounted on an equatorial stand properly rectified.[1] To net-micrometers of this kind, consisting of vertical and oblique lines, the method of photographically obtaining a small system upon collodion from a large one on paper is particularly applicable. (See chap. i.)

Fraunhofer's concentric circle micrometer. Another micrometer of Fraunhofer's is shown in fig. 48, and consists of concentric circles cut upon glass, and illuminated like the preceding one. The inner and smallest circle is like a dot. Other five circles are seen in a telescope of 5 feet focal length, magnifying 110 times. With a power of 63, eight circles are visible; and with the lowest power of 45, eleven circular lines are visible. The observer may choose any circle he likes for observing the passage of the star, avoiding those in which it would pass near the centre or near the circumference. The observation, too, may be made with more rings than one. The following are the dimensions of the circles in one of these instruments:—

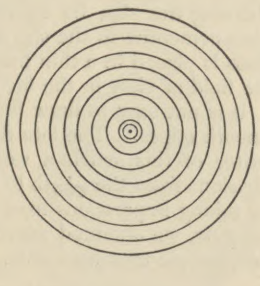

Fig. 48.

	Diameter in Paris inches.		Diameter in Paris inches.
Circle 1.	·0038	Circle 7.	·4426
2.	·0243	8.	·5264
3.	·0840	9.	·6338
4.	·1678	10.	·7178
5.	·2513	11.	·8012
6.	·3590		

By subtracting these numbers from one another we obtain the breadths of the spaces between the rings.

Fraunhofer's suspended circular micrometer. Fraunhofer's suspended annular micrometer, which is a more perfect instrument than the preceding, is shown in fig. 49, which represents a disc of glass, having a hole in its centre a little larger than the inner diameter of a metallic ring RR, turned truly in a lathe. This ring is cemented on the glass disc, and when placed in the field of view of a telescope, the observer notes the instants when a star or the limb of a planet enters and emerges from each side of the ring. The only data required for computing the difference of right ascension and declination are the times that an equatorial star takes to pass along the internal and external diameters of the ring. The passage of stars whose relative position is required, must be observed at a distance from the centre, as well as from the upper edge of the ring. Admiral Smyth mentions, that in one of these instruments which he possesses he found, by repeated measurements of stars near the ecliptic and on the meridian, that the radius of the ring was 472·5 seconds in arc.[1] The formulæ of Bessel for using this and other circular micrometers will be found in Zach's *Monatliche Correspondenz*, vol. xvii., xxiv., and xxvi.

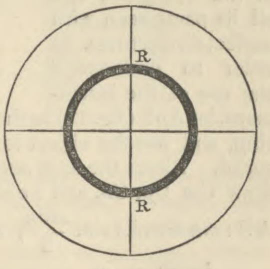

Fig. 49.

Photographic annular micrometer. An annular micrometer, with one or more rings of different diameters and breadths, may be advantageously formed photographically upon collodion by the process already described. By reducing large rings formed by black ink and fine compasses,[2] a more correct circular edge may be obtained than by the turning lathe. Luminous rings may be formed of such extreme narrowness that the star will, as it were, leap through the interval in passing across the field of the telescope. (See chap. i.)

Cavallo's mother-of-pearl micrometer. A simple and useful fixed micrometer, proposed by Mr Cavallo, is a divided slip of thin mother-of-pearl stretching across the diaphragm of the telescope, and finely divided into 200ths of an inch. It is shown in fig. 50 crossing the diaphragm of the telescope. The value of the division may be ascertained either by measuring a bar, or by the passage of an equatorial star across the field of view.

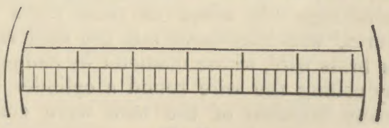

Fig. 50.

In a portable telescope this micrometer is very convenient, though it has the great disadvantage of shutting out the field of view. In telescopes upon stands it will measure only angles in one direction, unless there is a contrivance to turn it round. This micrometer has also the additional imperfection that its divisions, from being unequally distant from the eye-glass, are not all seen with the same distinctness.

---

[1] *Celestial Cycle*, vol. i., p. 339, note.

[2] The outer and inner margins of a ring having been formed with fine compasses, the interval may be filled up by the blackest ink.

Fixed Micrometers.

Circular mother-of-pearl micrometer.

To remove these imperfections Sir David Brewster proposed in 1805 the circular mother-of-pearl micrometer, which is shown in fig. 51, where the black ring which forms part of the figure is the diaphragm of the telescope, and the more luminous part is an annular portion of mother-of-pearl divided on its inner circumference into 360°. This divided circumference can be placed exactly in the focus of the eye-glass, and all its parts seen with perfect distinctness. In order to understand the use of the instrument, let A*p*B (fig. 52) be the inner edge of the mother-of-pearl ring, and *mn* the object to be measured. Bisect the arch *mn* in *p*, and draw C*m*, C*p*, C*n*, and we shall have $\mathrm{AB} : mn = \mathrm{rad.} : \sin. \frac{mpn}{2}$, and $mpn = \sin \frac{\frac{1}{2}mpn}{\mathrm{rad.}} \times \mathrm{AB}$, a formula by which the angle subtended by the chord of any number of degrees may be readily found. The first part of the formula is constant, while AB varies with the magnifying power employed.

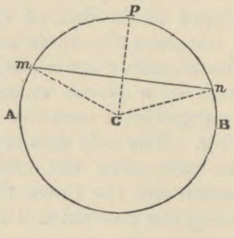

Fig. 52.

CHAP. IX.—DESCRIPTION OF MICROMETERS FOR MICROSCOPES.

Micrometers for microscopes.

All the micrometers above described may be adapted to compound microscopes where the eye-glass has a considerable focal length. A good micrometer, however, for single microscopes, which can be used with facility, and at the same time give accurate results, is still a desideratum. When the single lens is so minute, or when the first lens of a microscopic doublet or triplet almost touches the surface of the object, it is an extremely difficult matter to introduce any scale, or any minute body of known dimensions, with which the object may be compared. In some cases, when the object to be measured is minute, the seed of the *Lycoperdon bovista* or *puff-ball* might be introduced, its diameter being about the $\frac{1}{8500}$th part of an inch; and when the object is less minute, the seed of Lycopodium may be used, its diameter being $\frac{1}{940}$th of an inch. We may advantageously adopt in some cases the method of Dr Jurin,[1] who introduced into the field small pieces of silver or brass wire, whose diameter he had previously ascertained by coiling the wire round a cylinder, and observing how many breadths of the wire were contained in a given number of inches.

This method of introducing a substance of known dimensions may be carried much farther. We may use all the variety of hairs and wool which have a known diameter; and for this purpose Dr Young's tables of substances measured by the eriometer will be of great use. The following are a few of them:—

	Diameter in parts of an inch.	
Lycoperdon bovista, seed of	8500th	of an inch.
Smut of barley	4600th	...
Silk, fibre of (average)	2500th	...
Human blood, particles of (*Bauer*)	2500th[2]	...
Mole's fur	1875th	...
Goat's wool	1575th	of an inch.
Saxon wool	1320th	...
Farina of Laurestinus	1100th	...
Seed of Lycopodium	940th	...

Micrometers for Microscopes.

The distance of the fibres of the crystalline lens of fishes may also be advantageously used, and also the distance of the teeth which unite the fibres. For this purpose the lens must be well dried and perfectly hard, so that with a sharp knife we can detach minute portions of any of the laminæ. The thinnest should be used; and as the fibres always taper to the pole, and the teeth become smaller in proportion as the fibres diminish, we must determine the distance of the fibres, and also those of the teeth, at both ends of the laminæ, by the method described by Sir David Brewster in the *Philosophical Transactions* for 1833, p. 324. The larger lined scales of moths and butterflies may also be used, especially as we can measure the distance of the lines by the coloured spectra which these lines produce.[3] These operations will require much dexterity on the part of the observer, and they are recommended only to those who cannot succeed in their measurements by other methods.

An excellent method of measuring microscopic objects is to project the image of the object against a divided scale at a given distance from the eye. The scale must be seen either by the same eye which is looking into the microscope, or by the other eye. In the first case the rays from the microscope will enter one side of the pupil, and the rays from the divided scale the other side; the aperture through which we look at the scale, and the aperture of the microscope, being at a distance less than the diameter of the pupil. When the right eye looks at the divided scale, the left, which looks into the microscope, will see the object projected against the scale, although it has no vision of the scale itself. This second method may be carried into effect in two ways. The scale may form no part of the instrument, and may be viewed by the naked eye; or it may form part of the instrument, like a binocular telescope, the left eye looking into one tube, viz., the microscope, while the right eye looks into another tube, in which a divided scale is magnified by an eye-lens.

The earliest micrometer of any value is the *Stage Micrometer* of Mr Coventry, which consists of a number of very fine lines ruled with a diamond point upon slips of glass, metal, ivory, or mother-of-pearl. These lines were drawn at various distances, from the $\frac{1}{100}$th to the $\frac{1}{1000}$th of an inch, and upon the slip thus formed the object to be measured was placed. The object and the lines being seen at the same time, the number of linear spaces covered by the object gives its magnitude in the parts of an inch corresponding with the distance of the lines. As these lines are not easily seen, Mr George Jackson renders them visible by rubbing into them very finely levigated plumbago, and in order to prevent the plumbago from being wiped out in cleaning the slip, he covers the lines with a thin piece of glass cemented to the slip by Canada balsam. The slip of glass is placed in a thin frame of brass, and is moved across the field of view in the focus of the eye-glass by a screw.

It is not easy to draw fine lines upon glass so as to have smooth edges. The late Sir John Barton executed for the writer of this article a variety of slips of steel containing divisions from the $\frac{1}{500}$th to the $\frac{1}{10000}$th part of an inch; and by taking impressions from these upon transparent films of gelatine, we obtained micrometer slips of great utility for microscopic measurements. M. Froment of Paris has exe-

---

[1] *Physico-Mathematical Dissertations*, p. 45.

[2] We consider this the best measure.

[3] The late Mr Pond has observed, that the pale, slender, double-headed scales of the *Pontia* or *Pieris brassica*, which taper to a point, and terminate in a brush-like appendage, are of an invariable length, about $\frac{1}{80}$th of an inch.

Micrometers for Microscopes.

cuted divisions upon glass surfaces exceedingly minute and singularly fine.

Photographic scale.

The mode of executing a system of black parallel lines photographically upon transparent collodion, already described (chapter i.), has a particular value in microscopical measurements. The collodion in thin plates is as transparent as glass, even under very high powers, and the lines are absolutely black and smooth at the edge. Circular spots of the minutest size can be formed in a similar manner, so as to enable us to compare with them similar microscopic objects, such as the discs of blood; and small angular spaces, opaque and transparent, with divisions along the lines which contain the angle, may be advantageously used in microscopical micrometry.

Ross's eye-piece micrometer.

Mr Ross's eye-piece micrometer consists of circular discs of glass divided into small squares, as shown in the annexed figure. This system of squares, which may be finely executed upon collodion, is placed in the focus of a positive eye-glass or between the lenses of a negative one. When the divisions on the slips of glass are covered with the thinnest glass cemented to the slip, the object and the division are not exactly in the same plane; but, excepting in the use of high powers, this is of little importance, as both the object and the lines are seen with sufficient distinctness for the purpose of measurement.

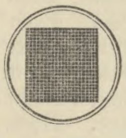

Fig. 53.

Dr Wollaston's lens-micrometer.

Dr Wollaston has constructed and used a very ingenious micrometer on the first of the principles above mentioned, viz., when the object and the scale are viewed by the same eye; but its use is limited to microscopes with small lenses. When the lenses are larger we have adopted another method, namely, to perforate the lens with a small hole in or near the centre, or, if it is thought better, near the margin of the lens. A slit extending from the margin of the lens may often be executed more easily.

The following is Dr Wollaston's own description of this instrument:—

"This instrument," says Dr Wollaston, "is furnished with a single lens of about $\frac{1}{12}$th of an inch focal length. The aperture of each lens is necessarily small, so that when it is mounted on a plate of brass, a small perforation can be made by the side of it in the brass, as near to its centre as $\frac{1}{25}$th of an inch.

"When a lens thus mounted is placed before the eye for the purpose of examining any small object, the pupil is of sufficient magnitude for seeing distant objects at the same time through the adjacent perforation, so that the apparent dimensions of the magnified image might be compared with a scale of inches, feet, and yards, according to the distance at which it might be convenient to place it.

"A scale of smaller dimensions attached to the instrument will, however, be found preferable on account of the steadiness with which the comparison may be made; and it may be seen with sufficient distinctness by the naked eye, without any effort of nice adaptation, by reason of the smallness of the hole through which it is viewed.

"The construction that I have chosen for the scale is represented in fig. 54. It is composed of small wires about $\frac{1}{60}$th of an inch in diameter, placed side by side so as to form a scale of equal parts, which may be with ease counted by means of a certain regular variation of the lengths of the wires.

"The external appearance of the whole instrument is that of a common telescope consisting of three tubes. The scale occupies the place of the object-glass, and the little lens is situated at the smaller end, with a pair of plain glasses sliding before it, between which the subject of examination is to be included. This part of the apparatus is shown separately in fig. 55. It has a projection, with a perforation, through which a pin is inserted to connect it with a screw, represented at *b* (fig. 56). This screw gives lateral motion to the object, so as to make it correspond with any particular part of the scale. The lens has also a small motion of adjustment, by means of the cap *c* which renders the view of the magnified object distinct.

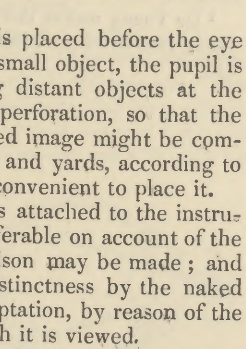

Fig. 54.

Micrometers for Microscopes.

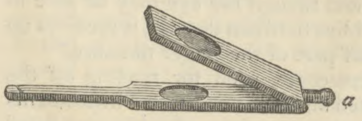

Fig. 55.

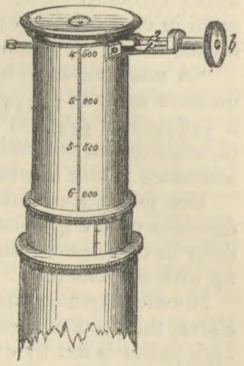

Fig. 56.

"Before the instrument is completed, it is necessary to determine with precision the indications of the scale, which must be different according to the distance to which the tube is drawn out. In my instrument one division of the scale corresponds to $\frac{1}{10000}$th of an inch when it is at the distance of 16·6 inches from the lens; and since the apparent magnitude in small angles varies in the simple inverse ratio of this distance, each division of the same scale will correspond to $\frac{1}{5000}$th at the distance of $8\frac{3}{10}$ inches; and the intermediate fractions $\frac{1}{6000}$th, $\frac{1}{7000}$th, &c., are found by intervals of 1·66 inch, marked on the outside of the tube. The basis on which these indications were founded in this instrument was a wire, carefully ascertained to be $\frac{1}{200}$th of an inch in diameter, the magnified image of which occupied fifty divisions of the scale when it was at the distance of 16·6 inches; and hence one division $=\frac{1}{50\times 200}=\frac{1}{10000}$. Since any error in the original estimate of this wire must pervade all subsequent measures derived from it, the substance employed was pure gold drawn till 52 inches in length weighed exactly five grains. If we assume the specific gravity of gold to be 19·36, a cylindrical inch will weigh 3837 grains; and we may hence infer the diameter of such a wire to be $\frac{1}{200}$th of an inch, more nearly than can be ascertained by any other method.

"For the sake of rendering the scale more accurate, a similar method was, in fact, pursued with several gold wires of different sizes, weighed with equal care; and the subdivisions of the exterior scale were made to correspond with the average of their indications.

"In making use of this micrometer for taking the measure of any object it would be sufficient, at any one accidental position of the tube, to note the number on the outside as denominator, and to observe the number of divisions and decimal parts which the subject of examination occupies on the interior scale as numerator of a fraction, expressing its dimensions in proportional parts of an inch; but it is preferable to obtain an integer as numerator, by sliding the tube inward or outward, till the image of the wire is seen to correspond with some exact number of divisions, not only for the sake of greater simplicity in the arithmetical computations, but because we can by the eye judge more correctly of actual coincidence than of the comparative magnitudes of adjacent intervals. The smallest quantity which the graduations of this instrument profess

Micrometers for Microscopes.

to measure is less than the eye can really appreciate in sliding the tube inward or outward. If, for instance, the object measured be really $\frac{1}{9900}$, it may appear $\frac{1}{10000}$, or $\frac{1}{9800}$, in which case the doubt amounts to $\frac{1}{50}$th part of the whole quantity. But the difference is here exceedingly small in comparison to the extreme division of other instruments, where the nominal effect of its power is the same.

"A micrometer with a divided eye-glass may profess to measure as far as $\frac{1}{10000}$th of an inch; but the next division is $\frac{2}{10000}$th or $\frac{1}{5000}$th; and though the eye may be able to distinguish that the truth lies between the two, it receives no assistance within one-half part of the larger measure."[1]

The micrometer microscopes used for reading off the divisions on the graduated limb of astronomical instruments differ in no respect from the eye-pieces of telescopes fitted up with micrometers.

Notwithstanding the value of the methods described above, the want of a simple micrometer for microscopes of high power is felt by every person who has been practically occupied with this class of researches; and we cannot give a better proof of this than by adducing, in support of our opinion, the different measures that have been given by able and ingenious observers of the size of the particles of the human blood:—

Dr Thomas Young	1-6060th	part of an inch.
Dr Wollaston	1-5000th	...
MM. Prevost and Dumas	1-4076th	...
Captain Kater	1-4000th	...
M. Ehrenberg[2]	1-3600th	...
Messrs Hodgkin and Lister	1-3000th	...
Sir David Brewster	1-2556th	...
Dr Jurin[3]	1-1940th	...
Mr Bauer's best observation	1-2500th	...
next best	1-2000th	...
worst observation	1-1000th	...

The three measures of 1000, 2000, and 2500, were given by Mr Bauer himself, as the different steps which he made towards what he conceives the best measure, viz., 1-2500th, which he obtained repeatedly with an improved achromatic microscope. As Dr Young obtained his measure *eriometrically*, namely, by measuring the diameter of the first red ring produced by looking through the blood at a luminous object, we cannot conceive it possible that he could have committed such a mistake as to make the diameter of that ring nearly *thrice as great* as it should be, according to Mr Bauer's results, or more than thrice as great as the concurring measures obtained by Jurin and Leewenhoeck. The only explanation we can give is, that the particles of the blood must have an organized structure, or consist of portions separated by lines which have the magnitude assigned by Dr Young. In order to submit this explanation to the test of experiment Sir David Brewster examined the particles of blood a few minutes after it was drawn, when dried by natural evaporation on a plate of glass. Each particle he found to consist of a dark rim, within which is a bright circle, then a darkish central spot, which spot in some globules may be resolved into a dark ring, a bright ring within this, and then a small central black spot. Here, then, is the cause of Dr Young's mistake. The red ring of light which he measured in the eriometer was not that which was due to the globule as a whole, but to the parts of the globule. Being anxious to obtain more complete evidence of this fact, we placed Lycopodium powder beside the globule of blood, and found that the diameter of the globules was to that of the Lycopodium seed as 5 to 18. We then compared the diameter of the red ring produced by the seed with the diameter of the red ring produced by division on steel, in which there were 1250 to the inch, as executed for us by the late Sir John Barton, and found the diameter of the seed to be the 697th of an inch. We compared it also with the ring produced by divisions of which there were 625 to the inch, and found its diameter the 717th part of an inch. The mean of these two is the 710th[1] part of an inch, which, increased in the ratio of 5 to 18, gives the 2556th part of an inch as the measure of the diameter of the globules of blood, agreeing almost exactly with the measure of Mr Bauer.

---

[1] *Phil. Trans.*, 1813, p. 119.

[2] In measuring the size of the fossil infusorias discovered by himself, M. Ehrenberg assumes a globule of human blood to be $\frac{1}{300}$th of a line in diameter, or $\frac{1}{3600}$th of an inch, but of what inch is not mentioned. He does not state whether this measure is taken by himself or not. He reckons the thickness of a human hair at $\frac{1}{48}$th of a line at its mean thickness, or $\frac{1}{567}$th of an inch.

[3] This result was confirmed by Leewenhoeck, who used the same wire, which was sent to him by Dr Jurin. (*Phil. Trans.*, No. 377.)

[1] Dr Young makes this the 940th of an inch, but he has certainly committed a mistake in his observation.

MICROSCOPE.

MICROSCOPE, from μικρος, a *small object*, and σκοπεω, to *see* or *examine*, is the name of a well-known optical instrument for examining and magnifying minute objects, or the minute parts of large ones. Dr Goring has, in his various works on the microscope, used the word *engiscope*, from εγγυς, *near*, and σκοπεω, *to see;* but the old and venerable term is so associated with the history of optical discovery, and is so expressive of the application of the instrument, that we cannot consent to the proposed change.

Single microscopes, in the form of glass globes containing water, were used by the ancients. A magnifying lens of rock-crystal was found by Mr Layard among a number of glass bowls in the north-west palace of Nimroud. Hemispheres of glass, and afterwards lenses, were subsequently used, so that no person has pretended to claim the invention of the single microscope. The compound microscope, consisting of two lenses placed at a distance, so that the one next the eye magnifies the enlarged image of any object placed in front of the other, was invented by Zacharias Zansz, or his father Hans Zansz, spectacle-makers at Middleburg in Holland, about the year 1590. One of their microscopes, which they presented to Prince Maurice, was in the year 1617 in the possession of Cornelius Drebell of Alkmaar, who then resided in London as mathematician to King James VI.

There is probably no branch of practical science which has undergone such essential and rapid improvements as that which relates to the microscope. It has become quite a new instrument in modern times, and it promises to be the means of disclosing the structure and laws of matter, and of making as important discoveries in the infinitely minute world as the telescope has done in that which is infinitely distant.

CHAPTER I.

ON SINGLE MICROSCOPES.

Single microscopes.

When only one convex lens AB (fig. 1) is used for magnifying objects, the lens is called a single microscope. The object *mn* to be examined is placed before the lens AB, in its anterior focus; so that the rays which emerge from the lens after refraction by the humours of the eye CD may be parallel, and a distinct and enlarged image MN of the object *mn* formed on the retina. The simplest form of the single microscope is when the lens is fitted into a rim of brass furnished with a handle, so that when the object is held in the left hand and the lens in the right, it may be examined with facility. If the convex lens is very minute, and has a short focal length, such as from the 10th to the 100th of an inch, it cannot be conveniently used in the hand, and must therefore be either connected with an arm to hold the object, or placed in a firm microscope stand, having a shelf or stage for the object, a screw or a rack and pinion for placing it in the focus of the lens, either by moving the object or the lens, and a larger lens or mirror, or both, for throwing light upon the object. In this form, however complex be its structure, it is still called a single microscope.

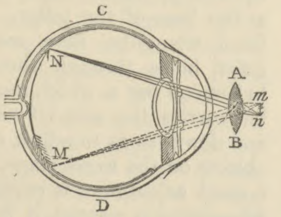

Fig. 1.

The lens which constitutes a single microscope, in order to have all the excellence which art can give it, must consist of a substance perfectly homogeneous, like a fluid without double refraction, or any variation of density. Its figure ought to be that of a plano-convex lens, whose convex surface is part of a hyperboloid, in order to correct completely the spherical aberration. Its surface should be perfectly smooth and highly polished, so as not to disturb the perfection of vision; and the substance of which it is made should have the lowest dispersive power. As it is a great object to obtain high magnifying powers with as little convexity as possible, and a large aperture, substances with high refractive and low dispersive powers are the most suitable for single lenses, such as diamond or garnet, which have no double refraction when well crystallized; or such as ruby, sapphire, topaz, &c., which have double refraction. As fluor spar has the lowest dispersive power, it might be used with great advantage when high powers are not wanted, and when the diminution of colour is an object.

Of all the substances we have named, fluids have properties best suited for single microscopes. They possess perfect homogeneity; their surfaces, when made into lenses, are perfectly smooth; and it is possible to mould minute drops of them into a form approaching to that of the hyperboloid. Their defect, however, consists in their not having a high refractive power, in their want of durability, and the difficulty of forming sufficiently minute lenses for producing high magnifying powers. These defects, however, may be overcome by patience and experience; and in proof of this we may state that we have succeeded in forming minute fluid lenses of great excellence.

In the present state of this branch of science, it would be unprofitable to detail the methods of producing microscopic globules of glass, given by Dr Hooke, Father di Torré of Naples, Mr Butterfield, or Mr Sivright; because when they are made after their methods, and in the most perfect manner which these methods will permit, they are of no value compared with lenses of glass when ground and polished to the same focal length.[1]

We shall therefore proceed to describe a single microscope when fitted up in the best form for observation.

Description of a Single Microscope.

Single microscope.

The most essential part of this instrument is the lens or lenses, upon which the value of the microscope depends. The lenses are generally made of plate-glass, and should have focal distances varying from the $\frac{1}{10}$th to the $\frac{1}{60}$th of an inch. In order that the spherical aberration of these lenses may be the smallest possible, the radii of their two surfaces, when made of plate-glass, should be as 1 to 6; the surface whose radius is 1, or the most convex side, must be turned towards the eye. The lenses thus made are then set in the centre or the lower surface of concave brass caps, a section of one of which is shown in fig. 2.

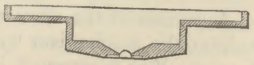

Fig. 2.

Pritchard's microscope.

One of the best modes of fitting up the single microscope is that contrived by Mr Pritchard, which is represented in fig. 3, on a scale about one-third of its real size. It is shown in an inclined position; but it may be used either in a vertical or a horizontal one, according to the convenience of the observer. The body of the instrument rests on a pillar *b*, supported by three legs, shown at *a*, and is connected with it by the clip *f*, being fixed by the pinching screw *f*. Within the tube *c* there slides a tube *h*, connected by a screw which passes through it to the triangular tube or bar *i*, carrying the arm *ij*, into which is placed the brass cap *j* which carries the lens. This lens is adjusted to the distinct vision of objects placed on the stage *l*, by sliding the tube *h* up or down, and a perfect adjustment is obtained by turning the milled head *k*. The stage *l*, which carries the objects, is fitted into the triangular box *r* at the extremity of the stem, by means of two pins, and can be removed at pleasure. The spring slider-holder, for holding the sliders in which the objects are placed, is fixed by a bayonet-joint into the stage; and it may be used to hold stops or diaphragms for limiting the field of view. The tube above *f* represents an illuminator fixed to the slider-holder. Upon the tube *c*, two sockets *d*, *e*, slide with sufficient spring and friction to keep them in their place. The socket *d* carries the reflector *d*, and the socket *e* carries the condensing lens, which is not inserted in the figure.

---

[1] These methods may be found by the following references:—Hooke's *Micrographia;* Di Torré, *Phil. Trans.* 1765, p. 246, 1766, p. 67; Butterfield, *Phil. Trans.*, 1678; Sivright, *Edin. Phil. Journal*, 1829, vol. i., p. 81.

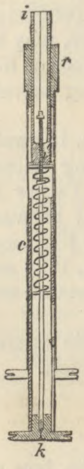

Fig. 4.

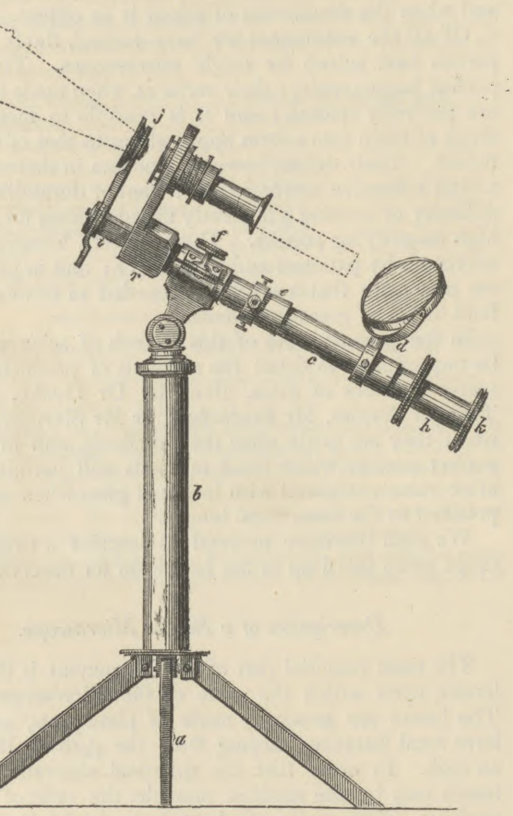

Fig. 3.

A section of the stem *rck* is shown in fig. 4, in order to exhibit the mechanism by which the adjustment is effected. Into the box *r*, screwed into the top of the stem, is fitted the triangular tube *ii*, which carries the arm *ij*. In the lower end i' of this triangular tube is a small block with a fine screw working in it, the stem of which turns along with the milled head *k* to which it is fixed. The upper end of a spiral spring, shown in the figure, bears against the block i' at the bottom of the triangular tube, while its lower end acts against a stop fixed within the sliding tube *h*. The method of managing, illuminating, and examining opaque objects with this microscope is the same as that used in the achromatic compound microscope, in the drawing of which it will be more distinctly seen.

The preceding instrument of Mr Pritchard's is intended for general purposes; but as the dissection of botanical and other objects is now a leading object with naturalists, we shall add an account of another microscope, constructed in 1831 by Mr A. Ross, with much skill, for Mr W. Valentine of Nottingham, an eminent vegetable anatomist, who succeeded in dissecting with it under a lens of $\frac{1}{20}$th of an inch in focal length.[1]

Ross's microscope.

A perspective view of this microscope is shown in fig. 5. It is supported on a closing tripod *aaa*, whose feet can be folded together, and are made of hard bell-metal, prevented from springing by edge bars, as seen on the left-hand foot. A firm pillar, which rises from the tripod, carries the stage *x*, which is fixed on brackets, to give a steady support to the hands of the operator. A capital, fixed to the top of the tube by three screws, has in its axis a triangular hole, into which is fitted a triangular tube, the lower end of which passes through another similar triangular tube fixed to the inside of the instrument. The triangular tube is made to slide up and down by a fixed screw, wrought by a large milled head, which is most judiciously placed at the base of the pillar. At the top and bottom of the fixed triangular tube are fitted two pieces, with triangular holes through them for receiving the triangular bell-metal bar *s*, which moves up and down in them. This bar carries the arm 10 with the lenses. It is moved up and down, so as to adjust the lenses to distinct vision of the objects on the fixed stage, by the rack and pinion *t*, when a quick adjustment is required; but when a slow and nicer adjustment is wanted, it is effected by the milled head *o*. A slit is made in the shaft of the pillar, to allow the neck of the small milled head *t* to move up and down; for when the screw is in action by the large milled head *o*, the triangular tube and the bar move together. The triangular bar is perforated at both ends,—the upper perforation for receiving a conical pin, and the lower for admitting the adjusting screw to preserve the length of the bar. The bearings of the pinion *t* are attached to the triangular tube. The bar moves $1\frac{1}{2}$ inch, and the tube $1\frac{1}{2}$, so that

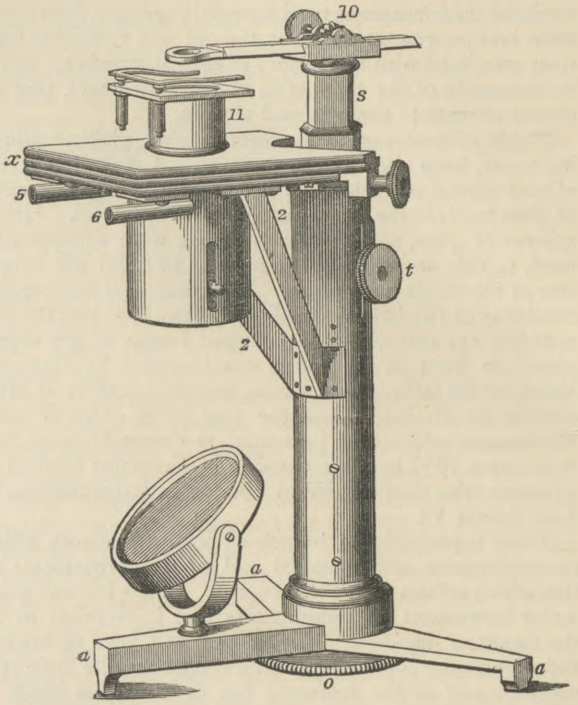

Fig. 5.

---

[1] See *Transactions of the Society of Arts*, vol. xlviii., where a full description of this microscope, with drawings of all its parts, will be found.

we can command an elevation of 3 inches. At the ingenious suggestion of Mr Solly, the screw moved by the milled head *o* has fifty threads in an inch, and the milled head is graduated into 100 parts, for the purpose of measuring the thickness of any vessel or other object in the direction of the axis of vision. For this purpose the upper surface of the body is brought into distinct vision; the division at which the index or pin of the tripod stands is then observed; and the under surface being in like manner brought into focus by turning the milled head *o*, the division is again observed. The number of divisions, which are each 5000ths of an inch, between these two numbers, *will indicate*, according to Mr Valentine, *the space through which the lens has passed, which is the diameter of a vessel.*[1]

In this microscope different parts of an object may be brought into the field, either by moving the stage or the lens; a very important requisite in a microscope used for the purposes of discovery. With this view, the large stage *x* is formed of three plates, the lowest of which is fixed to the pillar by the ring 1; and, to make it bear the weight of the hands, it rests upon the strong brackets 2, 2. The under side of this plate is shown in fig. 6; the middle plate (fig. 7) contains two pairs of dovetail slits, 3, 3 and 4, 4, the widest orifice of each being on opposite sides of the plate. The dovetail pieces in 4, 4 screw into the upper side of the upper plate (fig. 8), the points of the screws being shown at 4, 4 in that figure; while the dovetail pieces in 3, 3 are secured to the upper side of the under plate by the screws 3, 3 (fig. 7). The plates are thus moved diagonally, and at right angles to one another, by the adjusting screws 7 and 8 (fig. 8). In the adjusting screw 7 the ball is placed in spring couplings, and fastened to the under side of the upper plate. These screws are judiciously placed, one on each side of the pillar, that the hand may reach them easily and not intercept the light. By turning first one screw, and then the other, or both at once, any part of the object may be brought into the field.

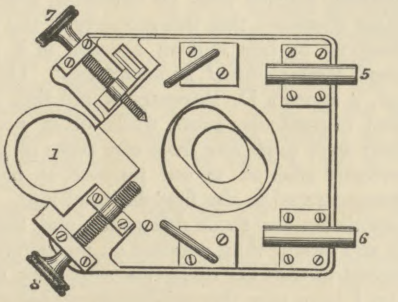

Fig. 6.

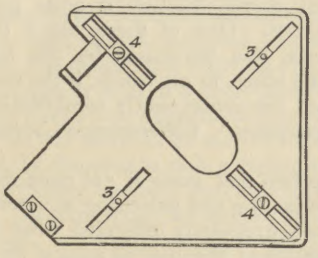

Fig. 7.

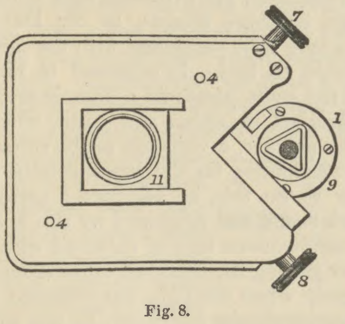

Fig. 8.

The arm for holding the lenses is shown at 10 (fig. 5). A conical pin projects from underneath, and fits into a hole made down the triangular bar, as shown at 9 (fig. 8). The lens will therefore have a circular movement in a horizontal plane, and it may be placed at any point in this plane by the action of the rack and pinion at 10. Hence the most complete adjustment can be obtained without any motion of the stage.

The elevated stage for holding the objects is shown at 11 in figs. 5 and 8. A tube screws into the upper plate, and upon this fits the tube 11, carrying the finger-spring, shown in fig. 5. Objects of different thickness are thus kept down upon the plates by the pins sliding in the small pipes. A condensing lens and pincers slide into the sockets 5 or 6 (fig. 5).

The large reflector above *a* (fig. 5) may be removed, and any other illuminating apparatus substituted.

As the stand and apparatus now described may be used along with all single microscopes, and also with what are called doublets and triplets, we shall now proceed to give an account of the various improvements which the single microscope has undergone.

Between the single lens held in the hand and the one mounted with much of the apparatus of a compound microscope, we may place what has been called the *simple microscope*, which is nothing more than a single lens mounted on a stand, so that it may be fixed in various positions suited to the purpose to which it is to be applied.

Mr Ross's simple microscope is shown in fig. 9. It consists of a stand A, with a sliding tube which can be raised or depressed. On the top of this tubular stand is fixed a jointed socket MN, through which a square bar CD slides, carrying at one of its extremities the lens L, the ring of which moves round a joint at C. Lenses of an inch, a half-inch, and a quarter of an inch focus should accompany the instrument, which may be packed into a small space.

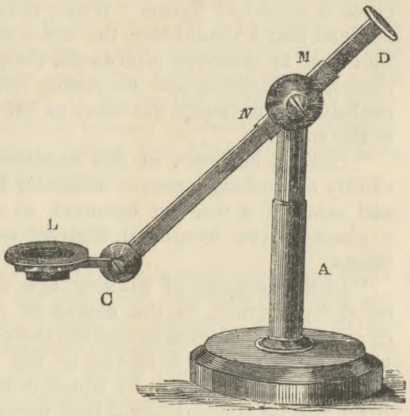

Fig. 9.

Single Microscopes made of Precious Stones.

Single microscopes of precious stones.

The low refractive power of glass rendered it necessary, when high powers were wanted, to use lenses with very short foci, and consequently with very deep curves and very small diameters, so as to admit only a narrow pencil of light into the eye.

Sir David Brewster was the first person who pointed out the value of using other materials for the construction of lenses;[1] and he remarked that no essential improvement could be expected in the single microscope, unless from the discovery of some transparent substance, which, like the *diamond*, combines a high refractive with a low dispersive power. Having experienced the greatest difficulty in getting a small diamond cut into a prism in London, he did not conceive it practicable to grind and polish a diamond lens,[1] and therefore did not put his opinion to the test of experiment. He got two lenses, however, executed by Mr Peter Hill, an ingenious optician in Edinburgh, the one made of ruby and the other of garnet, and these lenses he found to be greatly superior to any lenses that he had previously used.

---

[1] This is not the case, as the refraction of the light issuing from the lower side of the vessel or object is not considered. The right mode is, after having observed the upper surface of an object lying upon glass, remove the object, and observe the divisions when the surface of the glass is seen distinctly; the difference will be the true thickness. Mr Samuel Varley is said to have constructed an instrument on this principle for measuring the thickness of foci of lenses; but unless he removed his lens after observing the first surface, his results must have been all erroneous.

[1] *Treatise on Philosophical Instruments*, 1813, pp. 402, 403.

Dr Goring, whose zeal and success in the improvement of microscopes has not been surpassed, directed the attention of Mr Pritchard in 1824 to the passages in Sir David Brewster's Treatise on New Philosophical Instruments, respecting the value of the precious stones for single microscopes; and having immediately seen their full force, it was agreed that they should undertake to grind a diamond into a magnifier.

Diamond Lenses.

Diamond lenses.

The history of this attempt is so interesting, that we must give it in Mr Pritchard's own words:—"For this purpose," says he, "Dr Goring forwarded me a small brilliant diamond to begin upon; and it was proposed to give it the curves that in glass would produce a lens of a twentieth of an inch focus. This stone I ground with the proper curves, and polished the flatter side, contrary to the expectations of many whose judgment in these matters was thought of much weight, who predicted that the crystalline structure of the diamond would not permit it to receive a spherical figure. When thus far advanced, fate decreed that I should lose the stone, and my only consolation was, to discover afterwards, that, had it been completed, its thickness and enormous refractive power would probably have caused the focus to fall within the substance of the stone.

"Having, however, in this experiment, proved the possibility of working lenses of adamant, I set about another, and selected a rose-cut diamond, in order to form it into a plano-convex lens, and thereby save a moiety of the labour.

"In the progress of working this stone the heat generated by friction, in the course of the abrasion of the diamond, was perpetually melting the cement (shell-lac) by which the flat side was affixed to the tool, and compelled me to seek some means by which it might be prevented. After several trials, I found that when a portion of finely powdered pumice-stone was mixed with the shell-lac, the cement was much stronger, and less liable to melt, than any other similar substance.

"On the 1st of December 1824 I had the pleasure of first looking through a diamond microscope, and it was doubtless the first time this precious gem had been employed in making manifest the hidden secrets of nature. A few days after, I had polished it sufficiently to put it into the hands of Dr Goring, who tried its performance on various objects, both as a single microscope and as the objective of a compound. He states in a letter addressed to me, dated 3d January 1825, 'that it has shown the most difficult transparent objects I have submitted to it;' and again, 'I can clearly perceive the amazing superiority it will possess when completely finished.' I must, however, inform my readers, that we discovered in this state various flaws in the stone, in consequence of which we abandoned all thought of completing it. In this condition the project remained for about a year, when I determined to resume my attempts; and having worked several stones into lenses, I at last succeeded in obtaining a perfect one. In the course of these labours, a new though not unexpected defect appeared in several lenses, which would have subverted the whole scheme had not the first diamond lens been free from it.

"These lenses, instead of giving a single image like the first, gave a double or triple one. This rendered them utterly useless as magnifiers, and made the defects of soft and hard parts in the same stone, and the small cavities in others, of comparatively trifling consequence. The images exhibited in such lenses overlapped each other, but were never entirely separated, though the quantity of overlapping varied in different specimens.

"It was now evident that these defects arose from polarization, though this stone is described as 'refracting single.' I subsequently learned from Dr Brewster, after I had overcome these obstacles, that this property of the diamond had been observed by him, and an account of it given in the *Edinburgh Philosophical Transactions.*[1] On referring to his paper, it appears Dr Brewster found that some stones 'polarized in particular *parts*, while other *portions of the same stone were quite free from any trace of polarity*,' and thus perfectly adapted to our purpose, as had previously been demonstrated in the first diamond lens.

"Notwithstanding these difficulties, and the consequent expense and labour they entailed on me before sufficiently experienced in working upon this refractory material with certainty, I have now the satisfaction of being able, by inspection *à priori*, to decide whether a diamond is fit for a magnifier or not; and have now executed two plano-convex magnifiers of adamant, whose structure is quite perfect for microscopic purposes. One of these, about the twentieth of an inch focus, was purchased by the late Duke of Buckingham; the other, in my hands, is the thirtieth of an inch focus, and has consequently amplification enough for most practical purposes." (*Microscopic Cabinet*, p. 107-111.)

Although it is quite certain that many if not most diamonds possess a doubly-refracting and polarizing structure, owing to their having been irregularly indurated when in a soft state, yet the separation of the images, arising from this structure, is not sufficient to account for the overlapping of the images observed by Mr Pritchard. In order to have this matter investigated, Mr Pritchard sent a bad diamond lens, with two or three images, to Sir David Brewster, who was for a long time perplexed with the difficulties which it presented to him. It occurred to him, however, to examine if the stone possessed a homogeneous structure, as he had observed in amber and gums, which are indurated in a similar manner, a variation in the refractive density capable of accounting for the imperfections of the diamond. In order to do this, he admitted a narrow beam of light into a dark room, and examined by this light the flat surface of the plano-convex lens of diamond with a hand microscope. After getting the diamond into the most favourable position, namely, when the light was reflected as nearly as possible at a perpendicular incidence, he was surprised to see its whole surface covered with thousands of minute bands, some reflecting more and some less light. He at first thought that these bands were the edges of an infinity of laminæ of different reflective, and consequently refractive powers; but having observed that the same bands which reflected most light in one position reflected least light in another, he was driven to the conclusion that *all the bands were the edges of veins or laminæ whose visible terminations were inclined at different angles not exceeding a few seconds to the general surface.* Had this surface been an original face of the crystal, there would have been nothing surprising in its structure; but being a surface ground and polished by art, the phenomenon which it presents is one extremely interesting. The two or three images, therefore, which this lens gave as a microscope were produced by the convergency of the rays to different foci by the differently inclined faces of the laminæ.[1]

---

[1] Mr Pritchard informs us (see *Edinburgh Journal of Science*, No. 1, new series, p. 149, July 1829), that Messrs Rundell and Bridge, at the time when Mr Pritchard began his experiments, had many Dutch diamond-cutters at work, and that the foreman, Mr Levi, with all his men, assured him *that it was impossible* to work diamonds into spherical lenses. The same opinion, he adds, was also expressed by several others, who were considered of standard authority in such matters. When Mr Pritchard had, contrary to the expectation of many, succeeded in finishing his first lens, it was examined by Mr Levi, who expressed great astonishment at it, and added, that he was not acquainted with any means by which that figure could have been effected.

[1] *Edinburgh Phil. Trans.*, vol. viii., p. 157, 1817. See also *Geological Transactions*, new series, vol. iii., p. 455; and *London and Edinburgh Philosophical Magazine*, vol. vii., p. 245.

Similar lines on the cut faces of diamonds have been observed by MM. Trecourt and Oberhauser, who consider them as minute prismatic canals or interstices left during crystallization, and who suppose that they injure the image in consequence of ground-off particles lodging themselves in the orifices of the canals, and which afterwards come out and destroy the polish by the scratches they produce. This explanation is in no way applicable to the phenomenon we have described.

These observations will, we trust, induce opticians to use the diamond more frequently than they were disposed to do when they believed that its imperfections arose from its doubly-refracting structure. In a small lens the doubly-refracting structure, when it does exist, is too small to produce any bad effect; and it is not difficult to discover any defect that may exist in the surface such as we have described above.

As the expense of the diamond, and the labour of working it, are very great, about fifty or sixty hours being necessary to complete a diamond lens with double convexity, it is of the greatest consequence to ascertain beforehand if the substance of the diamond is homogeneous; that is, free from difference of density or double refraction, and if it does not contain any small cavities. The best way is to examine the stone, by cutting two flat faces upon it, unless it is a *laske* or table diamond, which always has two flat faces; but this labour may often be avoided by examining it when plunged or held in a glass trough containing *oil of cassia*, the fluid which approaches nearest to it in refractive power. This will diminish all the refractions at the irregular surface of the diamond to such a degree as to make any internal imperfections as easily seen as if its substance were plate-glass.

By comparing the indices of refraction of diamond and glass, it may be easily shown that the same magnifying power may be obtained with a *diamond* lens having its curvature with a radius of 8, as with a *glass* lens the radius of whose curvature is 3; and as the spherical aberration increases with the depth of curvature or the thickness of the lens, a lens of diamond will bear a much larger aperture than one of glass before indistinctness of vision is produced. Mr Pritchard has given a very useful ocular representation of the relative value of a diamond and a glass lens. In the annexed figure G is the section of a semi-lens of glass, and D the section of one of diamond. so placed that their principal focus F shall be at the same point. In the diamond semi-lens the marginal rays will intersect the axis at d, and in the glass semi-lens at g; the longitudinal aberration being dF in the *diamond*, and gF in the *glass* lens.

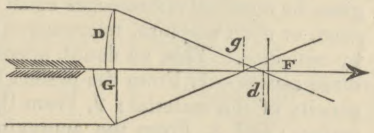

Fig. 10.

In order to obtain a numerical measure of these aberrations, Mr Pritchard computed them from the formula, and found that of the diamond lens to be $\frac{3}{7}$ths of its own thickness, that of the glass lens being $\frac{7}{6}$ths of its thickness; and by taking the thickness of the diamond lens to be 255, while that of the glass is 758, he obtained $\frac{3}{7}$ths of $255 = 108$, and $\frac{7}{6}$ths of $758 = 884$, and hence it follows that *the actual aberration of a* DIAMOND *lens is only about one-ninth of the aberration of a* GLASS *lens* of the same power and aperture.

If we suppose the diamond lens to be ground on the same tool with the glass lens, so as to have the same curvature, the same thickness, and the same diameter, the longitudinal aberration of the diamond will be to that of the glass lens as 43 is to 117, or nearly one-third of it; and if we suppose the focal length of both to be $\frac{1}{80}$th of an inch, the magnifying power of the diamond lens will be 2133, while that of the glass one will be only 800.[1] In order that a lens of glass may have the same magnifying power as that of the diamond above mentioned, its focal distance would require to be only the 200th part of an inch.

The durability of the diamond lens is also another valuable property, which allows it to be burnished into a disc of metal, and taken out and cleaned without any danger of being scratched. In treating of microscopic doublets and achromatic microscopes, we shall have occasion to recur again to the diamond lens. Some writers have objected to the use of diamonds because they are too costly. For ordinary microscopes, intended solely to amuse or to instruct, they have not been recommended; but if we wish to make great discoveries, to unfold the secrets yet hid in the cells of plants and animals, we must not grudge a diamond to reveal them. If Sir James South, Mr Cooper, and others, have given two or three thousand pounds for a refracting telescope, and if Lord Rosse expended L.15,000 on a reflecting one, why may not other philosophers open their purse, if they have one, and other noblemen sacrifice some of their household jewels, to resolve the microscopic structures of the lower world, to unravel mysteries most interesting to man, and secrets which the Almighty must have intended that we should know.

Sapphire Lenses.

Sapphire lenses.

The ruby and the sapphire are the same substance, differing only in colour. Mr Pritchard has, with his usual success, executed many lenses of sapphire, which, though inferior to those of diamond, are vastly superior to the best executed lenses of glass. When a double convex lens of sapphire and one of plate-glass are ground to the same focus, so as to have the same aperture and magnifying power, their relative curvatures are as 5 to 3, and their thicknesses as shown in the annexed figure, where A is the section of a semi-lens of sapphire, whose focus is at F, and B a section of a semi-lens of glass, having its focus at the same point. This figure points out in the clearest manner another advantage of using the precious stones in place of glass. In small lenses of glass, the thickness of the glass is such that there is no room between its anterior surface and the object for the admission of instruments for dissection, and not even for the thinnest plate of glass, so that it is impossible to use glass lenses of small foci in viewing objects placed in glass sliders. If the preceding figure represents lenses with a focus of $\frac{1}{30}$th of an inch, the distance of the glass lens B from F will be little more than $\frac{1}{60}$th of an inch, which is less than the thinnest glass.

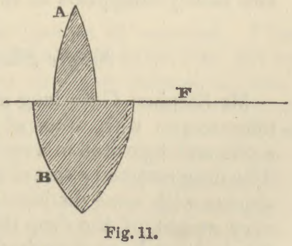

Fig. 11.

---

[1] See *Phil. Trans.*, 1841, p. 41, for a drawing of the phenomenon.

[1] See the last column of the table in page 771, col. 2.

In using the *sapphire* and *ruby*, or any precious stone which refracts doubly, such as *zircon*, *topaz*, &c., for lenses, we are exposed to a very serious defect, arising from the duplication of minute lines, in consequence of the double refraction of these crystals. In order to remedy this defect, the optician endeavours to cut the stone so that the axis of the lens may coincide with the axis of double refraction. This, however, is a difficult task; and, even if it were accomplished, we should not get rid entirely of the duplication of the images, as in all double convex lenses, as well as in plane convex lenses with the plane side turned to the object, the rays cannot pass through the lens in parallel directions, and therefore must suffer double refraction, however small. It may be reduced, however, to the smallest possible amount, and even to nothing; for pencils of rays diverging from a point in the axis, by making the lens plano-convex, and turning the plane side to the eye, as in the annexed figure, where rays issuing from F, and entering the eye parallel at E, must pass through the lens AB in parallel directions, suffering all their refraction at the first or curved surface of the lens. By adopting this form and position of the lens, we may, however, lose more than we gain; for the lens is placed in the position which gives a maximum spherical aberration. When the magnifying power is not very high, the residual double refraction is not injurious; and in proof of this we may state, that we have in our possession a double convex lens of sapphire, executed by Mr Pritchard, which exhibits minute objects with the greatest beauty and precision. The only way, therefore, is to employ precious stones, such as the *diamond*, the *garnet*, and the *spinelle ruby*, which have no double refraction.

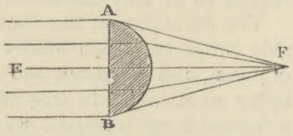

Fig. 12.

Garnet and Spinelle Ruby Lenses.

Garnet and spinelle ruby lenses.

The garnet is superior in its structure to the spinelle ruby, and the best and purest which we have seen is that which is brought from Greenland, and has a slight tinge of purple. We have used lenses made of this substance by Mr Hill, Mr Adie, Mr Blackie, and Mr Veitch, all of which exhibit minute objects with admirable accuracy and precision; and we can state with confidence, that we have never experienced the slightest inconvenience from the colour of the garnet, which diminishes with its thickness, and therefore nearly disappears in very minute lenses. (See p. 774.)

Single Fluid Microscopes.

Single fluid microscopes.

Mr Stephen Gray long ago proposed to construct single microscopes with drops of water, which he lifted up with a pin, and deposited in a small hole made in a piece of brass. The drop retained a sort of imperfect sphericity, and showed objects with some distinctness; but it is obvious that the very weight of the drop destroyed its spherical form, even if it had not been disturbed by minute irregularities on the circumference of the aperture in which it was placed.

Sir David Brewster long ago constructed fluid lenses in a different manner, so as to avoid the irregularities above mentioned. He placed minute drops of very pure turpentine varnish, and other viscid fluids, on plates of thin and parallel glass. By this means he formed plano-convex lenses of any focal length; and by dropping the varnish on both sides, he formed double convex lenses, with their convexities in any required proportion. By freeing the glass carefully from all grease with a solution of soda, the margin of these lenses was beautifully circular; and the only effect of gravity, which diminishes with the viscidity of the fluid and with the smallness of the drop, is to elongate the lower lens and flatten the upper one. These lenses were found to answer well as the object-glasses of compound microscopes.

Method of making them.

After experiencing the extreme difficulty of obtaining precious stones free of double refraction or difference of density, and from little cavities and imperfections, as well as the difficulty of giving their surfaces a perfect polish and a correct figure, Sir David Brewster made an extended series of experiments on the formation of minute fluid lenses, which should equal in power and distinctness those made of precious stones. The primary difficulty which was encountered in this attempt was that of depositing a sufficiently minute drop of fluid upon a surface of glass. This arose from two causes: from the difficulty of taking up on the slenderest fibre a minute globule of a fluid of any moderate tenacity, and the still greater difficulty of overcoming its adhesion to the fibre, and laying a portion of it on glass. The first of these difficulties he overcame by a suitable mixture of two fluids, and the second by a mechanical process. Having thus succeeded in obtaining lenses too small to be recognised distinctly by the eye, he next endeavoured to make their figure approximate to the hyperbolic form when the lenses were not of the smallest size; and the results which he obtained were far beyond his expectation. Some of these lenses preserved their perfection for more than a year, and if protected from dust might have been kept much longer. If fluids could be obtained of a high refractive power, and not of a volatile nature, microscopes of extreme perfection might thus be readily constructed.

In order to deposit upon glass a very minute portion of fluid, Sir D. Brewster employed a fibre of spun glass. When slightly dipped into the fluid, the portion which adhered to its extremity, in place of remaining in the form of a small globule, ran along the fibre, so that it could not be laid upon the glass. Upon holding the fibre vertically, and repeatedly knocking the hand which held it upon the thigh, the fluid was gradually made to accumulate at the end of the fibre, so that it could be made to touch the glass surface, and leave a small portion in the form of a plano-convex lens.

The desired result was produced more effectually by fixing the upper end of the fibre in the stand of a microscope, so as to suspend it vertically above the glass plate. By turning the milled head, and making the drop at the end of the fibre descend, or the glass ascend, till they were nearly in contact, it was easy, by a rapid separation of the two after contact, to leave the smallest portion upon the glass.

It is obvious that this operation could not be performed, if the fluid had much tenacity, like Canada balsam in its usual condition. Sir David Brewster therefore tried to obtain a fluid of the proper tenacity, and found that a mixture of castor oil and Canada balsam answered the purpose when carefully incorporated.

With this fluid, and with others, suspended, as shown in fig. 13, from plates of thin parallel glass, he obtained microscopes equal to the glass, or even sapphire, microscopes made by opticians. This, no doubt, arises from three causes,—1. From the perfect homogeneity of the material; 2. From the perfect polish of the surface; and, 3. From the approximation of the figure of the lens to the hyperbolic curve. The form of the curve will obviously vary with the size of the drop and the tenacity of the fluid.[1]

Fig. 13.

The curvature of the lens may be changed by suspending the drop from convex or concave surfaces, as in figures 14 and 15. With the view of altering the curvature of the fluid lenses, immiscible fluids were used, such as *treacle*

---

[1] The form of the lens may be ascertained by taking a highly magnified image of it.

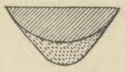

Fig. 14.

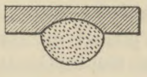

Fig. 15.

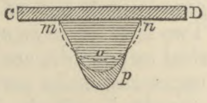

Fig. 16.

or *honey*, and *castor oil*. The dotted line *mon* (fig. 16) shows the original *castor oil* lens, and the horizontally lined lens the form into which it is pulled by the weight of the *treacle* or *honey* lens *p*. The effect of this combination was very good.

In place of the plate CD (fig. 16), we may use a convex

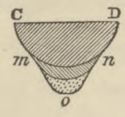

Fig. 17.

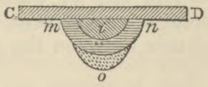

Fig. 18.

lens as in fig. 17, where *mn* is the *castor oil*, and *o* the *treacle* meniscus.

An achromatic combination may be made as in fig. 18, CD being the glass plate, *i* a plano-convex lens, *mn* a concave lens of a highly refractive and dispersive oil, and *o* a meniscus of treacle or Canada balsam softened.

We may pull down a fluid lens *abc* (fig. 19) into a hyperboloidal form by the weight of a lens of glass *mn*. In an experiment thus made there was not a trace of spherical aberration. There is no occasion in this case of a small

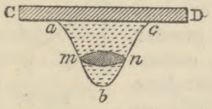

Fig. 19.

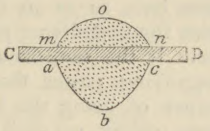

Fig. 20.

aperture, as the treacle lens *abc* excludes all lateral light. The effect of suspending the lens of a minnow at *mn* was good.

If the fluid lens is too hyperbolic, it may be corrected by a flattened lens *mon* (fig. 20) placed above the glass plate CD.

Single Catadioptric Microscope.

Single catadioptric microscope.

A single lens, by which light is both refracted and reflected, seems at first sight to be something paradoxical. Such a lens, however, which was proposed and used by Sir David Brewster, is shown in the annexed figure, where ABC is a hemispherical plano-convex lens, which, if we use it in the common way, will have a certain magnifying power; but if we use it as shown in the figure, it acts as a double convex lens of the same radius, and has consequently twice the magnifying power. Bisect the semicircle BAC in A, and join AB, AC. If we now place an object at *mn*, and look into the lens BA at F, we shall see by reflection from the surface BC the object *mn*, with the same distinctness, and under the same angle, as if we had placed the two lenses A*a*B*d*, A*a*C*d*, with their plane sides AB, AC together. Since the light is incident on the reflecting surface BDC at an angle of 45° and upwards, not a ray of it will be transmitted, as it suffers total reflection. The lens thus used, composed in reality of two plano-convex ones, A*a*C*d*, A*a*B*d*, has less spherical aberration than when used as a whole, ABC, and there is obviously no error from imperfect centering. This lens may be used as the object-glass of a compound microscope; and it will be seen in another section that it possesses other advantages than those which have been mentioned.

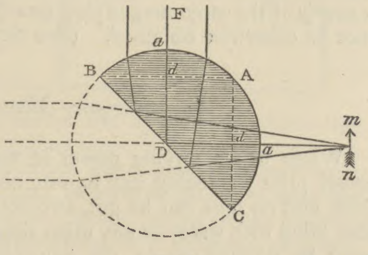

Fig. 21.

The Grooved Sphere.

Grooved sphere.

This lens derives its name from its having a deep groove cut round it in the plane of a great circle perpendicular to the axis of vision. Sir David Brewster was led to its construction by the doublet of Dr Wollaston, which will be described in another section. It consists of a spherical lens or sphere, with a deep concave groove cut round it, so as to cut off the marginal pencils, and thus give a wider field and a more perfect image. It is represented in the annexed figure, where ABDC is a sphere of glass, having the unshaded parts below AC and above BD cut away, in order to prevent rays that fall very obliquely from reaching the eye. The central thickness of the lens may be made so small as to render the spherical and even the chromatic abberration almost insensible. As all the pencils pass through the centre, every part of the image will be equally distinct; a property possessed by no other lens.

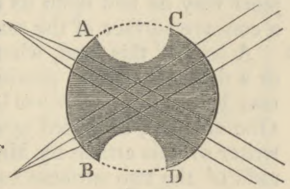

Fig. 22.

This lens, as fitted up by Mr Blackie for the inventor, is shown in the annexed figure; AB being a representation of it when closed, and ABC when open; the lens at A resembling a bird's eye.

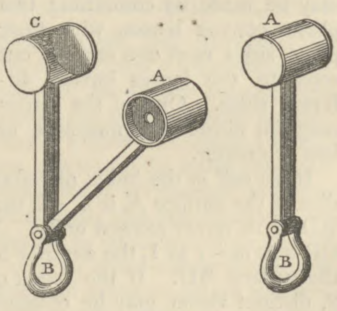

Fig. 23.

Mr Coddington,[1] who entertains a high opinion of the value of this lens, observes:—"Besides all this, another advantage appears in practice to attend this construction, which I did not anticipate, and for which I cannot now at all account. I have stated that when a pencil of rays is admitted into the eye, which, having passed without deviation through a lens, is bent by the eye, the vision is never free from the coloured fringes produced by eccentrical dispersion. Now with the sphere I certainly do not perceive this defect; and I therefore conceive that if it were possible to make spherical glass on a very minute scale, it would be *the most perfect simple microscope*, except, perhaps, Dr Wollaston's doublet,[2] than which I can hardly imagine anything more excellent, as far as its use extends; its only defects being the very small field of view, and the impracticability of applying it, except to transparent objects seen by transmitted light. Now, the sphere has this advantage, that whereas it makes *a very good simple microscope, it is more peculiarly* fitted for the object-glass of a compound instrument, since it gives a perfectly distinct image of any required extent, and that, when combined with a proper eye-piece, it may without difficulty be employed for opaque objects." We do not rightly apprehend the exact import of these observations. Mr Coddington distinctly asserts that the grooved sphere is the most perfect simple microscope, or the most perfect microscope with one lens; and yet he says in the next paragraph that it is only "a very good simple microscope," being "more peculiarly fitted for a compound instrument."[1]

---

[1] *Phil. Trans.*, 1830, part i., pp. 69–84.

[2] This exception was needless, as the doublet is not a simple microscope, having two lenses placed at a distance.

With regard to the difficulty of making it on a small scale, it is by no means great; for if we can grind and polish its two surfaces, we may readily excavate it round its margin. We have now before us a grooved sphere of garnet $\frac{1}{24}$th of an inch radius, executed by Mr Blackie: The focus is almost close to the lens, which in many kinds of observation is a great advantage, and its performance is remarkably fine.

It will be seen in our article on OPTICS, that when the refractive index of a sphere exceeds 2·000, its focus falls within the sphere. Hence a grooved sphere made of diamond is useless. When made with garnet it is invaluable; and its focus is just thrown so near its surface, that the objects may be laid upon its surface, or pressed against it by a concave surface of the same radius.

Concentric lenses.

A lens of this kind, whether the surfaces have the same or a different radius, provided they have the same centre, may be called a *concentric* lens, and has valuable properties. One of these, executed upwards of thirty years ago for the writer of this article by Mr Blackie of Edinburgh, has the radii of the two surfaces so adjusted that its anterior focus is on the least convex surface. It is shown in the annexed figure, where C is the common centre of the two surfaces A and BD; the groove round C being cut to the requisite depth.

An equivalent concentric lens may be made by combining two plano-convex lenses, with their plane sides next one another cut separate, the lenses having different sides. One of the lenses may be either a hemisphere or less or greater.

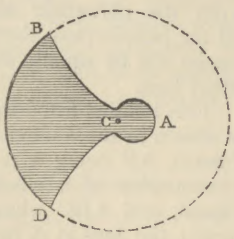

Fig. 24.

If we call m the index of refraction, then if AC, the radius of the surface A, is $m-1$, the radius CB of the surface BD must never exceed unity. When the ratio of CA to CB is as $m-1$ to 1, the anterior focus of the lens will be on the surface BD. If the index of refraction m is beneath 2, distinct vision may be obtained by looking into either surface. When the index is 2, the only concentric lens that can be made consists of two hemispheres united, or a sphere. When the index is above 2, distinct vision can be obtained only by looking into, or placing next the eye, the least convex surface.

The Fluid Grooved Sphere.

Fluid grooved sphere.

In order to construct a grooved sphere with fluids, Sir David Brewster adopted the arrangement shown in the annexed figure, where AB is a piece of plate-glass of a circular form, having a groove cut out of its circumference. Two fluid lenses m, n, as nearly hemispherical as possible, are then placed on its upper and under surface by the methods already described. The aberration both from form and colour will be reduced by the groove, as well as by the form of the under lens.

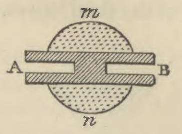

Fig. 25.

The same effect may be produced by substituting for the piece of glass AB two thin plates of parallel glass, or thin laminæ of split topaz *ab*, *cd* (fig. 26), separated by a circular plate of metal, with a proper aperture, the three plates being cemented into one by Canada balsam, or any homogeneous cement which may fill the aperture between the glass-plates.

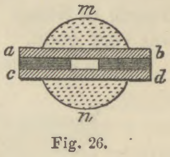

Fig. 26.

Compound Single Microscopes.

Compound single microscope.

We may give this name to any combination of lenses which acts solely as a single microscope. When we possess single lenses with little magnifying power, we may double or quadruple their power by cutting them into halves, quarters, or more numerous sections, and placing them transversely, as in the annexed figure. In this figure is represented a combination of two semi-lenses ABC, DEF cut from the same lens, so as to form a lens having twice the magnifying power of the original one. If the semi-lens ABC has a greater magnifying power than DEF, in consequence of being the half of another lens more convex, we shall have *three* different magnifying powers in the same combination,—the *highest* power in the portion EB, a *lower* power through the portions m, o, and a still lower power through the portions n, p.

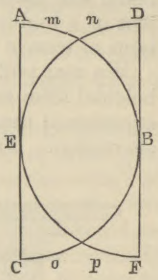

Fig. 27.

A combination of quarters of lenses, having the same properties as those above described, is shown in the annexed figure. The quarter lenses may be combined as in the upper or lower half of the preceding figure, and several of such combinations may be united for optical purposes, and made achromatic by the usual methods.

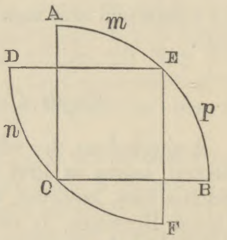

Fig. 28.

The preceding method of combining divided lenses enables us to make two or more lenses, or microscopes, or telescopes *exactly* of the same magnifying power; an effect which cannot be otherwise obtained. (See STEREOSCOPE.)

An Extempore Microscope.

Extempore microscope

When a magnifying power is wanted for reading any small print or seeing any minute object, and no lens can be got, two bottles filled with water or any other fluid may be crossed, as in the annexed figure, and the object viewed through the middle portion ABCD. Two very small bottles, or two test tubes, crossed in the same manner, will have a considerable magnifying power.

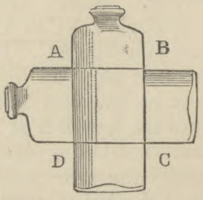

Fig. 29.

---

[1] This lens, which has very incorrectly been called the "Coddington lens," was not invented by Mr Coddington, nor was its invention ever claimed by him. It was invented by Sir David Brewster, and constructed in Edinburgh of glass and garnet long before 1820, and an account of it was published in the *Edinburgh Philosophical Journal*, April–July 1820. Mr Coddington takes no notice of it in his *Treatise on Optics*, published in 1823, but he mentions it without any name in his Treatise *On the Reflection and Refraction of Light*, published in 1829. Mr Coddington, we have reason to believe, got a grooved sphere made by Mr Carey or some other London optician, who, supposing it to be new, gave it a name to which it was not entitled. Had Mr Coddington been alive, he would have been one of the first to give it its true name.

Crystalline Lenses of Small Fishes.

The crystalline lens of minnows and small fishes may be taken out of the eye in a state of such perfection, that when used as single microscopes, they give a very perfect image of minute objects. In such lenses, which have an increasing density towards their centre, the spherical aberration is almost wholly corrected. Great care, however, must be taken to make the axis of the lens the axis of vision, to prevent its form from being injured by pressure against the aperture which holds it. The best way is to make a ring at the end of a piece of wire, having its diameter a little greater than that of the lens. A ring of viscid fluid is then made to line the ring of wire, and the lens is suspended in the ring of fluid, some of the fluid encroaching upon its anterior or posterior surface.

Magnifying Power of Single Microscopes.

Magnifying power.

Having thus described the various kinds of single microscopes, we shall now consider the subject of their magnifying power. When an eye in the prime of life, and neither long nor short sighted, views the minutest object which it can recognise, it will generally place it at the distance of about five inches. When the same object is viewed through a single microscope, the distance at which it is seen is equal to the focal length of the lens; and as the apparent magnitude of objects is inversely as the distances at which they are seen, we have only to divide the distance, five inches, by the focal length of the lens, in order to know its magnifying power, or the apparent magnitude of objects when seen through the lens.

The following table shows the magnifying power of lenses of all focal lengths, from 5 inches up to the 100th of an inch, and is applicable to all lenses, of whatever substance they are made :—

Focal Length.	Magnifying Power.	Focal Length.	Magnifying Power.
Inches.		Inches.	
5	1	$\frac{1}{17}$	85
2	$2\frac{1}{2}$	$\frac{1}{18}$	90
$1\frac{3}{4}$	$2\frac{5}{6}$	$\frac{1}{19}$	95
$1\frac{1}{2}$	$3\frac{1}{3}$	$\frac{1}{20}$	100
$1\frac{1}{4}$	4	$\frac{1}{25}$	125
1	5	$\frac{1}{30}$	150
$\frac{3}{4}$	$6\frac{2}{3}$	$\frac{1}{35}$	175
$\frac{1}{2}$	10	$\frac{1}{40}$	200
$\frac{1}{3}$	15	$\frac{1}{45}$	225
$\frac{1}{4}$	20	$\frac{1}{50}$	250
$\frac{1}{5}$	25	$\frac{1}{55}$	275
$\frac{1}{6}$	30	$\frac{1}{60}$	300
$\frac{1}{7}$	35	$\frac{1}{65}$	325
$\frac{1}{8}$	40	$\frac{1}{70}$	350
$\frac{1}{9}$	45	$\frac{1}{75}$	375
$\frac{1}{10}$	50	$\frac{1}{80}$	400
$\frac{1}{11}$	55	$\frac{1}{85}$	425
$\frac{1}{12}$	60	$\frac{1}{90}$	450
$\frac{1}{13}$	65	$\frac{1}{95}$	475
$\frac{1}{14}$	70	$\frac{1}{100}$	500
$\frac{1}{15}$	75		
$\frac{1}{16}$	80		

We have already mentioned the advantages which the precious stones have over glass ones, in having a much less spherical aberration. In order that a glass lens may have the least spherical aberration, its radii of curvature must be as one to six, the flattest side being turned to the object; but this is not the case with bodies of a different refractive power. Mr Coddington, in his *Treatise on the Reflection and Refraction of Light*,[1] has computed the ratio of the curves when the aberration is a minimum for various indices of refraction from 1·5 up to 2·0, and the amount of the aberration itself in parts of the thickness of the lens. This table is very important in a practical point of view, as will be seen from the observations which follow it.

Spherical aberration.

Table showing the Spherical Aberration of Lenses of Glass and the Precious Stones, and the proper proportion of their Radii when the Aberration is a Minimum :—

Substances.	Index of Refraction.	Ratio of the Radii of a Lens of Minimum Aberration.	Longitudinal Aberration, the thickness being 10.
Fluor spar……………… Cryolite ………………	1·4	1 to 3·66	10·96
Glass plate……………… Oil of almonds ………… Castor oil……………… Honey………………	1·5	1 to 6	10·71
Flint glass……………… Quartz……………… Topaz……………… Oil of cassia………………	1·6	1 to 14	9·33
Glass, lead 1, flint 2…… Sulphuret of carbon ……	1·7	1 to −93	6·66
Sapphire……………… Ruby……………… Spinelle ruby……………… Garnet……………… Glass, lead 2, flint 1½……	1·8	1 to −12	3·57
Sulphate of lead……… Glass, lead 2½, flint 1……	1·9	1 to −7	1·66
Zircon……………… Calomel……………… Sulphur ……………… Phosphorus ……………… Glass, lead 3, flint 1……	2·0	1 to −5	0·62

It appears from the preceding table, that when the refractive index is between 1·4 and 1·6 and a little more, but less than 1·7, the second surface of the double convex lens must be *convex*, in order to have the least spherical aberration; but that when the index is a very little above 1·6, the second surface must be *plane*, and when the index is nearer 1·7 than 1·6 the second surface must be *concave*, in order to make the aberration a minimum, and this concavity, in the case of zircon and sulphur, is so much as −5, so that in diamond it must be nearly −3; so that we must sacrifice a great deal of magnifying power in order to obtain this advantage in diamond; but the sacrifice will be well bestowed, for such a lens will be almost wholly free of spherical aberration.

Notwithstanding the difficulty of the task, we would earnestly direct the attention of artists to the subject of grinding plano-convex lenses of a hyperbolic form for single microscopes. The smallness of the lens must increase the difficulty; but in this case the effect may be accidentally obtained, as it is often done in giving a parabolic and an elliptical form to specula. Mr Potter has given, and put to the test of experiment, a method of obtaining any curve derived from revolution, by giving a particular form to the grinding and polishing tools. (*Edin. Jour. of Science*, new series, No. 12.)

CHAPTER II.

DESCRIPTION OF MICROSCOPIC DOUBLETS AND TRIPLETS.

Doublets and triplets.

Under this chapter we propose to describe all combinations of lenses in which two or more are placed in contact, or at such a distance that no image is formed between them.

---

[1] Page 111, Cambridge, 1829.

Wollaston's Periscopic Doublet.

Periscopic doublet.

The earliest proposal of a doublet lens was that which Dr Wollaston made (*Phil. Trans.* 1812, p. 375), under the name of a periscopic microscope. The following is his own description of it:—"The great desideratum," says he, "in employing high magnifiers, is sufficiency of light; and it is accordingly expedient to make the aperture of the little lens as large as is consistent with distinct vision. But if the object to be viewed is of such magnitude as to appear under an angle of several degrees on each side of the centre, the requisite distinctness cannot be given to the whole surface by a common lens, in consequence of the confusion occasioned by oblique incidence of the lateral rays, excepting by means of a very small aperture, and proportionable diminution of light. In order to remedy this inconvenience, I conceived that the perforated metal which limits the aperture of the lens might be placed with advantage in its centre; and accordingly I procured two plano-convex lenses ground to the same radius, and applying their plane surface on opposite sides of the same aperture, in a thin piece of metal (as is represented by a section, fig. 30), produced the desired effect, having virtually a double convex lens, so contrived that the passage of oblique pencils was at right angles with its surface, as well as the central pencil. With a lens so constructed, the perforation that appeared to give the most perfect distinctness was about *one-fifth* part of the focal length in diameter; and when such an aperture is well centered, the visible field is at least as much as 20° in diameter. It is true, that a portion of light is lost by doubling the number of surfaces; but this is more than compensated by the greater aperture which, under these circumstances, is compatible with distinct vision."

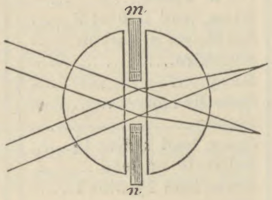

Fig. 30.

PERISCOPIC SPHERE.

Periscopic sphere.

In the preceding passage Dr Wollaston describes only a double convex periscopic microscope, consisting of two plano-convex lenses; but he does not take the case where these two lenses are hemispheres, and consequently where the doubly convex one which they form is a sphere. When the lenses are not hemispheres, the pencils are not centrical, and the rays from different parts of the object do not each suffer the same species of refraction as they do when passing through a sphere, so that every part of the field is not equally distinct. It is obvious also that Dr Wollaston did not think of filling up the central aperture with a fluid of the same refractive power as the lens, in order to remove the loss of light from the double number of surfaces, which he mentions as a defect in his microscope.

The construction of a periscopic sphere proposed by Sir David Brewster combines these two properties. The lenses, whether they are hemispherical or not, must be so placed that their convex surfaces form part of the same sphere, as shown in the annexed figures.

In fig. 31 the plano-convex lenses AB, CD may be cemented to a piece of plate-glass *mn*, of such a thickness in one direction as to complete the sphere, and of such a diameter in the direction *mn* as to form a suitable contraction of the aperture.

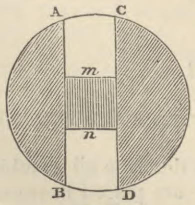

Fig. 31.

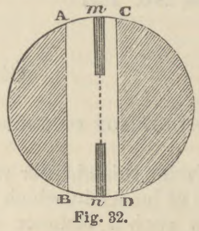

Fig. 32.

In fig. 32 the space between the two unequal lenses may be filled up, as in the figure, by two pieces of plate-glass A*mn*B, C*mn*D, between which is a plate of brass, or of thin black paper, containing a suitable aperture in the centre of the lenses. Here there are *six* surfaces within the sphere; but by uniting them with a proper cement, the whole becomes a single sphere, in which there is no perceptible loss of light.

In fig. 33 lenses of unequal size and thickness are combined either with a plate of glass or a fluid between them of the same refractive power as the glass, and the apertures may be placed on the plane surfaces AB, CD.

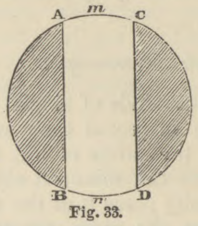

Fig. 33.

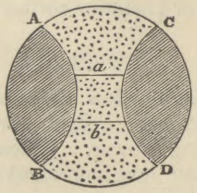

Fig. 34.

In fig. 34 two convex lenses may be combined into a sphere, the intermediate portion being filled up with a fluid of the same refractive power. This may be readily done by cementing each lens on the end of a brass or glass tube *ab*, and introducing the fluid by an aperture.

In uniting these lenses, it is obviously necessary that the convex outer surfaces should be exactly of the same curvature and of the same kind of glass. The best way of effecting this is to grind a thick lens ABC, either greater or less than a hemisphere, and then to bisect it at AD, and out of the portions ADB, ADC to form two plano-convex lenses ABE, ACF, or two double convex lenses AEBG, AFCH. The outer surfaces of these two lenses will belong accurately to the same sphere. The perfect similarity of the inner surfaces is of less consequence, as all refraction by them is wholly removed by the cement if it has the same refractive power.

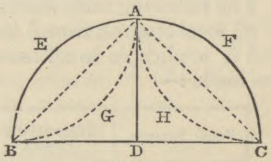

Fig. 35.

By these different steps Sir David Brewster was led to the idea of the grooved sphere, or the lens already described under the head of single microscopes, in which the aperture is contracted by excavating the sphere all round in one of its great circles.

PERISCOPIC ACHROMATIC SPHERES.

Periscopic achromatic sphere.

If, in the construction shown in fig. 36, in place of making the fluid *op* of the same refractive and dispersive power as the two lenses, we make it such as to correct the colour of these lenses, we shall obtain an achromatic sphere, as proposed by Sir David Brewster; and the compound lens may be still farther improved as a microscope by attaching, either by cement or not, to the back of the first lens AB a convex speculum of silver or steel for illuminating the object, the contracted aperture being the hole in the centre of the speculum. The concave fluid lens is shown at *op*; and such a curvature must be given to the convex reflector *mn* that it may reflect parallel or diverging rays upon the object.[1]

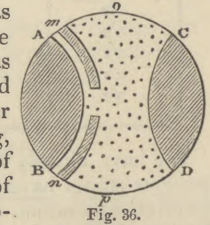

Fig. 36.

---

[1] *Edinburgh Philosophical Journal*, 1820, vol. iii., pp. 74–77; and Pritchard's *Treatise on Optical Instruments*, in the Library of Useful Knowledge, p. 41, § 66.

Mr Coddington[1] thus treats of the preceding contrivance:—"An achromatic sphere may be constructed by interposing between two crossed lenses (double convex ones), in opposite positions, a concave lens of a medium more highly dispersive than that of the lenses, adjusting the curvatures so that the outer surfaces of the crossed lenses shall be portions of the same sphere, and that the interior surfaces shall exactly fit into each other.

"In such a system, we may consider the effect to be the same as that of an entire sphere of the same medium as the two lenses diminished by that of a concave lens having for its refractive ratio that which exists between the two media in question.

"Thus, if μ_1 be the ordinary index of refraction for the convex lenses, μ_2 for the concave one, $\pi : 1$ the ratio of the dispersive powers, r the radius of the sphere s, σ those of the internal surfaces, we must have

$$\left(\frac{\mu_2}{\mu_1}-1\right)\left(\frac{1}{s}+\frac{1}{\sigma}\right) : 2\frac{\mu_1-1}{\mu_1}\frac{1}{r}=\pi : 1;$$

whence it follows that $\frac{1}{s}+\frac{1}{\sigma}=2\pi.\frac{\mu_1-1}{\mu_2-\mu_1}\frac{1}{r}$.

For example, let $\mu_1=1,5$; $\mu_2=1,65$; $\pi={}_11,25$.

$$\text{Then, } \frac{1}{s}+\frac{1}{\sigma}=\frac{1}{4}\cdot\frac{,5}{{}_1,5}\frac{1}{r}=\frac{1}{1,2r}.$$

If the first internal surface be plane, or $s=\infty$, we have in general $\sigma=\frac{1}{2\pi}\frac{\mu_2-\mu_1}{\mu_1-1}r$; or, in this particular example, $\sigma=1,2r$, or $\sigma : r=6 : 5$."

DOUBLET OF NO ABERRATION.

Herschel's doublets of small aberration.

So long ago as 1668, a doublet was described in the *Philosophical Transactions*, in which a large and flat field was obtained. This subject, however, was never investigated with care till Sir John Herschel took up the subject in 1821. The doublet, made of glass, which Sir John proposes for obtaining perfect distinctness in microscopical observations, is shown in the annexed figures 37, 38, the convex sides being turned to the eye when the doublet is used as a microscope, and to the sun when it is used as a burning-glass. The following are the radii and focal length of these lenses:—

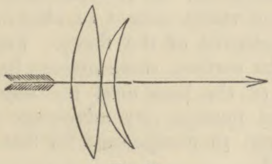

Fig. 37.

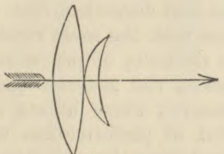

Fig. 38.

	Fig. 37.	Fig. 38
Focal length of the *first* lens	+10·000	+10·000
Radius of its first surface	+ 5·833	+ 5·833
Radius of its second surface	−35·000	−35·000
Focal length of the *second* lens	+17·829	+ 5·497
Radius of its first surface	+ 3·688	+ 2·954
Radius of its second surface	+ 6·291	+ 8·128
Focal length of the *combined* lenses	+ 6·407	+ 3·474

"Whether we ought or ought not," says Sir John, "to aim at the rigorous destruction of rays parallel to the axis, the use to which the lens is to be applied must decide. In a burning-glass it is of the highest importance. A slight consideration will suffice to show, that the difference of temperatures produced in the foci of a double convex lens of equal radii, and one of the same focal length, but of the best form, must be very considerable. In order to try whether even the latter might not be improved by the shortening of the focus, and the superior concentration of the exterior rays, by applying a correcting lens of one of the forms above calculated, in spite of the loss of heat in passing through a second glass, I procured two lenses to be figured to the radii assigned in the first column of the foregoing table. They were about three inches in aperture, and when combined as above described, the aberration was almost totally destroyed, and probably would have been so completely had the index of refraction proper to the glass been employed instead of that adopted in our calculation for brevity. Their combined effect as a burning-lens appeared to me decidedly superior to that of the first lens used alone, and there is therefore good reason to presume that the effect of the other construction, which, with the same loss of heat, affords a much greater contraction of the focus, would be still better; and I regret not having tried it in preference.

"In eye-glasses and magnifiers, if we would examine a minute object with much attention, as a small insect, or (when applied to astronomical purposes) if we would scrutinize the appearance of a planet, a lunar mountain, the nucleus of a comet, or a close double star, where extent of field is of less consequence than perfect distinctness in the central point, too much pains cannot be taken in destroying the central aberration." (*Phil. Trans.* 1821. p. 246-248.)

Mr Pritchard has executed some of these doublets for the object-glasses of compound microscopes, "for which," he says, "they answer remarkably well, but their angle of aperture is small compared with combinations of double achromatics." (*Microscopic Cabinet*, p. 163.)

Herschel's Periscopic Doublet.

Herschel's periscopic doublet.

We owe also to Sir John Herschel the construction of a periscopic doublet with a very large field of moderate distinctness. "In spectacles," says he, "reading-glasses, magnifiers of moderate power, and eye-glasses for certain astronomical purposes, the correction of the aberration in the centre of the field may be sacrificed with little inconvenience. By far the best periscopic combination I am acquainted with consists of a double convex lens of the best form, but placed in its worst position (radii as 6 to 1) for the lens next the eye, and a plane concave whose focal length is to that of the other as 2·6 to 1, or as 13 to 5, placed in contact with its flatter surface, and having its concavity towards the object, as in the annexed figure, for the farthest; yet for destroying the aberration of rays parallel to the axis nothing can be worse. In fact, our formula gives for the aberration in this construction 22·02, or about 22 times what the best single lens of equal power would give; yet on accidentally combining two such lenses in this manner, I was immediately struck with the remarkable extent of oblique vision, with the absence of fatigue, on reading some lines with a power much beyond that of the natural eye, and with the freedom from colour at the edges of the field, arising from *the opposition of the prismatic refractions* of the two solids; an advantage which a single meniscus does not possess." The focal length of the compound lens which Sir John tried was 1·84 of an inch. The field of tolerably distinct vision extended fully 40° from the axis, and the letters of a book might be read, and the forms of objects distinguished, with management, as far as the 75th degree. In using such a combination the lenses should be very thin, and the eye applied as close as possible.

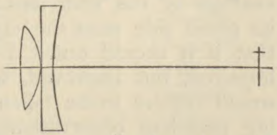

Fig. 39.

---

[1] *Treatise on the Reflection and Refraction of Light*, p. 256.

Plano-Convex Doublet.

Plano-convex doublet.

A doublet of much simpler construction, and with its spherical aberration greatly diminished, has also been proposed by Sir John Herschel. It is represented in the annexed figure, and consists of two convex lenses of equal focal lengths, the convex sides being placed in contact, and the eye and object opposite the plane sides. In this case the aberration will be only 0·6028. But if we make the focal length of the first to that of the second as 1 to 2·3, the aberration will be reduced to 0·2481. In order to have an idea of the value of such a doublet, we shall give the series of aberrations for single lenses, as investigated by Sir John Herschel:—

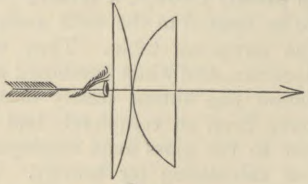

Fig. 40.

	Aberration.
Plano-convex, plane side first	4·2
Plano-convex, convex side first	10·81
Double convex	1·567
Best form of a single lens	1·00
Doublet of two equal plano-convex lenses	0·6028
Doublet of two plano-convex lenses with their focal lengths as 1 to 2·3	0·2481
Doublet of garnet, with suitable focal lengths	0·08

Garnet doublets.

As these calculations are made for glass, the advantage of such a doublet made of garnet or sapphire must be much greater. In a garnet the minimum aberration takes place when the form of the lens differs very little from that of plano-convex; and as it is then to that of glass as 35 to 107, the aberration will be only about 0·08, or next to imperceptible.

Wollaston's Doublet.

Wollaston's doublet.

The consideration of the Huygenian eye-piece for astronomical telescopes suggested to Dr Wollaston the probability that a similar combination should have a similar advantage, of correcting both achromatic and spherical aberrations, if employed in an opposite direction as a microscope.[1] With this view, he took two plano-convex lenses, the ratio of whose focal lengths was as 3 to 1, and he placed them as in the annexed figure, so that the distance of their plain surfaces was from $1\frac{4}{10}$ to $1\frac{5}{10}$ the focal length of the smallest. The plane sides of the lenses are towards the object. The advantage of the first lens having its plane side next the object is, as Dr Wollaston states, that if it should touch a fluid, the view is not only not impaired, but improved, whereas a double convex lens would require to be taken out and cleaned. The following excellent observations on this doublet are made by Pritchard:—

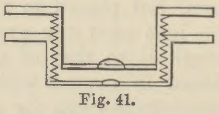

Fig. 41.

Pritchard's improvements.

"Having mounted some plano-convex lenses of the relative foci named by Dr Wollaston, in such a manner that the distances might be varied at pleasure, I was surprised to find that after the doublet was adjusted *by trial*, so as to obtain the maximum of distinctness, the distance between the lenses did not accord either with the rule given by Huygens, or that of Dr Wollaston. Supposing that I had not got the combination intended by Dr Wollaston, I procured several doublets made by different artists, and to my astonishment found they agreed with my own, and therefore presumed the Doctor was mistaken in the distance by the thickness of the lenses and the minuteness of the space between them. The distance which appeared to me essential to obtain the best effect, *is the difference of the focal length of the two lenses, making a proper allowance for their thickness.* The proportion of the foci of the two lenses may be varied *ad libitum.* All that is requisite in this respect is, that the difference must be greater than the thickness of the anterior lens, while it may be observed (in high powers), that the greater the difference between their two focal lengths the more space will be left in front; and as this is of great practical importance, they should never be less than as 1 to 3. I have made some very good ones, differing as much as 1 to 6. . . . . The following details are necessary to insure their goodness:—

"*First,* The convex surface of each lens must be *truly spherical.* If this is not obtained, it will be in vain to procure a good doublet, however beautifully the lenses may be polished or accurately adjusted. From this circumstance I have found globules perform very well, providing they are free from air-bubbles, which, however, is rarely the case. It should be observed, that a slight scratch on their surface is trifling compared to air-bubbles; for the latter not only stop the light, but, by the reflection around the edges of each bubble, produce considerable fog or glare. *Second,* The distance between the lenses is the next point of importance; its adjustment is best accomplished by trial, mounting the lenses in such a manner that their distance can be varied at pleasure, and capable of being turned round, so as to adjust the centering. When this is obtained, they should be fixed so that their distance and position cannot be altered. This it is necessary to regard, as I have sometimes spent whole days in re-adjusting a doublet that had been separated to examine the lenses singly. *Third,* The stop or diaphragm, for limiting the aperture in these combinations, should be placed immediately behind the anterior lens. From the difference of the situation of the stop in the various doublets I have examined, it will appear that their makers did not know that the field of view depended upon the plane of the stop. I have found, that when the stop is situated *close* behind the anterior lens, no other is required, and the field is enlarged without sensibly augmenting the aberration. On this account the lenses of the finest doublet, when used singly with the same aperture as combined, has so much aberration and distortion that distinct vision cannot be obtained, even with the most rigid adjustment of the focus. From the difficulty of procuring a flat surface, some makers have worked the anterior surface of the lens next the object concave: these lenses do not possess any advantage in point of performance, not even to compensate for loss of power from the negative side."

Blaikie's doublet.

Mr Pritchard remarks, that when the lens next the object is a jewel, the performance of the doublet is improved; but that he has not observed any advantage when both lenses are gems. This must be a mistake; for lenses of any gem, that are superior to glass ones when acting singly, must, if suitably combined, be superior also when united. In proof of this, we have a garnet doublet before us, executed by Mr Blaikie, the performance of which is quite remarkable. The lenses are made of Elie garnets, and their convex sides are placed towards each other. The radius of the smallest lens near the object is $\frac{1}{70}$th of an inch, and that of the other $\frac{1}{20}$th of an inch. Its magnifying power is very high, exceeding greatly that of the semi-jewel doublet made by Mr Pritchard, with a sapphire lens $\frac{1}{60}$th of an inch focus, combined with a glass lens $\frac{1}{10}$th of an inch focus.

On Fluid Doublets.

Fluid doublets.

Dr Wollaston's doublet, as shown in fig. 41, may be imitated with great facility by placing two plano-convex fluid lenses of different sizes upon plates of parallel glass.

---

[1] Mr Coddington has shown that such a correction is impossible. (*Treatise on the Eye and Optical Instruments*, p. 55.)

In such an arrangement it is necessary in the fluid, as well as in the glass doublet, to have the axes of the lenses perfectly coincident; a result which, by the method already referred to, may be more accurately effected in the fluid one.

Pritchard's Triplet.

Pritchard's triplet.

Upon the same principle as the doublets, Mr Pritchard constructed triplets, the third or posterior lens having a longer focal length than the two others. This combination requires much more precision in the adjustment, and more attention in the centering. Mr Pritchard remarks, that, "when perfected, they amply repay the pains bestowed upon them, in the accuracy with which they exhibit the most difficult lined objects, though it is to be regretted that neither these nor the doublets of deep power will show pleasantly cylindrical bodies of large diameter, such as a large mouse or bat's hair." Having long made use of one of Mr Pritchard's triplets, we can amply confirm the account which he has given of the excellence of this combination. Mr Blackie has executed for us a triplet, the centre lens of which is garnet, the posterior one of quartz, and the anterior one of flat glass. It is a very powerful combination, and performs admirably.

Sir David Brewster has made triplets, in which two of the lenses are fluids and the third a solid, and some in which they are all fluids.

Gairdner's microscope.

A very simple method of fitting up doublets and triplets, or even single lenses, has been proposed by Dr William Gairdner of Edinburgh, and executed by Mr Bryson.

In this instrument a Wollaston's doublet A is fixed at the end of a handle AB. A ring C is attached to the end of a bent brass stem CD, which is secured to the handle AB at D. This ring contains a disc of thin glass, on either side of which objects may be placed for examination; fluids on the outside, and other objects on the inside of it. By means of a milled head M, the screw of which passes through the handle and acts upon the arm CD, the observer is enabled to bring the objects into the focus of the doublet. This little instrument has been recommended by botanists, physiologists, and medical practitioners.

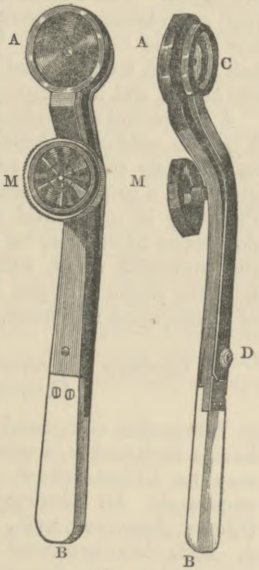

Fig. 42.

Single Achromatic Microscope.

Single achromatic microscopes.

In many of the doublets which we have already described, the chromatic aberration is partially, and sometimes greatly corrected, but still not to such a degree as to entitle them to the name of achromatic. The great improvement which has taken place in the art of grinding and polishing small lenses, has enabled the optician to execute *double* and *triple* achromatic lenses having a diameter so small as from $\frac{1}{4}$th to $\frac{1}{16}$th of an inch. Mr Pritchard has made them of the latter size with an angle of aperture of 65°. These lenses may be advantageously used in single microscopes where very high powers are not required, or when they cannot be applied, though it is usual to employ them as the object-glasses of compound microscopes, as we shall afterwards see.

Sir David Brewster has executed achromatic lenses, both *double* and *triple*, by combining a fluid *concave* lens with one or two convex lenses of the precious stones or glass. When the lenses are *double*, the fluid lens is of course a meniscus in which the concavity predominates, as it is impossible to form a fluid lens doubly concave.

Single Achromatic Fluid Microscope.

Single achromatic fluid microscope.

A single lens of glass, or of any of the gems, having a high refractive and low dispersive power may be made achromatic, or the colour much corrected, by suspending a fluid concave lens M upon a double convex lens L, as in fig. 43; CD being a plate of metal, or if the solid lens L is plano-convex, it may be cemented upon a plate of glass as in fig. 44. In order to increase the correcting power of the fluid lens M, we may make it doubly concave as in fig. 45; or AB may be a plano-convex lens with its plane side uppermost.

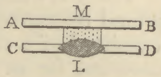

Fig. 43.

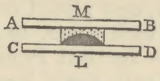

Fig. 44

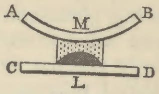

Fig. 45.

Fluid Achromatic Doublets.

Fluid achromatic doublets.

A fluid achromatic doublet may be made by placing a suitable fluid *mn* between the lenses, as in the annexed figures, in which all the lenses may be fluids, provided *mn* and the other fluids be immiscible.

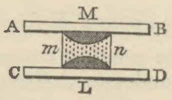

Fig. 46, *a*.

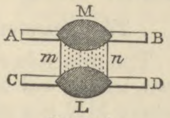

Fig. 46, *b*.

When M, L are of glass or precious stones, they may be set in brass plates.

Single Reflecting Microscopes.

Single reflecting miscroscopes.

Single reflecting microscopes are not much in use. They consist of a concave metallic speculum of a short focal length, so that any minute body placed in its focus will be seen magnified. The form of the speculum should of course be parabolic. Such a microscope is principally useful for looking at one's own eye, or any part of it not far from the pupil. In these cases no image is formed, as the rays enter the eye parallel.

Gray's.

The following ingenious contrivance for a fluid reflecting microseope we owe to Mr S. Gray (*Ph. Tr.* 1697, No. 228, p. 539). Having taken a small globule of quicksilver, and dissolved it in a menstruum of 10 parts of water and 1 of nitric acid (aquafortis), he dipped the end of a stick in this solution, and rubbed with it the inner circle of the ring A, so as to give it a mercurial tincture. This ring is made of brass, and is about the 30th of an inch thick, having its mean diameter not exceeding $\frac{2}{5}$ths of an inch. When the inner surface of the ring wetted with the solution has been wiped dry and laid upon a table, pour a drop of quicksilver within it, and when this drop is gently pressed with the ball of the finger it will adhere to the ring, and when cleansed with a hare's foot will form a *convex* speculum. If the ring and speculum are now taken up and carried horizontally, and laid on the margin of the hollow cylinder B, the mercury will become a *concave* reflecting speculum, in consequence of its upper surface sinking down by gravity. The cylinder B rests upon a pillar with a screw on its outside, and supported by the base D. A stage, ECFG, may be moved up and down, so as to place the object, which is fixed at G, in the focus of the concave speculum.

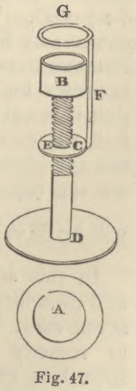

Fig. 47.

CHAPTER III.

ON COMPOUND MICROSCOPES.

Compound microscope.

A compound microscope is an instrument in which a distinct and enlarged image of an object is formed by an object-glass or a speculum, and this enlarged image again magnified by one or more eye-glasses.

There is every reason to believe, that the earliest compound microscopes which were used by Zansz and Galileo, consisted of a convex lens for an object-glass, and a concave one for an eye-glass, like the telescope which was at that time in use.

Fontana in 1646 used *two* convex lenses; Dr Hooke *three*, and Eustachio Divini *four;* the two next the eye being plano-convex, and placed in contact, with their convex sides towards each other, to give a high power and a large and flat field. In 1691 Philip Bonnani[1] used a compound microscope with three lenses, and added to it an illuminating apparatus with two lenses.

The reflecting compound microscope was first suggested by Sir Isaac Newton, and its construction varied and made more complex by Dr Barker and Dr Smith of Cambridge. The simple contrivance of Sir Isaac has in modern times been greatly improved by Amici, Potter, Tulley, Cuthbert, and Dr Goring.

The Common Compound Refracting Microscope.

Compound refracting microscope.

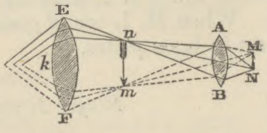

Fig. 48.

The principle of the common compound microscope with two lenses will be understood from the annexed figure, where MN is a minute object placed in the focus of the object-glass AB, or rather a little farther from it than its principal focus. An image of this object will be formed at *mn*, at some distance behind AB, the distance *n*A increasing as AM diminishes. The size of the image *mn* will be to that of the object MN as *n*A is to AM, their distances from the lens AB. If we now view this magnified image *mn* through an eye-glass EF, so placed that *mn* is in its principal focus, we shall again magnify it in the inverse proportion of E*n* to the distance at which the eye sees minute objects most distinctly, which is about 5 inches. The object MN is thus doubly magnified, so that if *n*A is six times AM, and the lens EF has a focal length of half an inch, the magnifying power will be $6\times\overline{5\div\frac{1}{2}}=60$. While the lenses are the same, the magnifying power may be increased to any extent by increasing the distance between the lenses EF and AB; but the object becomes indistinct as the magnifying power increases, so that it is not advisable to make the distance *n*A more than five, six, or seven inches; or calling *f* the focal distance of the eye-glass, D = AM, d = A*n*, and Δ the distance at which we see objects distinctly, then this magnifying power M will be $M=\frac{d}{D}\times\frac{\Delta}{f}$.

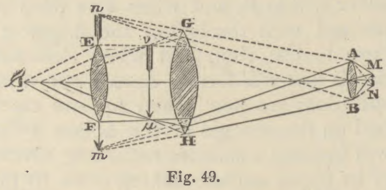

Fig. 49.

In this arrangement of lenses the field of view is small, and therefore we cannot see the whole of many small objects at one view. In order to remedy this, a large lens, called the amplifying glass, is placed between the image and the object-glass, as shown in fig. 49, where *nm* is the image formed by AB alone; but in consequence of the interposition of GH, it is contracted into $\nu\mu$, and this contracted image is magnified by the eye-glass EF.[1] In order to widen the field still farther, aud make it flat, two plano-convex lenses have been placed at E, F, having their convex sides in contact. In order to find the magnifying power when the lens GH is used, we must multiply the magnifying power, as obtained by the preceding formula, by the quantity $=\frac{L}{\phi}$, ϕ representing the focal length of the lens GH and $L=\frac{\delta^2}{\delta-\phi}-d-f$, δ being the distance between the first and second glasses, and d the distance between the first and third glasses.

Dr Goring prefers the following method of finding the magnifying power of these microscopes. Measure the aperture of the object-glass and call it a, make AM $=f$, and having measured with a micrometer scale the diameter of the usual pencil of rays before they enter the eye, call it d; then $a:f=d:$ F, F being the focal length of a single lens having the same power as the compound microscope. But the magnifying power m of a lens F is $\frac{\Delta}{F}$. Hence the magnifying power M of the compound microscope will be $M=\frac{\Delta a}{fa}$.

In the construction of this microscope some attention is requisite in adjusting the apertures of the object-glasses employed. The smaller they are, the less will be the spherical and chromatic aberration of the object-glass, but the less will be the light. When a plano-convex lens about half an inch focus is used, its plane side should be towards the object, and its aperture limited to $\frac{1}{15}$th of an inch.

A compound microscope is sometimes so constructed that it can be used on a single microscope stand. This is done by screwing the lower end of the body round the object-glass into a projecting arm at the top of the stand. When the body is unscrewed and removed, a single lens or a doublet or triplet may be screwed into the same place, and the moveable stage, with the slider and object, brought near the single lens, just as if it had been the object-glass of a compound microscope. (See fig. 3.)

Dr Goring's Improvement on the Object-Glass of the Compound Microscope.

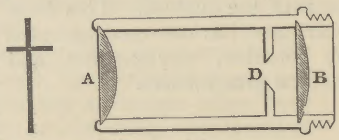

Fig. 50.

When the compound microscope does not require to have a high power, a compound object-glass of two lenses may be advantageously employed. Dr Goring (*Quart. Jour.* vol., xvii., p. 202) has contrived the combination shown in the annexed figure, where A is a plano-convex lens, with its flat side next the object, having its focal distance about one-half or two-thirds that of the plano or double convex lens B. A stop D is placed in the posterior focus of the object-glass A. Mr Pritchard remarks, that when the focal length of A "is not less than half an inch, this combination has been employed with considerable advantage, both as regards distinctness and aperture."

Mr Coddington's Improvement on the Eye-Glasses of the common Compound Microscope.

The improvement suggested by Mr Coddington on the eye-pieces of compound microscopes is shown in fig. 51.

---

[1] Observationes circa viventia, quæ in rebus non viventibus reperiuntur.

[1] These two lenses, when plano-convex with their plane sides next the eye, and when their distance is equal to half the sum of their focal lengths, form the Huygenian eye-piece, which partially corrects chromatic and spherical aberration.

The object of the contrivance is to fulfil the condition proposed by Huygens in his excellent telescopic eye-piece; namely, to have the refraction of the pencils divided between the two lenses, and to produce the greatest possible flattening of the field. Mr Coddington found that the most proper form of the lenses was that shown in fig. 52, where the two eye-glasses consist of a meniscus A next the eye, and a double equi-convex lens B, while the field-glass is composed of two meniscuses C, D. Mr Coddington, however, informs us that he "found no sensible error arise from the substitution of plano-convex lenses for the meniscus-glasses, which are difficult and expensive to form." He remarks also, that theory indicates "a farther flattening of the field to be made by separating the eye-glasses a little, which requires the distance of the first eye-glass from the field-glass to be diminished by about half as much; but he did not perceive any improvement arising from this alteration in practice, and therefore he does not recommend the change. The object-glass which Mr Coddington uses in this microscope is the grooved sphere proposed by Sir David Brewster.

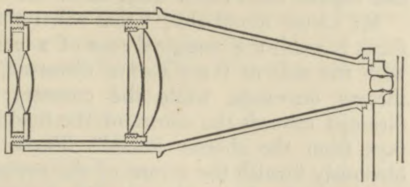

Fig. 51.

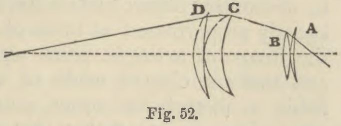

Fig. 52.

In his Treatise on the Eye and Optical Instruments Mr Coddington has proposed a different combination for the eye-glasses and the field or amplifying glass. Supposing the distance between the object-glass and field-glass to be 1 inch, the focal length of the field and eye-glasses 1 inch each, and the distance between the field-glass and nearest eye-glass 1 inch, he finds the distance of the two eye-glasses to be $\frac{3}{8}$th of an inch. He finds also, "that all indistinctness arising from the oblique refractions will be corrected when the field-glass is convexo-convex, nearly convexo-plane, the first eye-glass convexo-convex (the flattest side next the eye, radii as 3 : 1), and the second eye-glass a meniscus (the most convex side next the eye, radii as 1 : 5)."

Taking another case, he supposes the distance of the object-glass from the field-glass to be 2 inches, and the eye-glasses to be in contact, as in fig. 52; then "it appears that for the achromatism we must have the distance between the field-glass and the second eye-glass 1 inch." Then the field-glass must be convexo-plane nearly; the first eye-glass equi-convex, and the second eye-glass a meniscus with the radii as 1 : 5.

Dr Goring, who examined one of the instruments constructed on these principles, states, *that both the chromatic and spherical aberration of the objective part was wholly untouched, and that the eye-piece, consisting of four glasses, was achromatic.* He adds also, that nothing can surpass the beauty of the field of this microscope for extent of flatness. Now we think that Dr Goring has mistaken Mr Coddington, who never pretended to correct the spherical and chromatic aberration of the object-glass.[1] He considers the chromatic and spherical aberration of the grooved sphere, which is the object-glass he uses, as reduced to very small quantities, by leaving only a small channel in its axis for the passage of the rays. Whatever the residual aberration may be, Mr Coddington is not answerable for it, as his object was merely to make the other part of the microscope good, which, according to Dr Goring, he has succeeded in doing.

In accurate investigations with the microscope the instruments above described are of little use, and have been completely superseded by the compound achromatic microscope.

Compound Achromatic Microscope.

Compound achromatic microscope.

Although the achromatic microscope has only recently come into use as an effective and superior instrument, yet it can scarcely be considered as a new one. Every person knew that achromatic object-glasses were most desirable in the compound microscope. So early as 1776 Euler proposed to employ them in compound microscopes; but so late as 1821 M. Biot considered their introduction as out of the question, from the impracticability of making achromatic lenses as small as those which the microscope requires!

M. Selligues, 1823.

In 1823 M. Selligues and Dr Goring were both occupied with the subject, the former having employed MM. Chevalier, two excellent opticians in Paris, and the latter Mr Tulley, to execute small achromatic object-glasses. It is to M. Selligues, however, in so far as we can learn, that we are indebted for the new and happy idea of making the object-glass consist of *four* achromatic compound lenses, each consisting of two lenses. This idea is the actual source of the superiority of the achromatic microscopes; and in proof of this we may state, that Professor Amici, who had early been following out the old idea of a single achromatic object-glass, abandoned his attempts in 1815, but afterwards successfully resumed them by adopting M. Selligues' plan of the superposition of several object-glasses. In M. Selligues' instrument the focal length of each object-glass was 18 lines, its diameter 6 lines, and its thickness at the centre 6 lines. In that of Amici the focal length of each was about 6 lines; and MM. Chevalier have executed them having only 2 lines in focal length. More recently, however, Mr Pritchard has surpassed all these artists, by making them of one-sixteenth of an inch in focal length.

Amici.

From this brief historical detail we shall proceed to give a more minute account of the lenses executed by these different individuals, for which we are indebted to Mr Jackson Lister, whose able memoir on this subject is, as we shall see, one of the most valuable contributions to the science of the microscope that has for a long time appeared.

Chevalier.

The achromatic object-glasses of M. Selligues' microscope made by MM. Chevalier, consisted of a plano-concave lens of flint-glass, and a double convex one of crown or plate glass, with their inner curves cemented together by a mixture of mastic and turpentine, to remove the reflection of the interior surfaces, and prevent the introduction of dampness. Four of these lenses, of from $1\frac{1}{2}$ to $1\frac{7}{8}$ of an inch in focal length, were made to screw before each other, so as to be used either all together, or any of them individually, in the usual manner, like the object-glasses of a compound microscope. The aberration of colour was thus corrected in a considerable degree, but the glasses were fixed in their places, with their convex sides towards the object, which is their worst position; and in consequence of this the spherical aberration was enormous, and was distinctly seen, even with the small aperture to which it was necessary to reduce them.

Notwithstanding this defect, the grand idea of the combination was acquired; and M. Chevalier having observed the mistake committed by M. Selligues, made them of less focal length, and more achromatic; and turning the concave lens to the object, he produced in 1825 an instrument far above that of M. Selligues. His deepest glasses were four-tenths of an inch in focal length; and in his first microscope two such compound lenses were combined for his highest power.

Fraunhofer.

The date of Fraunhofer's achromatic microscopes is not known. Many years ago the writer of this article ordered an achromatic object-glass from Fraunhofer for a large microscope, for the purpose of making a particular class of observations; but at that time he seems not to have made any compound lenses to be combined after the manner of Selligues. Mr Robert Brown (*Phil. Trans.* 1830, p. 188) obtained a series of five such object-glasses from Utzschneider, whose focal lengths are from 1·8 to 0·43 of an inch.

---

[1] *Treatise on the Eye and Optical Instruments*, pp. 58, 59, § 329.

Amici.

When Professor Amici visited London in 1827, he brought with him some compound object-glasses, which performed very well; and Mr Lister subsequently learned from him that he had executed a combination of 2·7 lines in focal length, and 2·7 lines in aperture, which greatly excels the former.

Lister.

Among the most successful improvers of the achromatic microscope we must rank Mr Jackson Lister, who has discovered some curious and valuable properties of these lenses that have escaped the notice of the most skilful analysis. Mr Lister has investigated the subject entirely as a matter of observation, and therefore his results are more likely to have a higher practical value.

Mr Lister takes as the basis of a microscopic object-glass two conditions,—1. that the flint-glass shall be plano-concave; and, 2. That it shall be joined by some cement to the convex lens. The *first* condition obviates the risk of error in centering the two curves; and the *second* diminishes by nearly a half the loss of light from reflection, which is very great at the numerous surfaces of a combination of compound object-glasses.

Now Mr Lister has found that in every such compound lens which he has tried, whether the flint-glass was Swiss or English, with a double convex of plate-glass, which has been rendered achromatic by the form given to the outer curve of plate-glass, the ratio between the refractive and dispersive powers has been such that its figure has been correct for rays issuing from some point in its axis not far from the principal focus on its plane side; and these rays either tend to a conjugate focus within the tube of the microscope, or emerge nearly parallel.

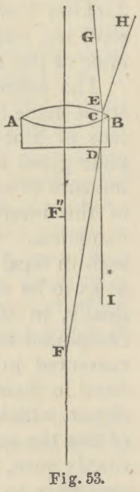

Fig. 53.

If AB represents such an object-glass, let us suppose that it is free from spherical and achromatic aberration for a ray FDEG radiating from F, then the angle of emergence GEH will be about three times as great as that of incidence FDI. If the radiant point is now made to approach the lens, the angles of incidence and emergence will approach to equality, and the spherical aberration produced by the two will bear a less proportion to the opposing error of the single correcting curve ABC, and hence in this case the rays will be *over-corrected* for such a focus.

As F continues to approach the lens, the angle of incidence continuing to increase, it will exceed that of emergence, which has been in the meantime diminishing, so that the spherical aberration produced by the two outer surfaces will recover their original proportion. When F has reached this point F″ (at which the angle of incidence does not exceed that of emergence so much as it had at first come short of it), the rays will again be free from spherical aberration. If F″ comes still nearer the lens, or is carried beyond F in the opposite direction, the angle of incidence in the former case, or of emergence in the latter, becomes disproportionately effective, and in either case the aberration exceeds the correction, or the rays are *under-corrected.* Hence Mr Lister gives the following rule:—

"*That in general an achromatic object-glass, of which the inner surfaces are in contact, or nearly so, will have on one side of it two foci in its axis, for the rays proceeding from which the spherical aberration will be truly corrected at a moderate aperture; that for the space between these two points, its spherical aberration will be over-corrected, and beyond them either way, under-corrected.*"

Mr Lister found also, "that when the longer aplanatic focus is used, the marginal rays of a pencil not coincident with the axis of the glass are distorted, so that a coma is thrown outwards, while the contrary effect of a coma directed towards the centre of the field is produced by the rays from the shorter focus." These interesting results obviously furnish the means of destroying both aberrations in a large focal pencil, and of thus surmounting what has been hitherto the chief obstacle to the perfection of the microscope. And when it is considered that the curves of its diminutive object-glasses have required to be at least as exactly proportioned as those of a large telescope, to give the image of a bright point equally sharp and colourless, and that any change made to correct one aberration was liable to disturb the other, some idea may be formed of what the amount of that obstacle would have been. It will, however, be evident, that if any object-glass is but made achromatic, with its lenses truly worked and cemented, so that their axes coincide, it may with certainty be connected with another possessing the same requisites, and of suitable focus, so that the combination shall be free from spherical error also in the centre of its field.

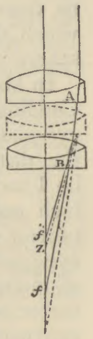

Fig. 54.

For this the rays have only to be received by the front glass B, from its shorter aplanatic focus *f*′, and transmitted in the direction of the larger correct pencil *f*A of the other glass A. It is desirable that the latter pencil should neither converge to a very short focus, nor be more than very slightly, if at all, divergent; and a little attention at first to the kind of glass used will keep it within this range, the denser flint being suited to the glasses of shorter focus and larger angle of aperture. If the two glasses, which in the diagram are drawn as at some distance apart, are brought nearer together (if the place of A, for instance, is carried to the dotted figure), the rays transmitted by B in the direction of the larger aplanatic pencil of A, will plainly be derived from some point (Z) more distant than *f*′, and lying between the aplanatic foci of B; therefore (according to what has been stated) this glass, and consequently the combination, will then be spherically over-corrected. If, on the other hand, the distance between A and B is increased, the opposite effects are of course produced.

In combining several glasses together, it is often convenient to transmit an under-corrected pencil from the front glass, and to counteract its error by over-correction in the middle one.

Slight errors in colour may, in the same manner, be destroyed by opposite ones; and, on the principles described, we not only acquire fine correction for the central ray, but, by the opposite effects at the two foci in the transverse pencil, all coma can be destroyed, and the whole field rendered beautifully flat and distinct. (*Phil. Trans.*, 1830, p. 199.)

Compound Achromatic Microscopes with Solid and Fluid Lenses.

Compound fluid achromatic microscope.

In 1812 a very simple method was employed by Sir David Brewster for making both single and compound achromatic microscopes. Almost all objects are seen to the greatest advantage when immersed in a fluid, even the finest test objects, such as the scales of the Podura. Having placed the object on a piece of glass, he put above it a drop of an oil having a greater dispersive power than the single lens, or than the concave lens which formed the object-glass of the microscope. The lens was then made to touch the fluid, so that the surface of the fluid was, as it were, formed into a concave lens. Now if the radius of the outward surface of this lens was such as to correct the dispersion, we have here a perfect achromatic microscope, both simple and compound. The best way is to over-correct the colour of the plate-glass lens by the fluid, and then to reduce the dispersion of the fluid by mixing it with one of a less dispersive power. This will be understood from the annexed diagram, where AB is an unequally convex lens, the flattest side of which is plunged in the fluid *mn*, placed in a watch-glass CD. The object is placed at *mn*, and the dispersion of the concave surface of the fluid compensates that which is produced by the lens. All errors of centring are here removed, and also the loss of light at the touching surfaces of solid lenses. If AB is a single microscope, the object *mn* will be placed in its principal focus, and the emergent parallel rays will enter the eye; but if it is the object-glass of a compound microscope, an image will be formed a few inches behind AB, by withdrawing AB a little from *mn*, or placing the object a little without its principal focus. We have already had occasion to describe an achromatic grooved sphere, but in the process of achromatizing it, the sphere loses in a very small degree its valuable property of refracting in the very same manner all the pencils that enter the eye. This property, however, may be preserved in the bird's-eye sphere by the achromatic method which we have now described. Let AB (fig. 56) be the grooved sphere, and CD the watch-glass containing the fluid; it is obvious that every ray which passes through the centre of the sphere will enter and quit it perpendicularly, without suffering any refraction. The same mode of achromatizing the sphere AB may be adopted with a solid concentric concave lens of flint-glass or other substance, or the sphere may be placed between two such concentric lenses. The greater the dispersion of the flint-glass, the nearer must the outer surface CD approach to AB. By these means the grooved sphere may be rendered perfect, both as a single microscope and as the object-glass of a compound one.

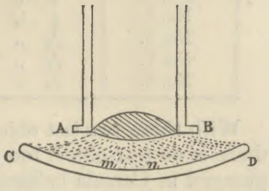

Fig. 55.

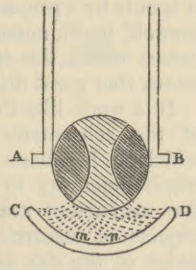

Fig. 56.

The principle above described may be applied to a system of object-glasses like those of Selligues' microscope. Let A, B, E (fig. 57) be three convex lenses, so placed at the end of the tube of a compound microscope, that the highly dispersive fluid in the watch-glass CD will enter between the glasses A, B, and E. The concave lenses of fluid will over-correct the three lenses A, B, and E; but if a very deep curvature on the outside of A is not sufficient to compensate this over-correction, it may be effected by a suitable lens at F. If the three lenses are made of the precious stones, with a high refractive power and a low dispersive one, the concave fluid lenses will not over-correct them.

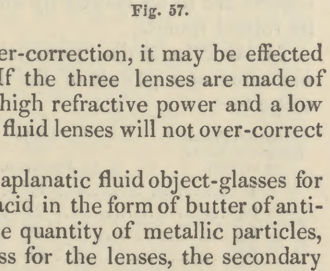

Fig. 57.

If, as Dr Blair did in his aplanatic fluid object-glasses for telescopes, we use muriatic acid in the form of butter of antimony, and containing a due quantity of metallic particles, for the fluid, and crown-glass for the lenses, the secondary colours will be completely corrected, and an instrument of the most superior kind produced. If a permanent and portable *aplanatic* object-glass is preferred, the butter of antimony may be placed between a meniscus and a plano-convex lens of crown glass, as in the annexed figure, where *o* is the object, CD a meniscus of crown-glass, AB a plano-convex lens, and *mn* a concave lens of the fluid. This construction of the object-glasses of compound microscopes is much more easily applicable in the case of the microscope than in that of the telescope. In the latter case the colour of the fluid, the changes which it undergoes by time, and the difficulty of retaining it, are objections of considerable amount; but in the case of the microscope, the colour of the fluid disappears owing to its small thickness, and it may be retained by capillary attraction alone, and renewed as often as we choose.

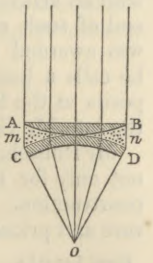

Fig. 58.

Recent improvements on the microscope.

Since these observations were published, the compound achromatic microscope has undergone great improvements in the hands of Pritchard, Ross, Powell, Messrs Smith and Beck, M. Nachet, MM. Oberhauser, and Professor Amici of Florence. These great improvements, by which the compound achromatic microscope has been brought to such a high degree of perfection, were no doubt owing to the spirit of competition excited by the London and Paris Exhibitions.

In the Crystal Palace of 1851, Mr Andrew Ross, Messrs Smith and Beck, and M. Nachet of Paris, were the leading competitors. Mr Ross and Messrs Smith and Beck received council medals, and M. Nachet a prize medal. The instruments of the first two artists were of first-rate quality, and those of M. Nachet were superior to those of all foreign opticians. The following tables show the relative angles of aperture and focal lengths of the object-glasses exhibited by the competitors:—

Mr Ross's.

Mr Ross's Object-Glasses in 1851.

Mr Ross intended to exhibit in Paris object-glasses of a still higher order than those which we have mentioned, and he would thus have found himself in competition with his eminent rivals Messrs Smith and Beck, and M. Nachet. He was prevented, however, by the pressure of business from exhibiting the new object-glass which he had prepared for that purpose; and Messrs Smith and Beck, who had no English rival, carried off the microscopic prize by receiving a medal of the first class. Although the microscope of M. Nachet was not equal to that of the English artists, it had such a high degree of merit that a medal of the same value was adjudged to him.

Oberhauser's.

MM. Oberhauser of Paris exhibited an excellent achromatic microscope, and also one intended for observations in the vacuum of an air-pump, for which a medal of the first class was adjudged.

Mr Pillischer's microscopes.

Mr Pillischer of Bond Street exhibited a microscope with an achromatic object-glass half an inch in focal length, and of such excellence that a medal of the second class was awarded to him. Mr Pillischer also exhibited what he calls a lenticular microscope, for examining urinary deposits at the bedside, which has been highly spoken of by the late Mr Golding Bird and Mr Quekett.

Mr Pillischer's "students' microscopes" were remarkable, not only for their cheapness, but the excellence of their construction. The following is a list of the angles of aperture and prices of his object-glasses :—

Focal Lengths.	Angles of Aperture.	Prices.
2 inches	14 degrees	L.2 2
1 ,,	26	2 2
$0\frac{1}{2}$,,	60	4 0
$0\frac{1}{4}$,,	90	5 0
$0\frac{1}{5}$,,	109	5 0

The following table contains a description of the achromatic object-glasses which Mr Ross intended to exhibit :—

Messrs Smith and Beck's.

Messrs Smith and Beck sent two achromatic microscopes to the Paris Exposition, namely, one of their very best instruments, and another of an entirely new construction, to which they gave the name of "The Educational Microscope."

The first of these microscopes differed very little from the one which they exhibited in 1851 at the Crystal Palace. It had, however, object-glasses of a shorter focus and greater angular aperture, as is shown in the following list :—

Focal Lengths.	Angles of Aperture.
$1\frac{1}{2}$ inches	13 degrees.
$0\frac{2}{3}$,,	27 ,,
$0\frac{4}{10}$,,	90 ,,
$0\frac{1}{5}$,,	110 ,,
$0\frac{1}{8}$,,	120 ,,

Educational microscopes.

The Educational Microscope exhibited by Messrs Smith and Beck is an instrument of great value, and from its low price and excellence it cannot fail to have an extensive sale. With object-glasses of one inch and a quarter, and apertures of 22° and 75°, its price, packed in a case, is only 1 .10, and the additional apparatus, including one Lieberkhun, a Wenham's parabolic reflector, a Wollaston's camera lucida for drawing, and a polarizing apparatus complete, with prisms of selenite, amount only to L.5 additional. Since the middle of 1855 no fewer than 100 of these educational microscopes have been sold, and two-thirds of this number had the additional apparatus.

M. Nachet's object-glasses.

The following were the object-glasses which M. Nachet exhibited in 1855, and which were much admired by the jury :—

Series.	Focal Lengths.	Angles of Aperture.	Prices.
No. 3.	$\frac{1}{4}$ inch	75°	L.2 10 0
No. 4.	$\frac{1}{6}$,,	90	2 10 0
No. 5.	$\frac{1}{8}$,,	95	3 3 0
No. 6.	$\frac{1}{10}$,,	110	4 0 0
No. 7.	$\frac{1}{14}$,,	125	5 5 0
No. 8.	$\frac{1}{18}$,,	165	7 5 0

With these two last object-glasses M. Nachet states that there is no test-object too difficult to be resolved when it is plunged in Canada balsam.

Fine microscope shown to the jury by Prof. Amici.

When the jury of Class VIII. were comparing the rival microscopes, Professor Amici of Florence, distinguished by his optical inventions, showed a microscope which exhibited certain striæ in test-objects better than any of the instruments under examination. This superiority was produced by the introduction of water between the object and the object-glass; but as Professor Amici was not an exhibitor, the jury was not called upon to adjudicate to him a medal.

His achromatic microscopes.

This microscope was of small dimensions compared with those with which it was compared, and shows how much may be effected by the ingenuity and optical knowledge of an observer like Professor Amici, thoroughly acquainted with optics. We have seen at Florence, in Professor Amici's studio, instruments of his construction which exhibit distinctly the lines in certain objects which have hardly been seen by other instruments; and we are convinced that it is only by a preparation of difficult objects by the observer himself, by illuminating them properly, and by optical processes which the optician neither knows nor pretends to know, that great discoveries are to be made.

In a work like this we cannot find room for an account of the achromatic microscope in the various forms in which it has been constructed. Every artist has shown much ingenuity in the construction of different parts of the instrument and in the adaptation of it to different objects of research, and the naturalist will be the best judge of the size and nature of the instrument which he wishes to employ. We shall therefore content ourselves with describing one of the earliest achromatic microscopes, namely, that of Mr Pritchard; the latest, and what we believe to be the best, namely, that of Mr Andrew Ross; and some forms of the instrument which possess special advantages.

Pritchard's Compound Achromatic Microscope.

Pritchard's compound achromatic microscope.

This instrument is represented in fig. 59 as fitted up by Mr Pritchard. All its parts are so distinctly shown in the figure that they require no description, especially as the uses of most of the parts have been described in a former chapter. Fig. 59 is a perspective view of the instrument in its most convenient position for examining transparent objects by reflected light. The stops and condensing illuminator, which are seen under the stage, should be removed when particular objects are to be examined. When test-objects are to be viewed by direct light the instrument can be turned round.

In Mr Pritchard's instrument the following are the dimensions and powers of the lenses for a complete microscope :—

Sidereal Focal Length in parts of an inch.	Angle of Aperture.	Magnifying Powers in Diameters by a standard of 5 inches.
1	16°	60 to 100
$0\frac{1}{2}$	21	100 to 360
$0\frac{1}{4}$	42	240 to 500
$0\frac{1}{8}$	55	500 to 1100
$0\frac{1}{16}$	65	900 to 3000

Of these object-glasses, that whose focal length is $\frac{1}{4}$th of an inch appears to be the most perfect and useful.

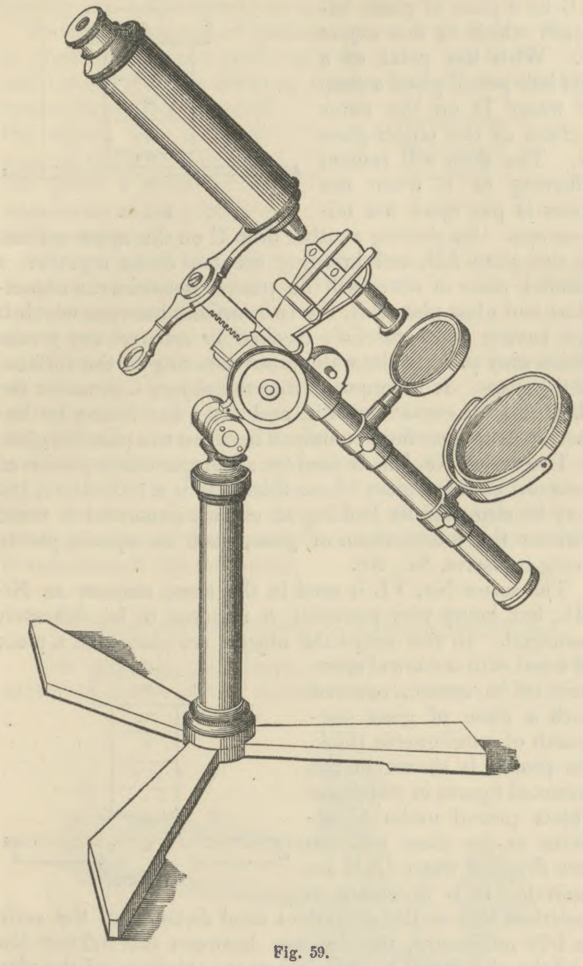

Fig. 59.

Mr Andrew Ross's Compound Achromatic Microscope.

Ross's microscope.

The great achromatic microscope of Mr Andrew Ross, in its most perfect and recent form, is shown in fig. 60.

The body of the microscope AB rests upon a massive stand so constructed as to prevent any perceptible tremor in the object under examination. The transverse arm *mn* into which it is screwed at *m*, is fixed by a screw E to the top of a strong flat bar, in the back of which is a rack into which works a pinion moved by the milled head M, which gives the *coarse* adjustment for bringing the body of the microscope into focus. Another milled head on the opposite side enables the observer to do the same thing with his left hand. The fine adjustment, for obtaining distinct vision of the object, is effected by the milled head C, which acts upon the tube at B, into which the object-glasses are screwed, one turn of it giving a motion of the 300th of an inch. On the top of the two pillars P, P is fixed a horizontal axis D, which passes nearly through the centre of gravity of the microscope, and upon which it turns, so that it may be placed at any angle whatever to the horizon. The stage S for holding the object, and the apparatus beneath it for modifying the light to illuminate the object, are most ingeniously constructed. The two rectangular or traversing motions of the stage are produced by the two milled heads below B. The secondary stage at T, for condensing and modifying the light reflected from the mirror V, receives all the requisite motions from the milled heads shown in the figure. In the cylindrical tube of which it is composed is placed the achromatic condenser and one of the polarizing prisms or rhombs, and other pieces of apparatus which are often required in particular researches.

Without depreciating the fine instruments of Smith and Beck, and Powell and Lealand, which evince great ingenuity, and have many new and admirable properties, the microscope of Mr Ross must be regarded as the finest hitherto constructed.

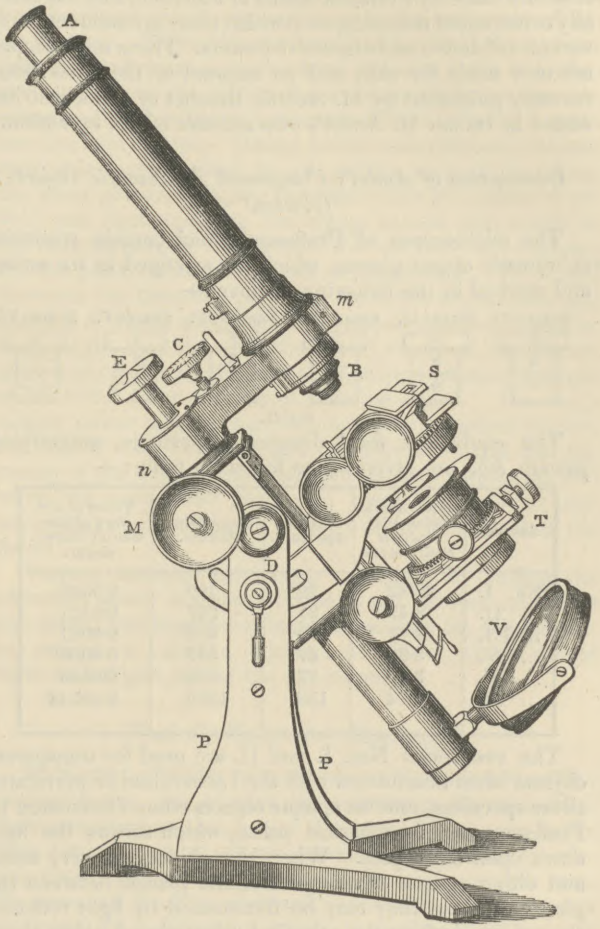

Fig. 60.

The future of the microscope.

The compound achromatic microscope may be considered as having nearly attained to perfection, while the practical optician confines himself to the use of flint and crown-glass lenses with spherical surfaces. It is hardly possible, however, that so noble an instrument, by which so much knowledge has yet to be acquired, will long remain in its present imperfect state.

The writer of this article has long ago, and repeatedly, urged upon the optician the necessity of constructing both telescopes and microscopes upon the aplanatic principle discovered by Dr Blair, a principle much more easily applied to small than to large object-glasses. Science has fully performed her part in showing how the colours of refracted light, both primary and secondary, may be corrected, but neither public liberality nor private enterprise has been called forth to put in practice her methods. Even in the case of the primary colours opticians have declined to take the trouble of making each lens of their eye-pieces achromatic, and, with one exception, they seem not even to have attempted to correct the errors of the secondary spectrum. The time, however, has now come to make this attempt; and we have no doubt that before the close of the century we shall have—what Dr Blair neither anticipated nor proposed to have—each lens of our optical instruments perfectly aplanatic, even if the art of grinding surfaces otherwise than spherical has not been discovered.

The employment of fluids of various dispersive powers gives the artist a wider range in his experimental researches, but even if he limits himself to the use of different kinds of glass and transparent minerals, we have no doubt of his ultimate success. This attempt has been boldly and so far successfully made by Professor Amici of Florence, who has actually constructed microscopes in which there are solid lenses of various refractive and dispersive powers. These microscopes are now made for sale, and an account of them has been recently published by M. Achille Brachet of Paris, who has added in Italian M. Amici's own account of his invention.

Description of Amici's Compound Achromatic Object-Glasses.[1]

Amici's achromatic object-glasses.

The microscopes of Professor Amici contain *seventeen* achromatic object-glasses, which are arranged in *six* series, and marked in the following manner:—

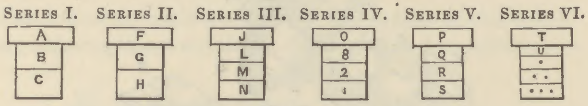

Fig. 61.

The equivalent focal distances, apertures, magnifying powers, &c., are given in the following table:—

SERIES.	Equivalent Focal Distance in Millimetres.	Angular Aperture.	Magnifying Powers.	Value of one part of the Ocular Micrometer.
No. I.	22·82	26°	100	0·0326
... II.	8·47	37	257	0·0121
... III.	4·27	70	535	0·0061
... IV.	3·92	57	577	0·0056
... V.	3·50	77	650	0·0050
... VI.	1·74	160	1310	0·00248

The two series Nos. I. and II. are used for transparent objects when illuminated with the Lieberkhun or perforated silver speculum, and for opaque objects when illuminated by Professor Amici's spherical prism, which throws the light down upon the object. When the objects are very small, and either opaque or transparent, and placed between two plates of glass, they may be illuminated by light reflected very obliquely from the spherical prism placed below them, and they are seen on a dark ground when the prism gives an obliquity greater than the angle of aperture of the object-glass employed. In the series No. I., for example, where half the angle of aperture is 13°, if the lower illuminating spherical prism is more than 13° distant from the optic axis, none of the refracted light will reach the eye, and the object will radiate only the light which its surface is capable of reflecting. This mode of illumination, which often produces an excellent effect, may be used with the series No. VI.

The series No. IV. is used for naked transparent objects, or when they are not covered with a plate of glass,—at least with one not very thin.

The series No. V. is used for transparent objects covered with a plate of glass 0·86 of a millimetre thick, of which there is a dozen. If a plate thicker than this—a millimetre, for example—is used, the object will be seen less distinctly.

The series Nos. III. and VI. are constructed on a new principle, which renders the image more clear and distinct, and does not require any correction of the error which the common system introduces, owing to the different thicknesses of the plates of parallel glass which cover the object. This advantage is obtained by immersing in a drop of distilled water the last lower surface of the series III. and VI. This operation is performed in the following manner:—Let AB be a plate of glass, beneath which is the object C. With the point of a wet hair pencil place a drop of water D on the outer surface of the object-glass N. The drop will remain adhering to it when the series is put upon the microscope. By putting another drop C on the upper surface of the plate AB, and bringing the two drops together, a parallel plate of water will be placed between the object-glass and glass plate AB, the two surfaces between which it lies having been carefully cleaned to remove any grease which may prevent the water from adhering to the surfaces of the glass. It is supposed that the object C is under the plate AB, in contact with it, and dry; but it may be immersed in another fluid contained between two plates of glass.

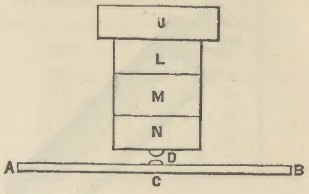

Fig. 62.

The series No. III. is used for all preparations preserved between plates of glass whose thickness is a millimetre, and may be also used for looking at objects immersed in water without the interposition of glass, such as aquatic plants, living infusoria, &c., &c.

The series No. VI. is used in the same manner as No. III., but being very powerful, it requires to be delicately managed. In this series the objects are placed on a piece of wood with a conical aperture in its centre, covered with a plate of glass one-fourth of a millimetre thick. Its profile is shown in the annexed figure, in which the object placed under C adheres to the glass, and the two drops of water D, E are united. It is necessary to mention, that as the equivalent focal distance of the series is 1·74 millimetre, the distance between the inferior lens and the object will be 0·4; and as the thickness of the plate of glass is one-fourth of a millimetre, or 0·25, the distance between the object-glass and the glass plate—that is, the thickness of the plate of water—will be only 0·15, a distance so small that the greatest care is necessary in finding the object, in order that the very thin glass may not be broken. If this does happen, we must substitute another of the same thickness, as measured by the spherometer.

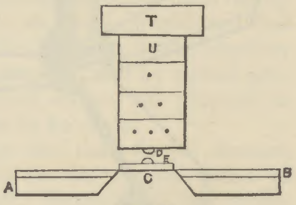

Fig. 63.

The series may also be used for any other thickness of glass less than 0·4, and down to zero, that is, when there is no glass over the object placed in water; but the effect is the best when the thickness of the glass is 0·25, as in this case the achromatism is perfect, even at the obliquity of $\frac{160^\circ}{2}=80^\circ$ with the optical axis, in which case we can see striæ or parallel lines whose distance is equal to $\frac{1}{6000}$th of a line, or $\frac{1}{72000}$ th of an inch.

If the object to be examined is in a fluid, such as the globules of blood, take a fragment of thin glass, a line or two in diameter, and place upon it the blood; it will, when put in contact with the plate on C, adhere to it by attraction, and retain its fluidity for many hours.

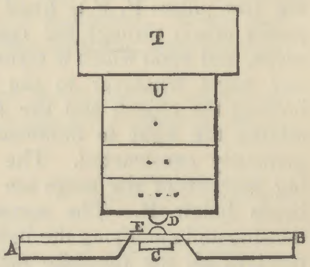

Fig. 64.

If we have occasion to look at any object with No. VI., when it is covered with very thin glass, or when it is in water, without the interposition of glass, the vision will be improved by removing the object-glass U, and leaving the series formed as in fig. 65.

---

[1] *Simples Preliminaires sur le Commentaire de la Notice du Meilleur Microscope Dioptrique, composé Achromatique du Professeur Amici.* Par M. Achille Brachet. Paris, 1856.

Professor Amici is of opinion that no object-glass hitherto constructed has a power as great as his series No. VI.; and considering the distance (about 0·4) which is left between the object-glass and the object, with an aperture of 160°, he thinks he has given a proof of the superiority of the principle he has invented.

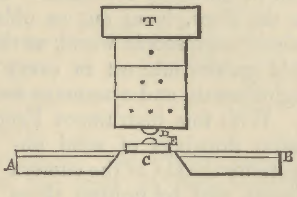

Fig. 65.

Professor Amici has not described the principle here referred to, nor mentioned the transparent substances of which his object-glasses are composed. He merely tells us that Nos. I. and II. are constructed with *four* different refractive and dispersive substances; Nos. III., IV., and V., with *five*; and No. VI. with *six* such substances.

In illuminating transparent objects Professor Amici uses only a single lens of flint-glass or rock-crystal, and maintains the strange opinion, contrary to theory as well as to the experience of every practical optician, that achromatic illumination is not necessary.

Professor Amici's Pocket Achromatic Microscope.

Amici's pocket achromatic microscope.

This portable microscope, which we have found very useful, is shown in the annexed figure, where AB is the

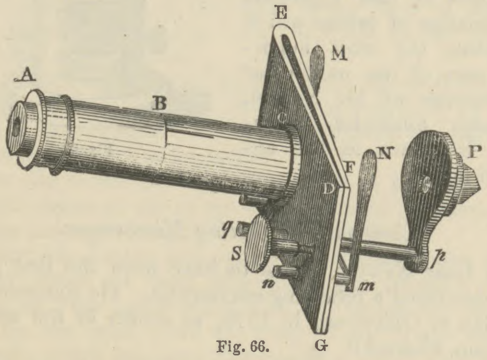

Fig. 66.

body of the microscope, 2½ inches long, sliding into the tube BC, $\frac{6}{10}$ths of an inch in diameter. The tube BC screws into the doubled plate of brass EDG, 2½ by 1½ inches, which acts as a spring, and may be opened or shut by the screw-nut S, for the purpose of moving the stage or object-holder MN*mn* towards or from the object-glass. This stage is a spring which holds the object-plate firm, by pressure; two pins *mn*, at the lower end of each arm N, M, sliding through holes in the plate EDG. When the object-plate is placed between MN and EF, and fixed by pressing the two plates together, the tube may be held horizontally, and distinct vision obtained by the motion of the body AB in the tube BC, and by the finer motion given by turning the screw-nut S, which shuts or opens the spring DEF, and places the object nearer or farther from the object-glass.

When it is desired to hold the microscope vertically, the object is illuminated by a rectangular prism P*p* attached to an arm *pq*, which slides in a little spring tube fixed in the plate EDG. The side of the prism next the object-glass is convex, for the purpose of condensing the rays which fall upon it.

The Microscopic Finder.

The microscopic finder.

Professor Amici has referred, in the description of his series No. VI., to the great difficulty of finding the object and placing it on the point of sight, and to the great danger of breaking the thin glass of the object-plate, owing to the distance between it and the object-glass being only 0·15 of a millimetre, or the $\frac{1}{170}$th part of an inch. A microscope, indeed, requires a finder as much as a telescope; but, in so far as we know, no person has attempted to give it one.[1]

We obviously cannot with advantage attach a second microscope to the principal one, as is done in the telescope; but the object may be gained in a simpler and more effective manner. When the observer is using his highest power both of object-glass and eye-piece, and loses sight, as he frequently does, of the object, or part of an object, under examination, he often finds it extremely difficult to bring it again into the field of view. Owing to the unsteadiness of almost every microscopic stand, he will seldom succeed by taking the lower powers, bringing the object into the centre of the field, and then replacing the higher powers with which he has been viewing it. But even if this method were successful, the labour which it imposes is intolerable. Sir David Brewster has therefore proposed the following method, and found it perfectly successful:—A concave lens of a greater focal length than the equivalent focal length of the object-glass is slipped upon the tube of the object-glass, or brought in front of it when withdrawn from the object. The magnifying power may be thus reduced in any required degree, the field of view enlarged, and the object brought into the centre of the field; the concave lens is then withdrawn, and when the instrument has been readjusted without any movement of its parts, the object will be found within the field.[2]

Various methods have been described for finding the object by means of scales, horizontal and vertical, applied to the slides; but however valuable these may be, the apparatus cannot be called a Microscopic Finder, which should form an integral part of the instrument.

Nachet's Multocular Microscopes.

Nachet's multocular microscopes.

M. Nachet, of whose microscopes we have already spoken in high terms, has adapted the microscope for anatomical demonstrations, so that two or three persons may see at the same time the result of microscopical dissections, by constructing two microscopes—a *double* and a *triple* one. By means of the first, one person can examine the progress and result of a dissection which is performed by another person; and by means of the second, two persons can enjoy this advantage.

In the microscope for two persons this result is obtained by placing above the object-glass a prism P (fig. 67), the section of which is an equilateral triangle. The rays from the object-glass, shown in the figure by the letter *ab*, *a′b′*, entering the lower face of the prism perpendicularly, the two halves of the pencil are reflected in opposite directions from the other faces of the prism at angles of 45°, and thus enter the two separate tubes, in each of which they form an image of the object. These images are in a certain sense erect; but in order to see them in exactly their natural position, in which case alone the ana-

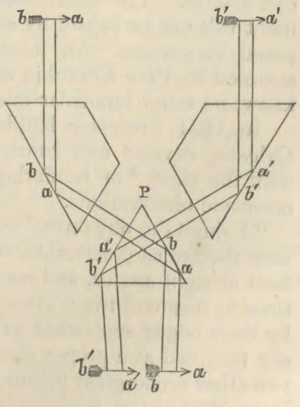

Fig. 67.

---

[1] See Brewster's *Treatise on Optics*, p. 486, edit. 1853.

[2] Opticians will adopt various modes of applying and withdrawing the concave lens.

tomist can use his scalpel, a prism is placed in each tube between the former prism and the eye-pieces, so that their planes of reflection are perpendicular to those of the other prisms. By this means the images are perfectly erect, and the demonstrator can proceed with his work without fatigue or difficulty. If the demonstrator and observer should have eyes of different focal lengths, the adjustment is effected by moving the eye-piece to or from the object-glass.

When the microscope is constructed for three persons, the pencil of rays from the object-glass is divided by three prisms placed in the same plane, and whose reflecting faces, if brought together, would form a triangular pyramid. The pencil from the object-glass is then divided and directed into three separate tubes, in which three prisms erect the three images, and place them in their natural position. This instrument is shown in the annexed figure.

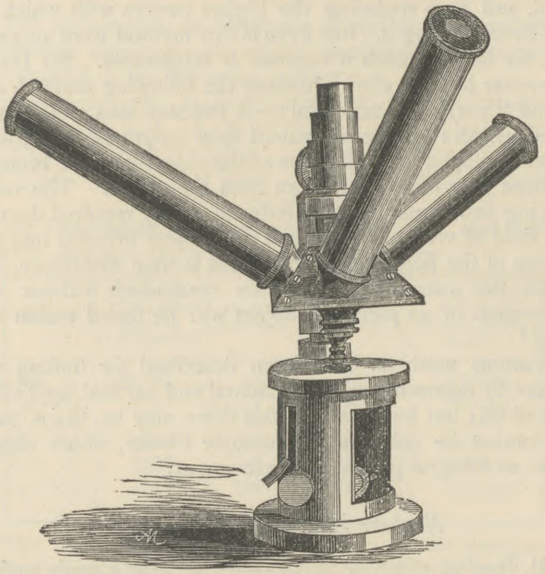

Fig. 68.

M. Nachet has also constructed the instrument for the use of *four* persons.[1]

Nachet's Binocular Microscope.

Nachet's binocular microscope.

The idea of a binocular microscope can hardly be called an invention, if constructed on the same principle as the binocular telescope with two object-glasses as well as two eye-glasses. The additional expense of such an instrument will not be repaid by any advantage which it is supposed to possess. An instrument of this kind was constructed by Père Cherubin about 1670; but in so far as we know, no other binocular microscope has been made.

In 1851 Professor Riddell, of the university of New Orleans, devised and constructed a binocular microscope with the view "of rendering both eyes serviceable in microscopic observations."

Professor Riddell's, of New Orleans.

"Behind the objective," says Professor Riddell, "and as near thereto as practicable, the light is equally divided and bent at right angles, and made to travel in opposite directions by means of two rectangular prisms which are in contact by their edges somewhat ground away; the reflected rays are received at a proper distance for binocular vision upon two other rectangular prisms, and again bent at right angles, being thus either completely inverted for an inverted microscope, or restored to their first direction for the direct microscope."

"With these instruments," the author adds, "the microscopic dissecting knife can be exactly guided. In looking at microscopic animal tissues, the single eye may perhaps behold a confused amorphous or nebulous mass, which the pair of eyes instantly shapes into delicate superimposed membranes with intervening spaces, the thickness of which can be correctly estimated. Blood corpuscles, usually seen as flat discs, loom out as oblate spheroids. In brief, the whole microscopic world, as thus displayed, acquires a tenfold greater interest in every phase, exhibiting in a new light beauty and symmetry indescribable."

With this instrument Professor Riddell obtained dissimilar drawings of solid objects by the aid of the camera lucida, and by uniting them in the stereoscope he brought them out in their natural relief.

When the two tubes of M. Nachet's double microscope are placed vertically and parallel to one another, and are brought so near to the central prism that their distance is equal to 2½ inches, the distance between the two eyes, the instrument becomes a binocular one, similar to that of Professor Riddell, to whom we must ascribe the invention of that ingenious combination of prisms which constitute the most important part of the multocular microscopes of M. Nachet. Nachet's binocular instrument is shown in the annexed figure.

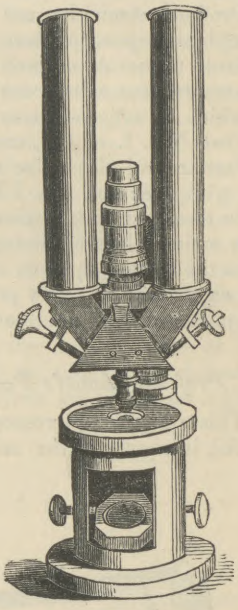

Fig. 69.

Compound Reflecting Microscopes.

Compound reflecting microscope.

Sir Isaac Newton seems to have been the first person who described a reflecting microscope. He communicated his plan to Oldenburg in 1679, as shown in the annexed diagram, where AB is a concave speculum, O the object, F the place where an image of it is formed, and CD an eye-glass for magnifying it. In another letter to Oldenburg, dated 11th July of the same year, he refers to another improvement on microscopes, which is to "illuminate the object in a darkened room, with *the light of any convenient colour, not too much compounded;* for by that means the microscope will, with distinctness, have a deeper charge and larger aperture, especially if its construction be such as I may hereafter describe." We are not aware that this idea was ever further developed by its author.[1]

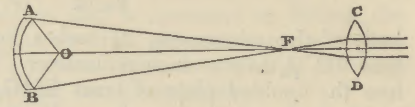

Fig. 70.

Mr Potter's Improvement upon it.

Potter's improvement.

Mr Potter[2] has recently proposed "a new construction of Sir Isaac Newton's microscope," principally with the view of removing the difficulty of illuminating the object. His first construction was for opaque objects; and in order to illuminate them, he cut a large circular aperture *abc* in the tube, between the object and the speculum; but the light which fell on the sides of the tube occasioned a good deal of indistinctness in the field of view. This defect, however, was completely removed by lining all the lower

---

[1] The use of Multocular instruments was proposed by Sir David Brewster in 1822. (See *Edinburgh Philosophical Journal* 1822, vol. vii., p. 327; and Coddington's *Elementary Treatise on Optics*, p. 133.)

[1] Brewster's *Memoirs of the Life, Writings, and Discoveries of Sir Isaac Newton*, vol. i., p. 242.

[2] *Edinburgh Journal of Science*, Jan. 1832, No. 11, p. 61.

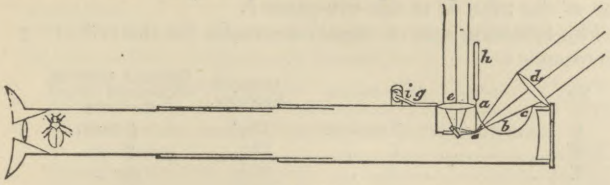

Fig. 71.

parts of the tube with black velvet. Mr Potter found it advantageous to concentrate the light on those objects that required it by a large lens at *d*. For transparent objects he applied a lens, as shown at *e*. Its convergent beam is reflected on the object placed at the end of the wire *ah*, by means of a small diagonal mirror in the axis of the tube, and inclined to this axis 45°. By this means a very strong light may be thrown through and past the object. By means of movable caps to cover the opening *abc*, and the lens *e*, all interference of foreign light is prevented; and without altering the position of the object, both methods of illumination may be successively adopted. Mr Potter attaches his objects to thin brass wires *a*, stuck into wooden handles *h*, and these pins pass through a slit cut into a small piece of cork attached to the sliding-piece *g*, which at the same time carries the lens *e* and the plane mirror, the whole of which are moved by the small arm connected to the crank, as at *i*. The adjustment of the object to the focus of the mirror is effected by turning a nut attached to the pivot on which the crank is fixed.

In the microscope used by Mr Potter he employs a speculum 1 inch in diameter, with a focal length of $1\frac{1}{2}$ inch; and he generally makes the distance between the object and the image from 12 to 14 inches.

The size of the speculum allows him to place an insect or other object of $\frac{1}{4}$th of an inch square in the tube, without any perceptible bad effect resulting from it.

When Mr Potter had adjusted the illuminators in the manner which we shall afterwards have occasion to describe, he "saw quite easily what are called the diagonal lines on the scale from the wing of the white cabbage butterfly, which has been proposed as a difficult test-object by Dr Goring; and it is such a one as those who have only seen the stronger longitudinal striæ or scales from the wings of moths and butterflies have little idea of." Mr Potter was also able to resolve a delicate blue tissue in the web of a spider called the *Clubiona atrox*, into its component fibres.

The great size of speculum used by Mr Potter arises from his being able to give all specula a true ellipsoidal figure, so as to remove the spherical aberration.[1] We have in our possession two of Mr Potter's instruments, one of them with a *spherical* and the other with an *ellipsoidal* mirror. The quantity of light and the defining power of the latter are unusual in such instruments.

Amici's Reflecting Microscope.

Amici's reflecting microscope.

This instrument is shown in section in figure 72, where *a* is a small ellipsoidal speculum about 1 inch in diameter, and $2\frac{6}{10}$ths in focal length. The object is placed on a stage *mn*, below the tube of the microscope, and the rays which issue from it fall upon a small speculum *b* inclined 45° to the axis of the ellipsoidal speculum, in the same manner as if the object had been placed in the tube as far to the right hand of the small mirror as it is below it. An image of this object is of course formed in the other focus of the ellipsoidal speculum, and may be viewed by a single or double eye-piece, as in other compound miscroscopes. Professor Amici, however, uses a negative eye-piece, consisting of two plano-convex lenses A, B.

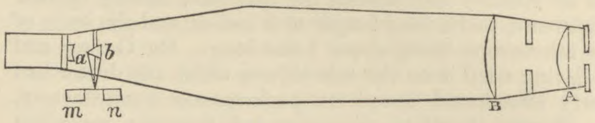

Fig. 72.

The new and peculiar part of this instrument is the use of the small speculum, which allows the object to be placed without the tube, and illuminated with the utmost facility.

Amici's Second Reflecting Microscope.

Amici's second reflecting microscope.

At the end of his Memoir, in the *Acts of the Italian Society*, on his first reflecting microscope, the author informs us that he had constructed another catadioptric one in 1813, which was more efficacious, and in which the aperture of the concave speculum was six lines, and its focal length eight lines, with an angular aperture of 44°. This form of the instrument is shown in the annexed figure, in which AB is the concave speculum, CD the plane speculum inclined 45° to the optic axis, and *m* a hole in its centre through which the rays from the object F pass to the speculum AB, from which they are converged upon CD and reflected to a focus at *f*, where they are received by the eye-piece at E. By polishing the speculum CD on the outside, opaque objects might be illuminated by the light which it may be made to reflect.

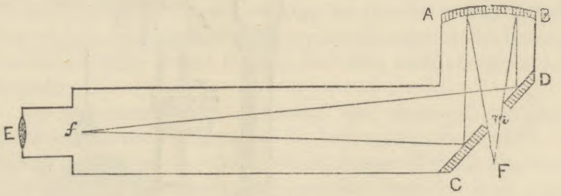

Fig. 73.

M. Vicenzo Amici, the son of the professor, has proposed to modify this construction, as shown in the annexed figure, where ABDC is a rectangular parallelopiped of glass, the curved surface of which, AB, is spherical or elliptical, and well polished and silvered. On the middle of CD a small cylinder of glass P is cemented with Canada balsam, the outer surface of which is concave, having its centre at F. The rays from the object at F enter the cylinder without refraction, and after reflection from AB and CD, as in the preceding figure, are conveyed to a focus at *f*, as in fig. 73.

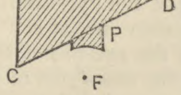

Fig. 74.

Another form of this instrument which we have seen, is shown in the annexed figure, where AB DC is a cylinder of

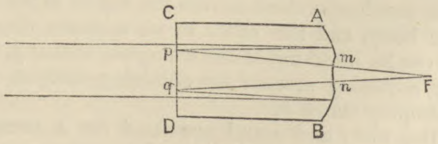

Fig. 75.

glass whose base AB is silvered, and has an unsilvered portion *mn* with its centre of concavity at F. The rays from the object at F pass without refraction to CD, part of which, *pq*, is silvered; and being reflected again from AB, they pass through the unsilvered portion Cp, Dq to their convergence as before at f, fig. 73, and enter the eye-piece E.

---

[1] The process by which he does this is fully described in the *Edinburgh Journal of Science*, No. 12, p. 228, new series.

Dr Goring's Improved Reflecting Microscope of Amici.

Goring's improved reflecting microscope of Amici.

Mr Cuthbert, an ingenious London optician, constructed one of Amici's instruments, the speculum having $1\frac{1}{2}$ inch of aperture, and a focal length of 3 inches, and the body of the microscope being about 1 foot long. Dr Goring and he having tried it on the test-objects which the doctor had newly introduced, found its performance unsatisfactory. Dr Goring therefore recommended that the speculum should be only half an inch in focal length, and the body 4 or 5 inches long. Mr Cuthbert accordingly finished a pair of metals $\frac{6}{10}$ths of an inch in focal length, and only $\frac{3}{10}$ths in diameter. Their excellent performance induced Dr Goring and Mr Pritchard to turn their attention to the improvement of the instrument; and, as Mr Cuthbert[1] has been able to execute perfectly ellipsoidal metals, having an aperture equal to their sidereal focal length, or 54°, and of so small a diameter as $\frac{3}{10}$ths of an inch, they have produced an instrument of a superior kind.

This microscope is represented in fig. 76, where it is seen to rest on a tubular pillar, its body being held by a split socket. The pillar is screwed on a solid cruciform stand, to one of the legs of which an adjusting screw is applied, to produce steadiness. The body moves round a cradle-joint at the top of the pillar, and may be firmly fixed at any degree of inclination. The body of the microscope is shown at a, the eye-tube at d, and the eye-piece, which is a Huygenian one, at e. The focal lengths of the interior glasses of the eye-pieces, of which there are usually three, are $\frac{3}{4}$ths, $\frac{3}{8}$ths, and $\frac{3}{16}$ths of an inch. The tube containing the specula is shown at bc. The triangular bar which carries the illuminating reflector, the stage, and the apparatus for adjustment, is shown at f, and is soldered to the neck of the body. The mirror k is plane on one side, and has a plaster of Paris surface on the other. The stage l is a combination of rack and screw work, wrought by two concentric milled heads at m. The smallest of these moves the object in the direction of the body, and the other in an opposite direction. The stage can be lifted out of the triangular socket g, which carries the adjusting screw i for obtaining distinct vision, and the clamping screw h.

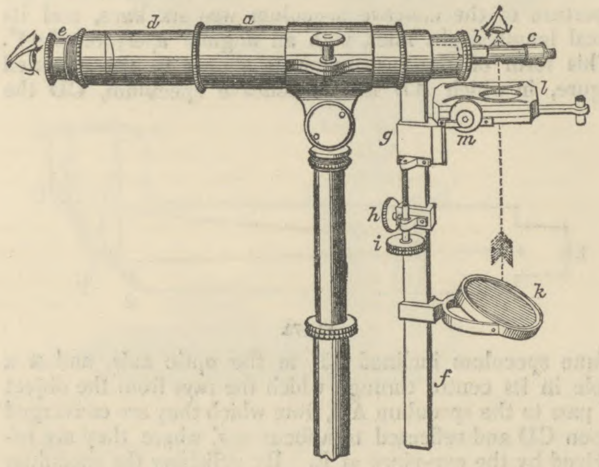

Fig. 76.

When the body and stand are used for a compound achromatic microscope, a tube containing the compound object-glasses below it, increasing in diameter from the object, is screwed into the body at b, in place of the tube bc. A rectangular prism, shown in dotted lines, reflects the pencils that pass through the object-glasses along the axis of the tube bc to the eye-piece e.

The following sets of metals are made for the reflecting microscope:—

No.	Solar Focus.	Angle of Aperture.	Distance between Object and side of the Tube.
1	2 inches.	$13\frac{3}{4}$°	$\frac{1}{2}$ inch.
2	1 „	$18\frac{1}{3}$	$\frac{1}{5}$ „
3	$\frac{6}{10}$ „	$27\frac{1}{2}$	$\frac{1}{10}$ „
4	$\frac{4}{10}$ „	$36\frac{1}{2}$	$\frac{1}{20}$ „
5	$\frac{3}{10}$ „	$41\frac{1}{4}$	almost 0 „
6	$\frac{3}{10}$ „	55	

The metals Nos. 1, 2, and 3 are those most useful for examining opaque objects. No. 3 is excellent also for all kinds of transparent objects. No. 5 can scarcely be used for opaque objects, as it leaves almost no space between the tube and the object for allowing the latter to be illuminated. No. 6 cannot be used at all for opaque objects, but is especially intended for the most difficult class of transparent test-objects.

Dr Smith's Reflecting Microscope.

Dr Smith's reflecting micro-scope.

Having constructed one of Sir Isaac Newton's microscopes in 1738, Dr Smith of Cambridge observed that the colours of objects were much more beautiful and natural than in refracting microscopes. He found that objects were very distinct and sufficiently light when the microscope had the following dimensions:—

Focal length of the speculum	$2\frac{1}{3}$	inches.
Diameter of ditto	1	„
Focal length of the plano-convex eye-glass	$2\frac{1}{3}$	„
Ratio of the distance of the object from the focus of the speculum to the focal distance of the speculum	1 to 19	„

Finding that, in order to obtain a high magnifying power, the speculum required to be very concave and small, he contrived another microscope with two reflecting spherical surfaces of any size, but so related to each other that the second reflection should correct the aberration of the first.

Dr Smith's microscope is shown in fig. 77, where AA is a concave spherical speculum, having its polished surface inwards. The rays from an object o placed in the slider mn will be reflected from the concave speculum AA upon the convex CC, and will have a distinct and magnified image of it formed before the convex eye-glass E, by which it will be magnified still more. This instrument, in short, is nothing more than the Cassegrainian telescope converted into a microscope, with this difference only, that in the telescope distinct vision is obtained by moving the convex mirror, whereas in the microscope it is obtained by a motion of the eye-glass. Dr Smith constructed one of these microscopes, which he found to perform "nearly as well in all respects as the very best refracting micro-

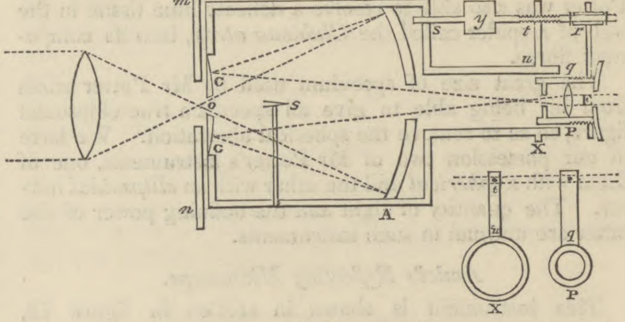

Fig. 77.

---

[1] The process by which Mr Cuthbert was able to accomplish this difficult task is similar to that by which he gave truly hyperbolic figures to the mirrors of small Gregorian telescopes, with three inches of aperture and five inches of focal length.

scopes;" and the writer of this article has one of them now before him, which performs wonderfully well, though both the specula have their polish considerably injured. It shows the lines on some of the test-objects with very considerable sharpness.

The following are the dimensions, &c., of Dr Smith's reflecting mirror, as given by himself:—

Focal length of both specula	1·0000
Distance of the centres of both specula	1·6558
Distance of the image from the centre of the concave speculum	1·1337
Focal length of the eye-glass	0·1407
Distance of the eye behind the eye-glass	0·1479
Diameter of the eye-hole	0·0190
Distance of the object from the centre of the convex speculum	0·0626
Length of the concave speculum	15° 49′
Arch of the convex speculum	4° 50′ 49″
Distance of the stop *s* from the object	0·4545
Diameter of the stop *s*	0·038
Diameter of the hole in the concave speculum	0·143
Diameter of the hole in the convex speculum	0·049
Magnifying power, the focal length, &c., of the eye being 8 inches	300 times.

The dimensions of the instrument in our possession is very different:—

Diameter of the concave speculum	2·17	inches.
Focal length	2·17	"
Diameter of the hole in it	0·376	"
Diameter of the convex speculum	1·03	"
Diameter of hole in it	0·10	"
Diameter of stop	0·13	"
Distance of stop from hole in convex speculum	0·67	"
Distance of specula	3·80	"
Focal length of doubly-convex eye-glass	0·17	"

Sir David Brewster's Reflecting Microscope.

Sir David Brewster's reflecting microscope.

Notwithstanding the excellence of Professor Amici's microscope, we are convinced that it is not the peculiarity in its construction which constitutes it a different instrument from Newton's. This peculiarity is a disadvantage, and we consider the instrument as recommended solely by its possessing an ellipsoidal speculum with a large angle of aperture. The only advantage which can be ascribed to the instrument is a more convenient mode of illumination; but this advantage, whatever be its amount, is purchased at great sacrifices. 1. The whole instrument is an awkward-looking piece of mechanism, with its triangular bar and all its appendages. 2. It cannot be used in the vertical position, which we consider a defect. 3. By the use of the small reflecting speculum, *one-half of the whole light is lost.* 4. With small concave specula, such as those $\frac{3}{10}$ths of an inch in diameter, opaque objects cannot be illuminated.

The construction which has been proposed by Sir David Brewster to remedy most of these defects is shown in the annexed figure, where ABCE is the body of the instrument, which screws at its lower end C into the horizontal projecting arm DE of the stand, either of the achromatic microscope or the single microscope; so that we get rid of all trouble about the objects placed at *mn*, and their mode of illumination, as everything concerning them is the same as in other microscopes. This is certainly a great advantage; for neither naturalists nor amateurs are disposed to purchase and use two sets of the extensive apparatus necessary for holding, moving, and illuminating microscopic objects. At the lower end C of the body, where the object-glasses of the common compound microscope and the achromatic object-lenses are placed, is a small tube *abcd*, at the lower end of which is fixed the concave speculum *cd*, perforated with a very small hole at its centre, and with its concave surface upwards. Above it is the plane speculum *s*, fixed by a slender arm to the side *bd* of the small tube, and having its diameter a little greater than the perforation in the speculum *cd*. This little tube *abcd* screws into the arm DE, as if it were a microscopic doublet or single lens; and the body ABC may either screw upon the outside of this tube, or, what is better, upon a stronger piece of tube forming part of the arm DE. A concave illuminating reflector *kh*, for opaque objects, may screw on the back of the speculum *cd*, or the speculum itself may be made thick, and ground and polished on both sides, so that while one side illuminates the objects, the other magnifies them.

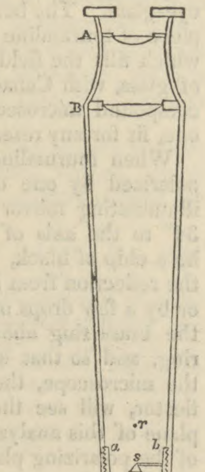

Fig. 78.

It is obvious that rays proceeding from an object at *mn* will be reflected from the plane speculum *s*, upon the concave speculum *cd*, exactly as if the objects were placed at *r*, as far above *s* as *mn* is below it, and an image of it would be formed in the other focus of the ellipsoid, *r* being the one focus, if the rays were not intercepted by the eye-piece AB, by which the image is farther magnified. By this mode of construction, the whole of the reflecting microscope, in place of having a separate stand and separate apparatus costing a large sum of money, is comprehended in the little tube *abcd*, and may be considered as a reflecting object-speculum, forming part of a general microscope, furnished with single lenses, doublets, and compound achromatics.

By the means now described are removed all the defects which we enumerated as belonging to Amici's combination, except the *third*, which is one of such importance that it is of consequence to consider how far it is capable of being remedied. Sir David Brewster has proposed to get rid of this loss of light by placing the object *mn*, as in Amici's instrument, outside of the tube, but inclined to its axis, and refracting its rays upon the speculum *cd*, by means of an achromatic prism *e*, in a manner analogous to his method of producing a similar effect in the Newtonian telescope.[1] The faces of this prism are equally inclined to the axis of the microscope and the axis of the pencil issuing from the point of the object under examination. As the prisms of plate and flint glass which compose *e* are cemented by a substance of nearly the same refractive power, there will be no farther loss of light than what is reflected at the two surfaces. A socket may be placed at D for holding an illuminating lens, or any other apparatus for opaque objects. But in order to avoid the incumbrance and expense of separate stands and apparatus for this as well as Amici's form of the instrument, we would propose that a strong piece of tube should be inserted in the opening, above *mn*, to screw into the upper side of the projecting arm, as shown in fig. 78; or a solid screw attached to the upper side of the tube, a little to the right hand of C, and above the opening, might screw into the lower end of the projecting arm DE. In these cases the object at *mn* will be placed on the ordinary stage, and illuminated in the common manner; but it will

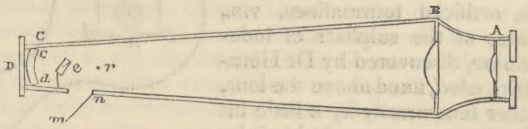

Fig. 79.

---

[1] *Treatise on Optics*, edit. 1853, p. 494. (See also article OPTICS.)

be necessary to have a counterpoise at D, to balance the weight of the body ABC.

Those who are acquainted with the principle of the Cassegrainian telescope, and of Dr Smith's compound microscope, will readily see that the reflecting microscope, with the perforated speculum, may be converted into a more compound reflector, analogous to Dr Smith's, by making the little speculum *s* (fig. 78) convex, the figures of *d* and *s* being made hyperboloids.

CHAPTER IV.

ON POLARIZING MICROSCOPES.

Polarizing microscopes.

The use of polarizing microscopes is to observe and exhibit structures and phenomena which are invisible with the common microscope.

These microscopes were first used by Sir David Brewster, upwards of forty years ago, in his experiments on the structure of *Apophyllite*, *Amethyst*, and *Analcime*, and other mineral bodies; and also in his examination of various animal and vegetable organizations. In employing the single microscope for these purposes, he cemented plates of agate and tourmaline with Canada balsam to the plane side of a plano-convex lens,[1] and thus analyzed the polarized light, by means of which the peculiar structure was rendered visible. In other cases he preferred for the analyzer an achromatized prism of calcareous spar, in which one of the images only was visible,[2] or one in which he had extinguished one of the images by a particular process,[3] which he has described.

When considerable magnifying power was necessary, or when the structure was to be drawn by an artist, he used the compound microscope, in which the light was polarized and analyzed by various means, accommodated to the nature of the structure to be examined.

Single Polarizing Microscope.

Single polarizing microscope.

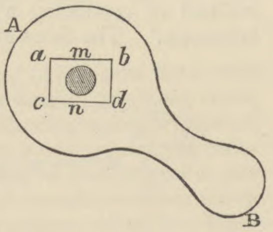

Fig. 80.

The simplest and most useful polarizing microscope is a hand one, such as AB, containing a convex lens *mn*. It is to be held in the right hand, as in fig. 80, and a plate of light reddish-brown tourmaline (or of the artificial tourmalines, viz., plates of the sulphate of iodoquinine, discovered by Dr Herapath), *abcd*, fixed above the lens, either temporarily by a little bit of soft wax, or cemented to it by Canada balsam. The last method has the advantage of preventing the loss of light by reflection from the first surface of the tourmaline, and removing any imperfection of polish that it may have. It would be advisable, indeed, to construct the microscope with two plano-convex lenses, and to place the tourmaline between them, joining it to both by Canada balsam, so that there would be no loss of light or imperfection of vision produced by the surfaces of the tourmaline.

The position of the plate *abcd* should be such, that when it is held as in the figure, the polarized light, which is to illuminate the object, should be unable to pass through it. This polarized light may be obtained either from light reflected at an angle of 56° from a plate of black glass, or from a bundle of plates of crown or flint glass, or mica (properly placed), or by transmission through a bundle of such plates, or from one of the images of a rhomb of calcareous spar.

When this light is obtained, the observer holds the microscope AB in his right hand, and examines through it the object in his left hand, turning AB slightly round, so as to bring it into the position in which it refuses to transmit any of the polarized light which passes through the object, and towards which, of course, the observer's eye is directed. When this is done, the peculiar structure of the object will depolarize or alter the polarization of part of the incident light; and this light, being no longer polarized, will pass through the plate of tourmaline to the eye, and exhibit on a dark ground, and in luminous and often beautifully coloured lines, the structure of the body.

If the body is transparent, and not flat, it may be advantageously placed in a little glass trough containing water or oil, or a fluid of the same refracting power as the body, so that the polarized light may be made to pass through it in all directions, and exhibit its entire structure.[1]

When the shape and surface of the body present no difficulties, the best method is to stick it by a transparent cement, or simply to place it upon a plate of tourmaline held in the left hand. The observer thus carries the polarizer and the object in his left hand, and in his right the magnifier and the analyzer.

When a second plate of tourmaline is not at hand, the object may be placed upon a rhomb of calcareous spar, above one of the images which that rhomb forms of a circular aperture on its lower or farther side, the light of the other image being stopped out by a piece of wafer.

When a small lens is needed, and strong light can be commanded, the magnifier and the analyzer may be united in one by making the magnifying lens of tourmaline.

When microscopic doublets or triplets are used, the plate of tourmaline may be placed between two of the lenses, and cemented to the plane side of any of the plano-convex lenses.

Compound Polarizing Microscope.

Compound polarizing microscope.

The simplest form of the compound polarizing microscope is to make the eye-glass into an analyzer, in any of the ways described for a single lens, the proper position of the plate of tourmaline being readily found by the motion of unscrewing the eye-glass. The polarizer is also a plate of tourmaline, laid on the slider-holder, and having the object laid upon its upper surface. If the polarizer is laid down in any accidental position, the proper position of the analyzer will be found by a slight unscrewing of the eye-glass. The best method is to place the small polarizing piece of tourmaline (which need not be larger than an object which fills the field of the microscope) between two pieces of glass, with Canada balsam interspersed. In this way a compound microscope may be converted into a polarizing one, fit for any researches, at the expense of a few shillings.

When tourmaline cannot be obtained, the light may be polarized by one or more plates of glass, placed on the illuminating mirror so that their surface may be inclined 34° to the axis of the microscope, and the analyzer may be a chip of black, blue, or any other kind of glass, having the reflection from its second surface removed by grinding, or by a few drops of black wax. If this chip is placed on the brass ring above the eye-glass so as to turn with that ring, and so that its surface is inclined 34° to the axis of the microscope, the observer, by looking into a little reflector, will see the object under examination when the plane of this analyzing plate is at right angles to the plane of the polarizing plate.

When the compound microscope is fitted up with Nicol's prisms,[1] and for the express purpose of exhibiting structures by polarized light,—which we believe was first done by Henry Fox Talbot, Esq.,—one of these prisms is fixed between the illuminating mirror and the slider-holder, to polarize the light, and another similar prism is placed above the eye-glass to analyze it. The last prism, however, is very inconvenient, as it contracts unpleasantly the field of view; and it is therefore necessary to substitute for it a plate of tourmaline, as already described; or, what is much better, as Sir David Brewster suggested, is to screw the analyzer into the lower end of the body of the microscope, immediately behind the object-glass.

---

[1] *Edinburgh Transactions*, vol. ix., p. 141, note.

[2] *Ibid.*, vol. viii., p. 371.

[3] *Ibid.*, vol. ix., p. 141, note.

[1] It was in this way, by cementing fragments of crystals of analcime to a piece of wood, and holding the mineral in a small trough of almond oil, that Sir David Brewster detected the extraordinary structure of that substance.

The expense of constructing a Nicol's prism, the difficulty of making the one next the eye perfectly colourless, and the risk of a change taking place in the cement which unites the two parts of it, renders it desirable to have a simple, a cheap, and a durable substitute for it. The polarizer which has been employed by Sir David Brewster in his experiments on elliptical polarization, and on the action of crystallized surfaces upon light, where tourmaline could not be used owing to its colour, was a single rhomb of calcareous spar, with its natural surfaces, having thin plates of colourless glass cemented to them by Canada balsam, which removes any imperfection of surface, and at the same time protects the surfaces from any accidental injury, or from the deterioration of the polish, which arises from frequently cleaning them. This rhomb ABCD had a circular aperture *a*, placed upon its lower surface, and of such a diameter that it just separated the two images *b*, *c*, seen from above. This rhomb may be placed either beneath the slider-holder or upon it, and by sticking a piece of wafer upon any one of the images *b*, *c*, and leaving the other exposed, and placed exactly beneath the aperture of the object-glass, we have the most perfect polarizer that can be constructed. The object to be examined may, if necessary, be laid above the circle *b*.

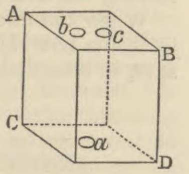

Fig. 81.

By this construction of the polarizer we obtain another advantage; we may so adjust the size and distance of the pencils *b*, *c* that both of them may be included in the field of view, and by placing one of the objects to be examined above *b*, and another of the same above *c*, we may observe them at the same instant under their opposite colours, if the depolarized light is coloured, which it generally is.[2]

These rhombs may be made even out of rhombs crossed with veins, which multiply the images, because the multiplied images are at too great a distance from the principal ones to be visible. This is a peculiar advantage, as it is often very difficult to get good pieces of spar free from this composite structure.

This method of constructing a polarizing rhomb enables us to take advantage of the two lateral images, which accompany the two principal images in crystals crossed by one vein. These lateral images, shown at *m*, *n*, are distant from one another, and from the principal images *b*, *c*; and as each of them consists of light wholly polarized in one plane, we have only to bring one of them under the aperture of the object-glass to have an admirable polarizer, without being at the trouble of stopping out any of the other pencils.

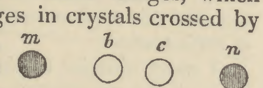

Fig. 82.

The images *m*, *n* are much less bright than the principal ones *b*, *c*; but this is really of no consequence, as we can obtain any degree of light we choose in the microscope, either by the condensation of artificial, or the use of solar light.

When the vein by which these lateral images are formed is above a certain thickness, their light is white; but they are most frequently coloured; and the observer who understands the cause of these colours may make this coloured pencil of great service in microscopical observations. If he uses a rhomb which gives to *m* a green of the second order, it will contain none of the extreme violet and blue rays, and none of the extreme red; so that it affords a more homogeneous pencil than if it were white light, and thus improves the performance of a microscope that is not achromatic.

He may in like manner use tints which give the red extremity or the blue extremity of the spectrum, or, even when the tint is divisible by the prism into periodical bands, he may absorb the least luminous of these bands, and create a homogeneous pencil of polarized light of inestimable value, in particular researches and with particular microscopes.

But, independent of these advantages, the method of using a lateral pencil *m* has the great advantage of not requiring much thickness in the rhomb. A Nicol's prism, and a rhomb in which the two principal images *b*, *c* are used, must be about an inch thick in order to be efficacious; but the distances *mn* or *mb* are the same at all thicknesses, so that we can use rhombs for this purpose which are quite useless for any other.

It is scarcely necessary to add, that similar rhombs in which either the principal images *b*, *c*, or the lateral ones *m*, *n*, are used, may also be employed for the analyzer. For this purpose a thin plate, in which *m* or *n* is white, is peculiarly applicable, as it enables us to see at once the whole field of the microscope.[1]

CHAPTER V.

ON SOLAR AND OXYHYDROGEN MICROSCOPES.

Solar and oxyhydrogen microscopes.

The solar microscope is a well-known popular instrument, for exhibiting on a white screen, in a dark chamber, magnified images of minute objects, illuminated by the condensed light of the sun. As the sun cannot often be commanded in our climate, this instrument may be considered as having fallen into disuse: but the discovery of the lime-ball light by Mr Drummond amply supplies the place of the great luminary, in so far as the microscope is concerned. The instrument has accordingly been revived under the name of the oxyhydrogen microscope, and is now a favourite public exhibition.

The solar microscope was proposed by Dr Lieberkhun in 1738; and early in 1739, when he paid a visit to London, he exhibited an instrument of his own construction to several members of the Royal Society, and to Mr Cuff, Mr Adams, and other London opticians.

This microscope is nothing more than a convex lens, in front of which, a little farther from it than its principal focus, is placed a microscopic object, the rays of the sun being reflected in a horizontal line, and condensed by a lens. This will be understood from figure 83, where CD is the convex lens, E the object placed before it, and AB the illuminating condenser. An enlarged image of E will be formed on the right hand of CD, upon a wall or screen, and the size of the enlarged image will be to that of the object as the distance of CD from the screen or wall is to CE, the distance of the object from the lens. Dr

---

[1] This ingenious prism, consisting of two pieces of calcareous spar cemented together so as to transmit only one image, derives its name from its inventor, the late William Nicol, Esq., of Edinburgh, and is of great use in all experiments on the polarization of light, particularly where the colour of tourmaline would interfere with the phenomena to be observed.

[2] The most interesting objects for the polarizing microscope are minute crystallizations of all kinds, but particularly composite minerals, such as apophyllite, amethyst, analcime, and a large class of crystals to which the name of "circular" has been given, and an account of which will be found in a paper in the *Edinburgh Transactions*, vol. xx., p. 60, 1853.

[1] We have recently (May 1857) seen these methods of using rhombs in place of Nicol's prisms successfully adopted by Professor Amici in his achromatic microscopes, and we are satisfied that those who have once employed them, either for the purposes of research or amusement, will never use any other pieces of apparatus.

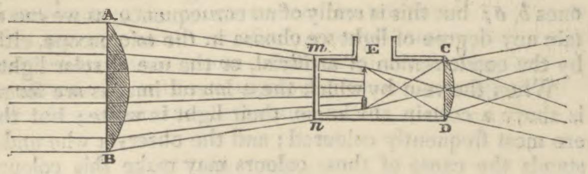

Fig. 83.

Lieberkhun's solar microscope had no mirror for reflecting the sun's rays into the tube, so that it could only be used for a few hours, when the tube could be conveniently pointed to the sun. The improvement of adding a mirror was made by Mr Cuff, who constructed the instrument in a very superior manner.[1] Dr Lieberkhun subsequently fitted up the solar microscope to show opaque objects; but the method which he employed is not known. Since the time of Mr Cuff the solar microscope has undergone many improvements. Mr Benjamin Martin added greatly to the value of this instrument by fitting it up both for opaque and transparent objects, in the manner shown in figs. 84 and 85. In fig. 84 it is shown as fitted up for opaque objects. The body ABCDEF has the part ABCD of a conical, and the part CDEF of a tubular form. A large convex lens, corresponding with AB in fig. 83, is placed at AB, at the end of the conical tube ABCD, which screws into the square plate QR, which is fastened to a window-shutter opposite a hole of at least the size of the lens AB, by means of the screws *e, d.* Upon the square plate QR there is a movable circular plate *abc.* To this circular plate is attached the silvered glass mirror NOP, placed in a brass frame, which moves round a joint PP, and which may be placed in any position with regard to the sun, so as to reflect his rays into the tube ABCD by means of rackwork and pinions at Q and R. The pinion Q moves the circular plate *abc* (to which the mirror NOP is fixed) in a plane perpendicular to the horizon, while the nut R gives it a motion in an opposite plane. The light introduced by this mirror falls upon the lens AB, which throws it in a condensed state upon any object in the tube. But before it reaches the opaque object it is received by a mirror M, placed in the box HILX, which reflects the condensed light back upon the face of the object E (fig. 83) next to the lens CD. This mirror is adjusted to a proper angle by the screw S.

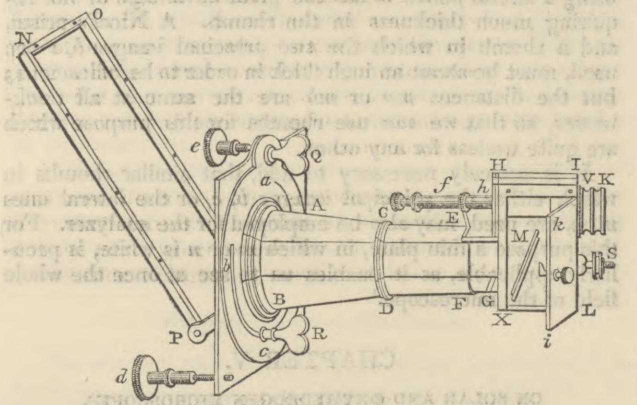

Fig. 84.

Above the body ABEF is seen the part *f* VK, which carries the sliders or objects, and the object-glass or lens CD (fig. 83). The tube K slides within the tube V, and V again slides into the box HILX. These tubes carry each a magnifying lens. The inner tube K is sometimes taken out of the other V, seen within the box, and used alone. The sliders and objects are introduced into a slit or opening at H. The brass plate to the left of H is fixed to a tube *h*, by means of a spiral wire within the tube, which presses the plate against the side of the box HILX, so that the sliders, when placed in the opening, are pressed against the side of the box.

In using this microscope, the sun's rays are first made to pass along the tube ABCD by the nuts Q and R. The box for opaque objects, HILX, is then slid by its tube G into the tube EF. The slider containing the object, having its face to be examined turned to the right hand, is then pushed into the opening at H, till the object is in the centre of the tubes V, K. The condensed light falling upon the mirror M is then thrown back on the face of the object of the slider, and the door *ki* shut. Upon a white paper screen or cloth, from 4 to 8 feet square, and placed at the distance of from 6 to 10 feet from the window, the observer, in the room made thoroughly dark, will see on the screen a magnified representation of the object, which may be rendered distinct at different distances of the screen, by pulling out or pushing in the tubes V, K containing the convex lenses. As the sun is constantly moving, its rays must be kept in the axis of the tubes by now and then turning the nuts Q and R.

When the microscope is to be used for transparent objects, the box HILX, with its tube G and other appendages, is removed, and the apparatus shown in fig. 85 substituted for it. This is done by sliding the tube Y of fig. 85 into the tube EF of fig. 84. A slider containing the magnifying lens is then slipped through the opening at *n*, and a second condenser may or may not be inserted in the opening at *h*. The slider with the object is then placed in the opening *m*, and when its magnified picture falls upon the screen, it is adjusted to distinctness by turning the milled nut O.

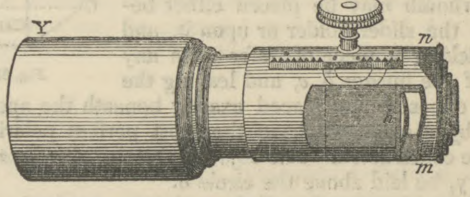

Fig. 85.

The picture formed by a solar microscope being in Dr Robison's opinion "generally so indistinct that it is fit only for amusing ladies," he proposed to use as an object-glass the achromatic eye-piece of four lenses, constructed by Mr Ramsden for telescopes. Having made the experiment, he found the image "perfectly sharp," and recommended this application "to the artists, as a valuable article of their trade."

New solar microscope.

A much simpler method, however, of correcting the defects of the microscope, is to use compound achromatic lenses, which were first suggested by Mr Benjamin Martin.

Another mode of improving the instrument was proposed in 1812 by Sir David Brewster,[1] who has described a new solar microscope which can be rendered achromatic. The method of doing this is shown in the diagram (fig. 83), where AB is the condensing lens, and CD the object-glass, cemented firmly into one end of a tube *m*CD*n*, which has a tubular opening at E, while the other end of the tube has a circular piece of parallel glass cemented upon it. The tube *m*CD*n* is then filled with water, or any other fluid; and the object, when placed upon a slider or held in a pair of forceps, is introduced at the opening E into the fluid. The mechanism for producing these effects is easily conceived. By the instrument thus constructed, imperfectly opaque and corrugated objects, rendered transparent, and extended by the fluid medium, may be examined in this microscope, though incapable of being used in any other. Objects may be even dissected in the aqueous tube. Nay, objects preserved in spirits might be exhibited by immersing the bottle, if it is small, in the trough or tube *m*CD*n*.[1]

---

[1] See Baker *On the Microscope*, vol. i., p. 22.

[1] *Treatise on New Philosophical Instruments*, p. 410.

But the most important purpose effected by this form of the instrument is, that it can be rendered perfectly achromatic by using a fluid of higher dispersive power than the glass lens CD, and making the interior curvature of the side CD, which touches the fluid, of that degree of convexity which will convert the fluid into a concave lens capable of correcting the colour of CD. The lens CD may be made most advantageously of fluor spar, which, from its low dispersive power, might form an achromatic combination with water.

Reflecting solar microscope.

Although, in so far as we know, metallic specula have never been regularly fitted up as a reflecting solar microscope for use, yet every person familiar with, and in the habit of using specula and lenses, must have made the experiment of forming magnified images both in solar and artificial light, with small concave specula. The perfection of these images cannot be doubted; and it has often appeared to us surprising that the optician did not avail himself of such a combination for a solar microscope. Neither the Newtonian nor the Amician form of the instrument offers facilities for this purpose. Sir David Brewster has therefore proposed to employ his form of the reflecting microscope for a solar and oxyhydrogen instrument. Its facilities for this purpose are very great, and there can be little doubt that it will be practically successful, and will be as superior to other solar microscopes as the best reflecting compound microscope is to the ordinary compound microscopes. Dr Goring made an experiment with the Amician microscope; but he obviously considers it as not likely to succeed, remarking, that "after all that could be done, a refractor would be sure to beat it hollow; therefore," says he, "I shall take my leave of the subject, as I cannot conscientiously recommend such an instrument."[2] It is no wonder that this experiment failed, because Dr Goring seems to have used *the whole of the Amician microscope*, eye-glasses and all, as the magnifier in the solar microscope, and therefore it could not be considered as a *reflecting* solar microscope, being in fact as much a *refracting* one. The construction to which we have above referred is shown in the annexed figure, where AB is the illuminating lens, throwing the condensed rays of the sun upon a transparent object *mn*. The rays from this object falling upon the small speculum *e*, are reflected to the deep concave speculum *cd*, so placed that the image is formed at MN on a screen at some distance behind it, distinct vision being obtained either by moving the object or the speculum.

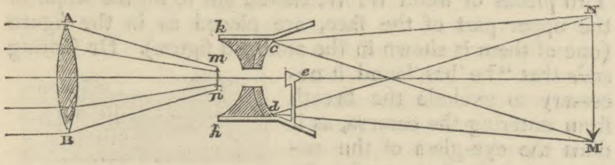

Fig. 86.

For opaque objects this form of the instrument is peculiarly adapted. The parallel rays of the sun falling upon the deep speculum *kh*, are condensed by it and thrown on the inner face of the object *mn*, of which a magnified image is formed, as before, at MN. A greater condensation of light may be obtained by using the lens AB, so that the speculum *kh* shall receive its convergent beam before the rays reach their focus and complete their convergency.

In this construction we have the disadvantage of two reflections, belonging also to the Amician form; but this may be considered as compensated by the image being without the tube, and more under our command. Though this is true in the compound microscope, yet the advantage of having the object outside the tube is of less consequence in a solar microscope. To avoid therefore two reflections, and two mirrors with their relative adjustments, Sir David Brewster has proposed to construct the reflecting solar microscope in the manner shown in the annexed figure, where *cd* is the perforated concave speculum, *mn* the object in one of its foci, and MN the magnified image in its other focus. The object *mn*, placed on a slider passing through an opening in front of the speculum, is illuminated as an opaque object by the lens AB, whose refracted rays are farther condensed by a lens placed in the aperture of the speculum. This form of the solar microscope is therefore singularly adapted for opaque objects; and as the whole of the effect of the instrument is produced by a single reflection from a single surface, it is the simplest optical instrument in existence. In order to throw light upon *mn* as a transparent object, the rays must pass through it in an opposite direction from the side MN, and this may be done by the very same method given by Mr Potter, and represented in fig. 71.

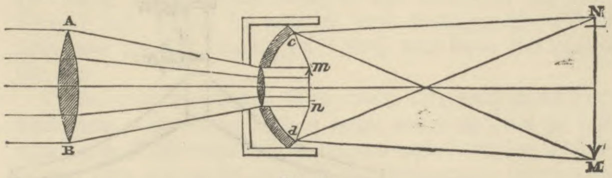

Fig. 87.

The simplicity and practical value of this instrument will be immediately recognised by comparing it with the complex opaque box, which in all solar microscopes is a necessary appendage for opaque objects. See fig. 84.

Dr Goring's Solar Camera Microscope.

Dr Goring's solar camera microscope.

Dr Goring has described in the *Micrographia* a very complete solar microscope, which has the property of exhibiting the image on a horizontal curved surface, placed in a darkened camera, at which two or more persons can look at the same time. It is, to a certain extent, a new instrument, but can also be used like the common solar microscope in a darkened room.[1]

This instrument, with all its parts, is shown in figs. 88, 89, 90, and 91; fig. 88 being a geometrical elevation of the instrument, *one-tenth* of the real size, the various parts being represented as if formed of transparent matter. A strong framework A of wood rests upon four legs, having a large hole in it, into which the instrument is fixed with two

---

[1] See *Treatise on New Philosophical Instruments*, p. 401, for an account of the advantages of examining objects immersed in fluids.

[2] Dr Goring states that a friend of his had constructed a solar microscope with metals on the Amician principle, and without a body or eye-glass, which exhibited a variety of test objects in a highly satisfactory manner.

[1] Dr Goring calls this instrument a "solar engiscope," while he gives the name of "solar microscope" to the *same* instrument when used in a dark room in the common way. The introduction of the image into a camera becomes thus the reason for changing a *microscope* into an *engiscope!* The word *engiscope*, however appropriate it may be as a companion to the word *telescope*, is quite inapplicable to any kind of solar microscope.

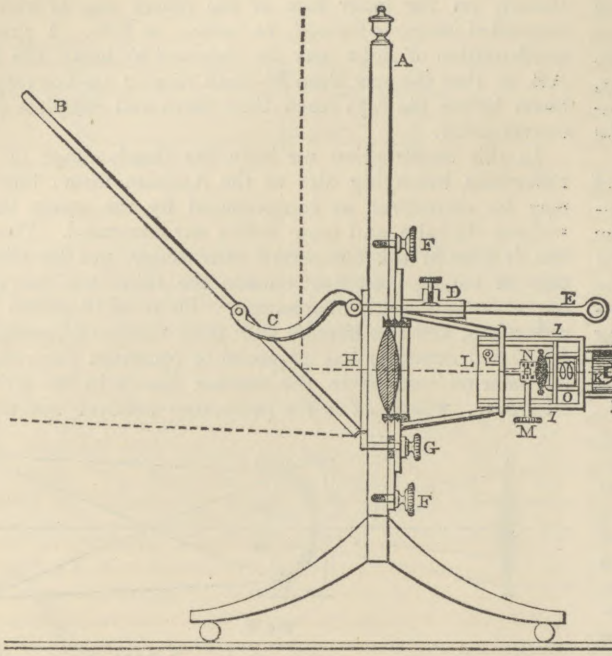

Fig. 88.

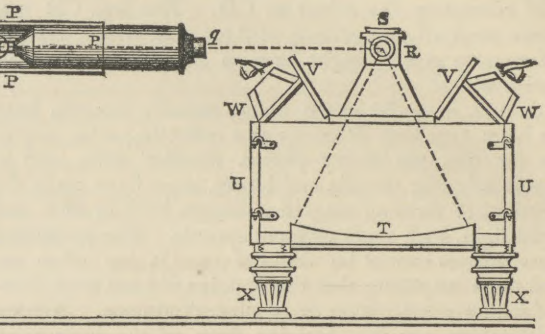

Fig. 89.

screws FF. The frame is large enough to protect the observer from the solar rays. A long plane mirror B is fixed to an arm C, which moves round a pin fixed to the side of the mirror frame, and also round a joint attached to a strong round wire E, which slides backwards and forwards in the tube D, having a spring within, and a pinching nut to fix it in its place. The inclination of the mirror is varied by pulling out or pushing in the wire E; and another motion of the mirror is produced by the action of the milled head G on a rack and pinion. A common illuminating lens, five inches in diameter and one foot in focal length, is placed at H. Dr Goring recommends an achromatic lens[1] (which would be a very expensive appendage), though he says that he has never used one. The main body of the microscope is conical, having a bayonet catch at L to receive the rest of the instrument, viz., the tube carrying the stage and rackwork. This tube 1 1 moves within the conical one by means of the milled head M and rack and pinion N. The end of this tube is closed, and an ordinary slider-holder O is fixed to it. On the inner side of the stage, near N, is fixed a condensing lens, about one and a half inch in diameter and two inches in focal length, which, by means of a sliding wire passed through a hole in the stage, can be moved from one side of the tube to the other, and also made to approach to or recede from the stage. A second tube PPP (fig. 90), slit open at the sides, is screwed into the tube in which the stage moves; and into this tube the optical part *q* is made to slide, the object-glass being placed at K. Dr Goring here remarks that "the focus may of course be roughly adjusted, by sliding the body backwards and forwards in its containing tube, before it is attached to the camera, fig. 89; but when this has been done, it must of course remain immovable. I look upon it," he continues, "as a *principle* in the solar microscope, *that the magnifier or object-glass should not be moved, but always remain at a fixed distance from the illuminator.*" Perhaps we do not distinctly understand the import of this passage; but we apprehend that the magnifier or object-glass may be, nay, must be, moved in any way that is necessary to produce distinct vision upon the screen, whatever be its distance; and that the essential condition is, that the distance of the illuminator and the object shall be invariable, the object being, if possible, accurately situated in the focus, unless where a slight deviation is necessary to prevent its destruction by the concentrated heat of the solar rays.

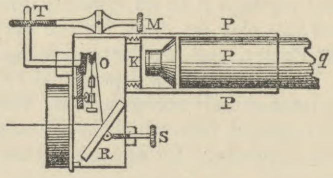

Fig. 90.

The end of the tube *q* is now pushed into another piece of tube at R, fig. 89, which communicates with a conical tube of brass, "having a rectangular prism, with its reflecting side silvered,[1] or a plane metal adjusted at its head S, so as to throw down the image to the bottom of the box or camera, where it is to be received on paper (at T), or on a surface of plaster of Paris duly curved to suit its shape." The camera WWXX is constructed with windows V, V, to permit two persons to view the picture on the table T. Two pieces of wood W, W, carved out to fill the slope of the upper part of the face, are placed as in the figure (one of them is shown in the annexed figure). Dr Goring adds that "he has found it necessary to exclude the breath from entering the camera, as it dims the eye-glass of the engiscope, and thus spoils the image;" but he does not mention whether this is the object of the pieces of carved wood, or whether they are used to keep extraneous light

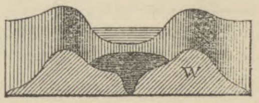

Fig. 91.

---

[1] See *Edinburgh Journal of Science*, No. 9, new series, p. 85; and our chapter on the Illumination of Microscopic Objects.

[1] Dr Goring is surely mistaken in saying that the side of the prism should be *silvered*; for as *total reflection* commences at 41° 49' for glass, and takes place at all greater angles of incidence, the light incident at 45° will be totally reflected. But even if the least oblique part of the conical beam should penetrate the reflecting surface (which it cannot do), part of the picture would have the light of silvered reflection, and the other part the *double* light of total reflection, which would never answer. We would prefer a plane metallic speculum to the prism, even if sufficiently homogeneous not to affect the accuracy of the picture.

Micro-scope.

from the eye,[1] which, in so far as the figure indicates, does not appear to be the case.

The sides U, U of the camera may be removed at pleasure, to allow the observer to draw the picture on the table, the light being excluded by some black drapery, while the hand passes through a suitable opening in it. Dr Goring recommends that the whole of the interior of the conical brass tube and camera should be well blacked, or lined with black silk velvet.[2]

In applying this instrument to opaque objects, the opaque box, shown in fig. 90, is applied to the conical tube in fig. 76 by means of the bayonet catch at L. A plane mirror R, adjusted by the screw S, throws the light of the illuminator to the object O placed in the conjugate focus of the eye-glass K, by means of the milled nut M and screw T, which causes the stage and the object to approach to or recede from the lens K.[3] The stage is formed by a piece of cork covered with black velvet. PP is the tube into which the body *q* of the microscope is inserted, as in fig. 76.

This instrument may be converted into a common solar microscope by unscrewing and removing the tube PP, and placing a simple object-glass in an appropriate mounting at M. The whole apparatus is then removed from the frame A, and screwed to a window-shutter in the usual way.

On the Oxyhydrogen Microscope.

On the oxy-hydrogen micro-scope.

The great popularity of the public exhibitions made with this instrument has turned the attention of opticians and amateurs to its improvement. Mr Pritchard has written a long and interesting chapter of nearly fifty pages on the subject of solar and oxyhydrogen gas microscopes, in the *Micrographia*, already referred to, and has given a most popular and minute account of all the details of the instrument. These details, to which we must refer out readers, do not belong to an article like the present; and we shall content ourselves with explaining what an oxyhydrogen microscope is, and how the optical apparatus of a solar microscope may be readily converted into that of an oxyhydrogen one, and *vice versa*.

An oxyhydrogen gas microscope differs from a solar one chiefly in this, that a brilliant light obtained by igniting a ball of lime the size of a pea (hence called the *pea* or *lime* light, or more appropriately the *Drummond* light, from its inventor, the late Mr Drummond) with oxyhydrogen gas, is substituted in place of the solar rays. This enables us to enjoy the amusement of the solar microscope apparatus in all weathers and at all hours of the day.

As the lime-ball light, however, is at our elbow, it sends forth diverging rays; whereas the rays of the sun are parallel. A very beautiful principle, already referred to in our article Micrometer, enables us to give the simplest construction for this purpose. Let AB (fig. 92) be the illuminating lens of the common solar microscope, throwing the parallel rays *ef* of the sun upon the object *mn*, and let the whole instrument be in perfect adjustment; then, without moving or changing any part of it, we may convert it into an oxyhydrogen microscope, where the light diverges from the lime-ball L, simply by placing in front of AB another lens CD, whose focal length is equal to the distance of the lime-ball light L from the lens AB. The oxyhydrogen microscope will then have its objects at *mn* illuminated in precisely the same way as they were by the sun's rays. The two lenses CD, AB, should be in contact, the space in the figure being left only to show the parallel rays *ef*. Now, as L is the focus of the lens CD, the converging rays *ef* will be parallel, and consequently will be refracted by AB exactly as if they had been the rays of the sun.

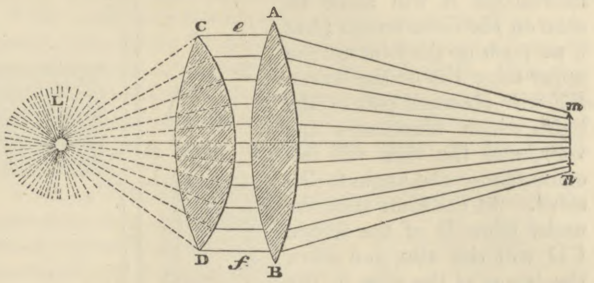

Fig. 92.

If the instrument had been made originally as an oxyhydrogen microscope, with a large and deep lens at AB, which would be required to refract rays diverging from L to *mn*, then we might convert the instrument into a solar microscope, by simply placing a *concave* lens in front of AB, whose focal distance is equal to the distance of L from AB. This concave lens will give such a divergency to the parallel rays of the sun that they will have their focus at *mn*.

Our readers will find the most ample details respecting the gas apparatus, and the method of managing and using the instrument, in Mr Pritchard's *Micrographia*.

Notwithstanding the precautions to prevent an explosion of the oxygen and hydrogen employed in this apparatus, we would recommend to Mr Pritchard, and those who may construct such instruments, to use a common oil or gas lamp supplied with oxygen gas, such as Sir David Brewster some years ago recommended as a safe substitute for the lime-ball light, when it was proposed to use the latter for lighthouses. This oxygen lamp, equally safe and brilliant, has been tried with success at the Trinity House, and will, we are confident, be soon in universal use, not only in lighthouses, but wherever strong lights are required.[1]

On the Apparatus for Dissolving Views.

On the apparatus for dissolving views.

By employing two microscopes similar to the oxyhydrogen microscope, but of a larger size, the interesting optical illusion of *dissolving views* is produced. In order to admit objects four or five inches square, condensing lenses 8 or 10 inches in diameter are necessary. The views to be employed are painted on glass with much more care and minuteness than those employed in the magic lanthorn. The following is the method of causing one picture to dissolve and pass gradually into another. The two microscopes are placed near each other, and at the distance of 20 or 30 feet from a white screen for receiving the images. The position of the microscopes is then adjusted so that each throws the image of the picture placed in it on the same part of the screen. When this is obtained the microscopes are fixed, and in front of them an apparatus like that in figure 93, where A and B are the front openings of the two microscopes, and CD and EF two dark screens moveable upon the centres *m*, *n*, and capable

---

[1] In using this and all other optical instruments where perfect vision is either agreeable or essential, we would recommend the use of the Greenland snow spectacles, cut, to suit the individual, from a plaster of Paris cast of the eyes, nose, and brow.

[2] Mr Potter found black velvet to be superior to any other blacking for the interior of his reflecting microscope, and we have used it successfully in the solar telescope in observing the extreme red rays of the spectrum. (*Edin. Jour. of Science*, No. 11, p. 62, new series.)

[3] The illumination is here far too oblique. The mirror should be nearer P, and the screw MT should be made to move the object-glass K, in order that the focus of the illuminator may always fall on the object O.

[1] Mr Drummond heated the lime-ball with three flames of a spirit-of-wine lamp. It may be done even with one flame urged upon the ball by a blowpipe of oxygen gas.

Dissolving views.

of moving up and down on the vertical rod GH. These screens are fixed in front of the openings A, B, and close to them. In the position of the dark screens, shown in the figure, the view in the microscope A will alone be seen on the white screen; but if we push up the joint *mn* the upper edge E*m* of the screen EF will obstruct part of the light which illuminates the view, and the view will become fainter and begin to dissolve. At the same time the under edge D of the screen CD will rise also, and allow the image of the view in the microscope B to appear very faintly, and mixed up with the image of the other view on A. As EF rises, and causes the view in A to dissolve, CD will rise, and cause the view from B to be brighter and more distinct. By continuing the upward motion of *mn*, the view from A will gradually dissolve till it disappears altogether, while the view from B will gradually become more and more distinct till it obliterate the view from A. By causing *mn* to descend the reverse will take place, the view from B now dissolving till it is obliterated by that from A.

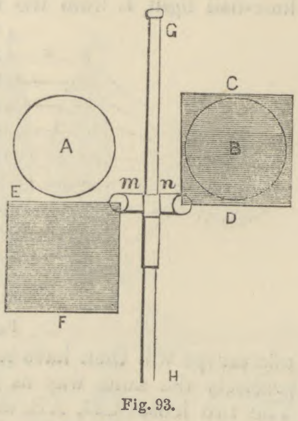

Fig. 93.

Simpler instrument for dissolving views.

Another very ingenious method of exhibiting dissolving views is to include *two* views in the same piece of paper, so that when you see the piece of paper by *reflected* light you see distinctly one of the views like an ordinary painting or engraving; but when you look through the paper you see the other view by *transmitted* light. This piece of paper is placed at the wide end of a conical tube, at the other end of which is a convex lens to magnify it. On the upper side of the wide end of the tube, a lid like that in the stereoscope opens and shuts, so that when open it throws light upon the face of the piece of paper containing the view to be seen by reflected light, and, when shut, the eye sees the picture to be seen by transmitted light. On the lower side of the wide end of the tube is another lid which opens and shuts. When shut it prevents the transmission of light, which would interfere with the view of the picture seen by reflected light. Now, the two lids are so connected by a wire that as one opens the other shuts, the one being completely open when the other is completely shut. By this means the picture seen by reflected light gradually dissolves till it is obliterated by a transmitted picture, and *vice versa*. The pictures for this apparatus are *circular*, and are very nicely executed by Parisian artists. A larger apparatus, which contains rectangular pictures about 8 inches by 6, has been constructed under the name of the Polyorama Pantoptique. A variety of natural effects, such as the motions of ships, &c., rainbows, fire, &c., may be produced by two, three, or more lanthorns. A trioptric lanthorn, in which one light is made to produce the effect of two or three lanthorns, has been described by Mr Beechey.[1] Microscopes are inserted in apertures at proper angles in the sides of the lanthorn, and three-sided prisms are used to reflect the rays to the screen. Photography now supplies us with beautiful drawings of all classes of objects for the instruments described in this chapter.

CHAPTER VI.

ON THE ILLUMINATION OF MICROSCOPIC OBJECTS.

On the illumination of microscopic objects.

The methods of illuminating microscopic objects that have been long in use have been described in the preceding chapters. They consist in throwing light upon the object, either by means of a mirror or a lens, or both combined; but the nature of the light employed, the magnitude of the pencil, its condition with regard to parallelism, divergency, or convergency, and the diameter of the pencil employed, or the direction in which it falls upon the object, have never been discussed as matters of science, although upon these the performance of the finest instrument essentially depends.

In so far as we know, the most important of these topics was pressed upon the notice of the scientific reader by Sir David Brewster, in the year 1820; and in order that the progress of improvement in this essential branch of the art of making discoveries with the microscope may be understood, we shall quote his observations on the subject:—

"The art of illuminating microscopic objects is not of less importance than that of preparing them for observation. No general rules can be given for adjusting the intensity of the illumination to the nature and character of the object to be examined; and it is only by a little practice that this art can be acquired. In general, however, it will be found that very transparent objects require a less degree of light than those that are less so; and that objects which reflect white light, or which throw it off from a number of lucid points, require a less degree of illumination than those whose surfaces have a feeble reflective force.

Rules for illuminating microscopic objects.

"The following rules may be laid down respecting the illumination of microscopic objects, and the method of viewing them:—

"1. The eye should be protected from all extraneous light, and should not receive any of the light which proceeds from the illuminating source, excepting that portion of it which is transmitted through or reflected from the object.

"2. Delicate microscopical observations should not be made when the fluid which lubricates the cornea of the observer's eye happens to be in a viscid state, which is frequently the case.[1]

"3. The figure of the cornea will be least injured by the lubricating fluid, either by collecting over any part of the cornea, or moving over it, when the observer is lying on his back, or standing vertically. When he is looking downwards, as into the compound vertical microscope, the fluid has a tendency to flow towards the pupil, and injure the distinctness of the vision.

"4. If the microscopic object is longitudinal, like a fine hair, or consists of longitudinal stripes, the direction of the lines or stripes should be towards the observer's body, in order that their form may be least injured by the descent of the lubricating fluid over the cornea.

"5. The field of view should be contracted, so as to exclude every part of the object excepting that which is under immediate examination.

"6. The light which is employed for the purpose of illuminating the object should have a small diameter. In the day time it should be a single hole in the window-shutter of a darkened room, and at night it should be an aperture placed before an Argand lamp.

"7. In all cases, and particularly when very high powers are requisite, the natural diameter of the light employed should be diminished, and its intensity increased by optical contrivances.

"8. When a strong light can be obtained, and indeed in almost every case, homogeneous light should be thrown upon the object. This may be done either by decomposing the light with a prism, or by transmitting it through a coloured glass, which has the property of admitting only homogeneous rays."

[2] See *Brande's Journal*, vol. ii., p. 127.

In the same article Sir David Brewster has described "a new method of illuminating objects in the solar and the lucernal microscopes." "The great defects," says he, "which still attach to the solar and lucernal microscopes, arise from the imperfect method of illuminating the objects. The method suggested by Æpinus, and employed almost universally by opticians, of reflecting the light concentrated by a lens upon the objects, by means of a plane mirror, is good enough as far as it goes; but in consequence of the light arriving from one direction only, the surface of the illuminated object is covered with deep shadows, and the intensity of illumination is by no means sufficient when the power of the instrument is considerable. We propose, therefore, that in the solar microscope the sun's light should be reflected by a very large mirror through four apertures, A, B, C, D (surrounding the tube T), each of which is furnished with an illuminating lens. The four cones, if condensed, are then received before they reach their focus, each by an inclined mirror, which reflects them upon the object; the distance of the lens from the mirror, added to the distance of the mirror from the object, being always less than the focal length of the illuminating lens. In the lucernal microscope it would be desirable to place an Argand lamp opposite each of the apertures A, B, C, D. By these means the light would *fall upon the surface of the object in four different directions;* a high degree of illumination would be obtained for very dark objects; and by *shutting up one or more of the four lenses, or parts of them, we shall be enabled to find the particular direction of the light which is best suited for developing the structure which it is the object of the observer to discover.*"[1] Although the focus of the illuminating rays should always fall upon the object, for the reasons already assigned, yet in the preceding method, applied to the solar microscope, a deviation from this rule becomes necessary, for *two* reasons:—1*st.* Because, if the focus of the illuminating lens fall exactly upon the object it might burn it, or destroy it by corrugation; and, 2*dly*, In the ordinary illuminating lenses, the diameter of the focal spot, or image of the sun, is not sufficient to cover the whole object, or to give a sufficient luminous field around it. For these reasons it is recommended in the preceding extract to place the object a little way within the focus of the illuminator, that is, between the illuminator and its focus. But if the object is such that it cannot be injured by the solar heat, and if the illuminator is sufficiently large to give a focal spot capable of filling the field of the microscope, then the object should be placed in the solar focus of the illuminator.

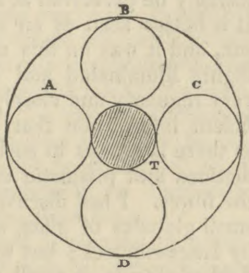

Fig. 94.

Oblique illumination.

Dr Wollaston's method of illumination.

After a lapse of nearly ten years, the subject of microscopic illumination was discussed by Dr Wollaston, in his paper on the Microscopic Doublet, published in the *Phil. Trans.* for 1829. This eminent philosopher, whose ingenuity never failed in executing in the best manner whatever he attempted, was then on his deathbed; and this, among other papers, was published without that complete revision which its author would otherwise have given it.

"The state of my health," says Dr Wollaston, "induces me to commit to writing rather more hastily than I have been accustomed to do, some observations on microscopes; and I trust that, in laying them before the Royal Society, they will meet with that indulgence which has been extended to all my former communications.

"In the illumination of microscopic objects, whatever light is collected and brought to the eye beyond that which is fully commanded by the object-glasses, tends rather to impede than to assist distinct vision.

"My endeavour has been, to collect as much of the admitted light as can be done by simple means to a focus in the same plane as the object to be examined. For this purpose I have used with success a plane mirror to direct the light, and a plano-convex lens to collect it; the plane side of the lens being towards the object to be illuminated."

These two principles of illumination, the first of which is the same as the first and fifth of the rules already given, though not so fully developed, and the second of which is founded upon a mistaken principle, have been carried into effect by Dr Wollaston in the following manner:—

"T, U, B, E represents a tube about 6 inches long, and of such a diameter as to preclude any reflection of false light from its sides; and the better to insure this, the inside of the tube should be blackened. At the top of the tube, or within it at a small distance from the top, is placed either a plano-convex lens UT, or one properly curved, so as to have the least aberration, about $\frac{3}{4}$ths of an inch focus, having its plane side next the object to be viewed; and at the bottom is a circular perforation A, of about $\frac{3}{10}$ths of an inch diameter, for limiting the light reflected from the plane mirror R, and which is to be brought to a focus at *a*, giving a neat image of the perforation A, at the distance of about $\frac{8}{10}$ths of an inch from the lens UT, and in the same plane as the object which is to be examined. The length of the tube, and the distance of the convex lens from the perforation, may be somewhat varied. The length here given, 6 inches, being that which it was thought would be most convenient for the height of the eye above the table, the diameter of the image of the perforation A must not, excepting with lower powers than are here meant to be considered, exceed $\frac{1}{20}$th of an inch.

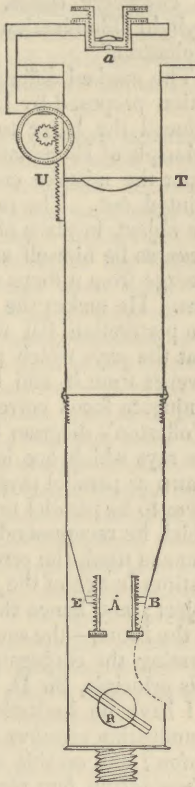

Fig. 95.

"The intensity of illumination will depend upon the diameter of the illuminating lens and the proportion of the image to the perforation, and may be regulated according to the wish of the observer. * * *

"The lens UT, or the perforation A, should have an adjustment by which the distance between them may be varied, and the image of the perforation be thus brought up to the same plane as the object to be examined. * *

"For the perfect performance of this microscope, it is necessary that the axis of the lenses, and the centre of the perforation A, should be in the same right line. This may be known by the image of the perforation being illuminated throughout its whole extent, and having *its whole circumference equally well defined.* For illumination at night, *a common bull's-eye lanthorn may be used with great advantage.* * * *

"Supposing the plano-convex lens to be placed at its proper distance from the stage, the image of the perforation may be readily brought into the same plane with the object, by fixing temporarily a small wire across the perforation with a bit of wax, viewing any object placed upon a piece of glass upon the stage of the microscope, and varying the distance of the perforation from the lens by screwing its tube *until the image of the wire is seen distinctly at the same time with the object upon the piece of glass.*"

---

[1] This is the earliest suggestion of oblique illumination for developing structures.

In the preceding passages we have extracted every one of Dr Wollaston's observations in reference to his method of illuminating microscopic objects, so that the reader will be enabled thoroughly to understand it.

This method of illumination was highly commended by optical writers. Dr Goring[1] considered it as most effective, and enumerates it among the inventions which founded a new era in the history of the microscope; and he elsewhere states, that "there is no modification of daylight illumination superior to that invented by Dr Wollaston."[2]

The marked difference between the methods of illumination proposed by Dr Wollaston and Sir David Brewster induced the latter to publish, in 1831, a paper "On the Principle of Illumination of Microscopic Objects."[3] In this paper the mistake committed by Dr Wollaston is clearly pointed out. The rays which Dr Wollaston throws upon the object, in place of being *rays actually converged to a focus*, as he himself says they ought to be, are rays which diverge from a focus situated between the object and the lens. He makes the focal point of the circular margin of the perforation fall upon the object, without considering that the rays which pass through that perforation do not diverge from it, and therefore cannot be collected in the conjugate focus corresponding to the perforation. In Dr Wollaston's diagram (*Phil. Trans.* 1829, plate ii., fig. 1), the rays which are incident on the mirror R are actually drawn as parallel rays; and it is quite clear that he meant them to be parallel rays issuing from the bull's-eye lanthorn which he recommends. But if we suppose that a common flame is used, the error is just of the same nature. It is a distinct image of the *flame* that should be thrown upon the object; and hence the perforation A should be placed close to the flame,—the source of light and the illuminated object forming the conjugate foci of the lens. After explaining this principle, Sir D. Brewster adds in the same paper:—"I have no hesitation in saying, that the apparatus for illumination *requires to be as perfect as the apparatus for vision*; and on this account I would recommend *that the illuminating lens should be perfectly free of chromatic and spherical aberration, and that the greatest care be taken to exclude all extraneous light, both from the object and from the eye of the observer.*"

At the meeting of the British Association at York in 1831 the preceding methods were communicated to Mr Potter, who was then engaged in inquiries with the reflecting microscope, and who had used only the common method of illuminating his objects. The effect which he obtained by it, is thus described:[4]—"I am indebted to Dr Brewster for information on the necessity of having the focus of the illuminating lens for transparent objects to fall exactly upon the object, when great nicety of vision is required. Having adjusted my microscope carefully on this point (see our figure 71, where the object is seen in the focus of the illuminating rays), I saw quite easily what are called the diagonal lines on the scale from the white-cabbage butterfly, which has been proposed as a difficult test-object by Dr Goring; and it is such a one as those who have only seen the stronger longitudinal striæ on scales from the wings of moths and butterflies have little idea of." By the same means Mr Potter's instrument "showed him easily, not only the striæ on the scales of the wing of the small house-moth, but also the diagonal lines." Mr Potter afterwards applied his microscope, and the new method of illumination, to "a much more difficult object than those just referred to." This object is the broad bluish band first noticed in the web of the spider, the *Clubiona atrox*.[1] "There can be no doubt," says Mr Potter, "that this blue band consists of lines produced by the spider, and woven into the delicate tissue. To demonstrate these fibres, however, is a work for an expert microscopist provided with a first-rate instrument. So critical a defining power is required, at the same time with a large quantity of light, that I doubt much whether any compound refracting microscope, even the best achromatic, will ever show the construction of this web on a transparent object. When viewed in this manner through good common compound microscopes, the blue band can scarcely be perceived at all with a moderately high power. It is better seen as an opaque object by the light of the sun, and it was on this method that I discovered it, when highly illuminated and highly magnified, to be covered very regularly and closely with white spots. This was sufficient information that it was of a uniform texture; but as there is always in such a light a strong display of irradiations and prismatic colours, it was impossible to trace the fibres. I had discovered something of the texture with small globules of glass, used after the manner prescribed by Leuwenhoeck; but with very high powers the distinct field of view is so small that I dared hardly to pronounce decidedly upon the general structure; *and it was only after adjusting the illuminating lens of my microscope very carefully that I saw with it the complete structure of a regularly woven net.*"[2]

After this strong testimony to the practical utility of Sir David Brewster's method of illumination, and the unquestionable optical principles on which it is founded, we were surprised to observe that Dr Goring and Mr Pritchard should, in the *Microscopic Cabinet*, published in 1832, still recommend and use a method so decidedly erroneous in theory, and founded on no optical principles whatever. Dr Goring has described what he calls an improved illuminator, which is just Dr Wollaston's with a stop in the focus of the lens.

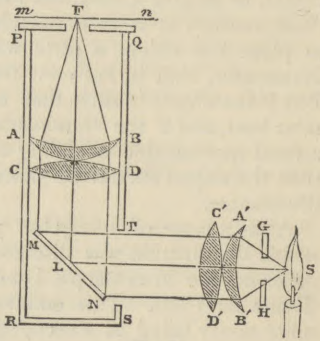

Fig. 96.

As the progress of discovery with the microscope must depend upon the scientific illumination of the objects under examination, we shall proceed to describe in detail the method of illumination used by Sir David Brewster. Let *mn* be the plane surface on which the object rests accurately perpendicular to the axis of the lens, lenses, or mirrors, which constitute the microscope. Let PQRST be a tube from 1½ to 2 inches long, and wholly lined with black velvet. This tube has an opening at ST, and must be so attached by an universal joint, or any analogous contrivance, to the slider-holder or stage, that the axis FL of the tube can be inclined at any angle to the surface *mn* from 90°, its general position, to 60° or less, for the purpose of oblique illumination. It should also have a circular motion about its axis, in order that the inclination may be made in any azimuth.[1] A doublet AB, CD, of no aberration, and having a focal length of from half an inch to an inch, is then placed in the tube, with a rack and pinion, or any other adjustment, to bring its focus for parallel rays F, or its conjugate focus for diverging rays, accurately to a point in the plane *mn*, and upon the object lying in that plane, for examination. A short way below it is placed a metallic speculum (not a silvered glass one), which receives parallel or diverging rays, entering the tube at ST, and reflects them upon the doublet ABCD. This speculum should be of pure virgin silver, notwithstanding its liability to tarnish, and should be wrought with the same care as the plane speculum of a Newtonian telescope;[2] or it might be a rectangular prism of good homogeneous glass, acting by total reflection. This part of the illuminator forms part of the microscope.[3] The other part of the illuminator, which is detached, is no less essential. It consists of the flame S, which should be as bright and small as will give the necessary quantity of light after condensation. As close to it as possible is placed a stand for holding a screen, with different circular apertures, and a variable rectilineal aperture. If a stronger light is required than can be obtained from the plane S, its light must be condensed into a parallel beam SL by another doublet of no aberration, A′B′C′D′ the flame S being in its anterior focus.

[3] *Edinburgh Journal of Science*, New Series, No. xi., p. 83.

[4] *Ibid.*, p. 64.

[1] It is found in the crevices of old walls, and may be recognised by its irregular fleecy-looking web.

[2] Mr Pritchard received from Mr Potter a specimen of this web; but though he detected the *blue* bands, yet, as the specimen was not a recent one, he was unable to perceive "the complete structure of a regularly woven net." (*List of* 2000 *Microscopic Objects*, pp. 6, 7.)

The illuminator, as now described, is adapted to homogeneous light, either as obtained from a monochromatic lamp, or by means of coloured glasses, or from the prismatic spectrum; but if we employ common light, the doublets ABCD, A′B′C′D′ must be achromatic. We have mentioned above a variable rectilineal aperture. This is a most essential accompaniment for giving perfection to the vision of lined objects. The aperture should be made to form every possible angle with a vertical line, and should be opened and shut by means of a screw till as much light is introduced as is necessary to obtain a perfect view of the object. The image of the slit, which is close to the flame, must be thrown upon *mn*, so as to be parallel with the lines of the object, or to form any angle with them. When the objects are circular, circular apertures are preferable to any other.

We have already stated that no light should reach the eye, either from the field of the microscope or any other source. For this reason it would be desirable to have circular and rectilineal apertures of different sizes, to be placed immediately beneath *mn*, so as to allow no part of the field to be seen, excepting that which is occupied by the object, or part of it, under examination.

The above apparatus being provided, let us suppose that the observer is called to examine some structure very difficult to be resolved, such as the blue band of the *Clubiona atrox*, or the structure and nature of the lines and test-objects. We omit at present the consideration of the preparation of the object and the eye of the observer, and also the nature of the light which he is to use, as these will be separately considered; and confine ourselves to the use of the illuminator. The object is first placed on a piece of thin colourless parallel glass, or film of topaz or sulphate of lime, near its middle, and the microscope is directed to it, so that it can be seen distinctly in the ordinary way. Put the illuminator in its place, and set the proper aperture close to the small plane. Adjust the doublet ABCD by its screw or pinion till a distinct image of the aperture GH is seen in the field; and, by means of the apertures below *mn*, any stronger or unnecessary light may be still more completely excluded. If the structure is not rendered sufficiently distinct by this process, it will be proper to try the effects of *oblique illumination* by inclining the axis FL of the illuminator to the plate *mn*, and observing carefully the effects which it produces in different azimuths. If all these means are insufficient, we must have recourse to new auxiliaries,—to monochromatic light, if the microscope is not achromatic, or to monochromatic illumination, if it is achromatic; and we must prepare both the eye and the object, the one for exhibiting and the other for viewing to the best advantage the structures which we are anxious to develop.

As the method of illumination which we have described has been neither understood nor appreciated by some writers on the microscope, the following observations may be useful:—If we examine with a polarizing microscope certain minute fibres which depolarize light, we shall, with high powers, see them very indistinctly, owing chiefly to the fringes formed by diffraction; but if we examine them when the field is dark and the fibres alone luminous, they will be seen with great distinctness, and unaccompanied with fringes. The reason of this is, that no light passes by their edges, so that no diffraction fringes can be formed either within or without their image.[1] They are seen as if they were self-luminous. In like manner, a fine wire made red hot, if examined in a dark field, will be unaccompanied with fringes. Hence it appears that if we can converge light upon a transparent object so that the points of convergence or the foci of the rays fall upon the object, the light will, as it were, radiate from the parts of the object which they illuminate as if they were self-luminous; and consequently there will be no diffraction fringes. The light, therefore, must be either achromatic or monochromatic. Hence it follows that a common lens which has different foci for the different colours of the spectrum, and also for different parts of its surface, is unfit for microscopic illumination.

These views have been adopted by the most distinguished opticians, as well as by the most eminent observers, and all the finest instruments are accompanied with an achromatic condenser or illuminator.

This method of illumination was, as we have already stated, proposed by Sir David Brewster in 1831, and used by Mr Potter in the same year. It was more fully described by the inventor in this work in 1837, and in his separate Treatise on the Microscope published in the same year;[2] and yet the very same apparatus was communicated to the Academy of Sciences in Paris as a new invention, by M. Dujardin, and published in September 1838.[3] It can hardly be expected that foreigners should be acquainted with every English invention, and we have no doubt that M. Dujardin had not seen the books to which we have referred; but it is discreditable to the science of England that the authors and compilers of English treatises on the microscope should continue to ascribe to M. Dujardin an invention which has not only been used in their own country for 25 years, but distinctly described in English works, easily accessible, and well known in the scientific world.

Before we conclude this chapter we must gratify the reader with an account of Mr Wenham's very ingenious

---

[1] This contrivance, though published twenty years ago, has been recently brought forward as a new invention by Mr Sollit in the *Quarterly Microscopical Journal*, 1855, vol. iii., p. 88.

[2] Such specula may now be made by the observer himself by the beautiful method of depositing a layer of silver upon glass, invented by Mr Power—a method which M. Foucault has applied with great success to the construction of specula for reflecting telescopes. We have had occasion to see at the Imperial Observatory in Paris two excellent telescopes thus made by M. Foucault, one 18 inches, and another about five feet in focal length.

[3] If the axis of the microscope is placed horizontally, or even with some obliquity, we may dispense with this speculum altogether, and direct the tube at once to the illuminating flame.

---

[1] These views are successfully explained in the *Phil. Mag.*, 1848, vol. xxxii., p. 161.

[2] See also the *Phil. Mag.*, 1848, vol. xxxii., p. 163.

[3] *Comptes Rendus*, &c., Sept. 10, 1838, tom. vii., p. 620.

method of illuminating opaque microscopic objects when object-glasses of very high power are employed. It is impossible to apply a Lieberkhun to objects covered with a plate of glass,[1] and equally so to throw in upon the object reflected light sufficient to illuminate it. Mr Wenham has therefore conceived the ingenious idea of illuminating the object by light that has suffered total reflection from the interior of the upper surface of the thin glass which covers the object. The method of doing this is shown in the annexed figure, where *aa* is the surface of the plate of glass upon which the object is laid, and *mn* the thin glass which covers the object, with Canada balsam or some other fluid interposed. The frustum *b* of a hemispherical lens is placed beneath the slide *aa*, with water or any other fluid interposed. When rays *c, c, c, c* fall perpendicularly through the sides of the lens *b*, they will pass on to the upper surface *mn* of the thin glass cover, and if they fall at the proper angle upon that surface, they will be wholly reflected upon the object between the two glasses.[2] By placing a small highly dispersing prism beneath *aa*, so as to form a fine spectrum from a narrow slit, the most perfect monochromatic illumination may be obtained. The prism may be very near the hole, as a spectrum of very little length is required.

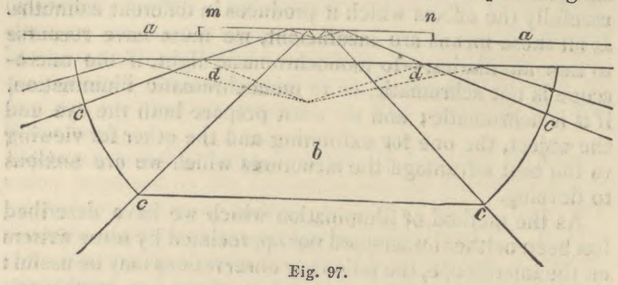

Fig. 97.

In order to illuminate objects obliquely by condensed light, a prism, called Amici's prism, which is the same as Newton's curvilineal prism, has been used; but it is obvious that the lenticular reflecting prism, or the plano-convex lens used as a reflector, as shown in fig. 21, is much superior in accuracy, and much more easily made. To place two spherical faces upon a prism, so as to have the same centre and the same inclination to the base, is a very difficult operation; whereas, in the lenticular reflector the centres are necessarily coincident and equally inclined to the base.

CHAPTER VII.

ON THE MONOCHROMATIC ILLUMINATION OF MICROSCOPIC OBJECTS.

Monochromatic illumination of microscopic objects.

If a simple and easily applied system of monochromatic illumination, that is, of illuminating objects with homogeneous light—which a prism, and consequently a lens, is not capable of dispersing or refracting in different directions—could be contrived, we should never again hear of compound achromatic microscopes. We believe it will be admitted that in Sir John Herschel's doublet of no aberration the spherical aberration is more completely corrected than in any double, or even triple, achromatic object-glass. Hence it follows, that in homogeneous light such a doublet would be a better microscope than the compound lens. But in the best system of achromatic compensation that can be executed the secondary spectrum still remains without a remedy; and hence the doublet of no aberration, in which there can be no secondary colour in homogeneous light, must be a superior instrument to the compound achromatic lens. Now, in telescopes it is impossible, except in viewing the sun's disc,[1] to work with homogeneous light; but in microscopes, where the quantity of light is in our power, it is perfectly practicable to make that quantity so great that all the yellow or red rays which it contains may give sufficient light for microscopical observations. This insulation of homogeneous light may be effected in three ways; first, by a monochromatic lamp, as proposed and constructed by Sir David Brewster; secondly, by the absorption of coloured media; and thirdly, by the prism.

1. The monochromatic lamp is shown in the following figure, where AB is a lamp having its globe A filled with diluted alcohol, which descends gradually through the tube C into a thin platina or metallic cup, in which it burns. A strong heat is kept up by a spirit-lamp inclosed in a dark lanthorn, and when the diluted alcohol is inflamed, it will burn with a fierce and powerful yellow flame. If the flame should not be perfectly yellow, or rather of a *nankeen* colour, owing to an excess of alcohol, a small proportion of salt thrown into the cup D will have the same effect as a farther dilution of the alcohol. Sometimes a little blue light will be found mixed with the yellow, but this may be easily absorbed by a piece of yellow glass placed on any part of the microscope through which the rays pass. Although this light is feeble compared with that of white flames, yet, by using larger lenses for condensing it, it is quite easy to obtain a pencil sufficiently powerful for all microscopic observations.[2]

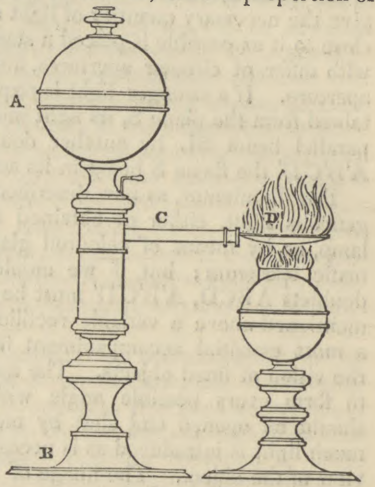

Fig. 98.

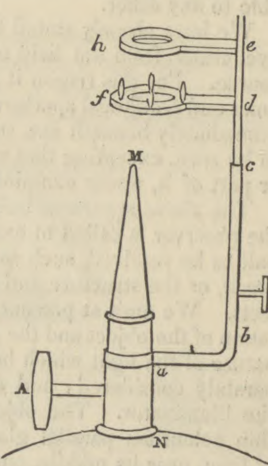

Fig. 99.

A stronger flame may be produced by using a gas lamp, or, what is still better, a portable gas one containing compressed gas.[3] This gas, when rushing out in a full stream, explodes when burned with atmospheric air, emitting much heat and a faint bluish and reddish light. As the force of the issuing gas is sufficient to blow out the flame, a contrivance for sustaining it becomes necessary. The method which we contrived for this purpose is shown in the annexed figure, where N is the main body of the lamp, MN the principal burner, and A the screw which opens the main cock. A small gas tube *abc*, communicating with the main burner, terminates above the burner, and has a short tube *de* movable up and down within it, but so as to be gas light. This tube *de*, closed at *d*, communicates with the hollow ring *fg*, in which four apertures are perforated so as to throw their jets of gas to the apex of a cone whose base is *fg*. When the gas is made to issue from the burner M, it rushes also into the tube *abcdf*, and issues in four small flames at the apertures in the ring *f;* and the height of these flames is regulated by the stop-cock at *b*. The explosive mixture of air and gas which rushes up through the ring is sustained in combustion by these small flames, through which it passes. A broad collar, made of coarse cotton-wick, and thoroughly soaked in a saturated solution of common salt, is fixed on a ring *h*; and when the bluish flame of the explosive mixture rises above *h*, it will be converted by the salted collar into a strong mass of homogeneous yellow light. A hollow cylinder of sponge, with numerous projecting tufts, may be substituted for the cotton collar, or a collar of abestos cloth might be used, and supplied from a capillary fountain containing a saturated solution of salt.[1]

---

[1] Mr Ross, we understand, has contrived a Lieberkhun for his highest powers to illuminate uncovered opaque objects.

[2] *Microscopical Journal*, vol. iv., p. 58.

[1] A *solar telescope* should never be an achromatic one, but should consist of a compound lens of no aberration, all the colours of the spectrum but one being absorbed by the darkening glass. One of these telescopes, in which the object-glass is corrected for spherical aberration upon Sir John Herschel's principle, was constructed for Sir David Brewster by Dollond, at the expense of the Royal Society of London, and has been used in his observations on the lines of the spectrum.

[2] *Edinburgh Transactions*, vol. ix., p. 435.

[3] When this was written, such lamps were used in Edinburgh, and supplied by a company which did not succeed.

When the few blue rays which sometimes mingle themselves with this yellow light are absorbed, every part of the light will be found to have a definite refrangibility, greater than any other artificial light that can be produced. The minutest objects and the smallest type will appear perfectly distinct in this light when seen or read through the largest possible angle of the greatest dispersive prism,—an irrefragable proof of the perfect homogeneity of the light.

2. The second method of producing homogeneous light, and by far the simplest and most easily applicable to microscopes, is that of absorption ; and the best rays to leave unabsorbed or insulated are the red. It requires some experience and scientific knowledge of the action of different absorbing media to select those which will leave the *narrowest and brightest band* of the *red* space in the spectrum. We have now under our microscope (a grooved sphere of garnet executed by Mr Blackie[2]) two scales of a moth lying in sulphuric acid and covering each other. With solar light the spaces between the lines glitter with all the hues of the rainbow ; but when a thickish plate of red mica is combined with another plate of red glass, and placed beneath the object, all these colours instantly disappear, and a perfection of vision is obtained, which can be disturbed only by the very small portion of spherical aberration which must exist in the sphere, and which an increased depth of the groove would render almost insensible. Blue glasses, and green and yellow as well as coloured fluids, may be successfully used in narrowing the range of refrangibility of the red space.

3. The third method, or that of prismatic refraction, is perhaps the surest and the best method of obtaining homogeneous light with the smallest extent of refrangibility. A certain effect may be produced by small prisms ; but in order to have a perfect apparatus, the *microscope should form part of the apparatus for examining the lines of the solar spectrum ;* that is, it should screw into the eye-piece of the telescope, in front of the object-glass of which is placed a fine large prism, for forming the spectrum within the telescope. By this method, which we have put to the test of experiment, microscopical observations can be carried on with an accuracy and satisfaction which nothing can exceed. We enjoy the luxury of perfectly monochromatic vision greater than which the most perfect achromatic compensation cannot give ; and while we have the spherical aberration corrected, we have *no secondary colours*, and none of the imperfections of vision which must arise in transmitting light through six or eight lenses of plate and flint glass.

Although we hope the scientific reader will admit that the preceding views are demonstrably correct, yet Dr Goring has pronounced a most unfavourable opinion of the system of monochromatic illumination.[1] We endeavoured to convert him from this heresy, and hoped that we had succeeded ;[2] but in the *Micrographia*, since published, he devoted a whole chapter to the reproduction and support of his former views.[3] We shall therefore again examine his objections in their order, as they obstruct the progress of improvement among those who justly admire Dr Goring's ingenuity and knowledge in everything which relates to the microscope.

1. Dr Goring's first objection to monochromatic illumination is, that it is too weak, and must be about one-seventh of the whole beam of light. This we are not disposed to dispute ; but Dr Goring is too well acquainted with the resources of optical science, to forget that this monochromatic *seventh* of a beam of light may be made *seven* times more intense than the whole beam. The objection, however, does not apply to the solar spectrum, for one-seventh of the sun's light is too intense for any eye to bear.

2. The second objection of our author is, that the colours of the spectrum, when separated by the prism, are actually separated into different colours when they are refracted in oblique pencils by a microscope. If this observation is correct, then we must denounce the prism that produced such a spectrum as utterly useless. Dr Goring, however, conceives his observation and his prism to be good, and endeavours to explain the result by referring to Sir David Brewster's analysis of the spectrum, in which it is shown that white light exists at every point of it ; but this white light, which has been rendered visible by absorption, cannot be decomposed by refraction of any kind, as it consists of *red*, *yellow*, and *blue* rays, of the same refrangibility. Such white light is the light that is wanted for the microscope ; and there can be little doubt that absorptive media will yet be discovered to effect its insulation in sufficient quantity for practical purposes.

3. Another objection to monochromatic light is, that it will not show the real colours of microscopic bodies. This is true ; but the *object of the microscope is not to find out colours but structures.* A common glass lens, with common light, will let the observer know all that he wants of the colours of objects ; and when he has learned this, he will then gladly avail himself of coloured light for more important purposes. We can truly say, that though we have wrought with the microscope for fifty years, we do not at present recollect a single case where we required to know anything of the precise colours of minute bodies. Notwithstanding this discussion, Dr Goring concludes his chapter with the following observation, in which we entirely concur :—" A monochromatic light, therefore, being once obtained *in a sufficient state of intensity for practical purposes*, bids fair to conduct us to the highest perfection of which aplanatic object-glasses and magnifiers are susceptible." It may be proper to add, that the best system of compound achromatic object-glasses now in use would be freed of all their secondary colours by using monochromatic light ; and they may be also greatly improved by employing suitable coloured media to absorb what are called the outstanding rays in an achromatic combination. Although Dr Goring has objected to the use of monochro-

matic light, he has himself given some remarkable illustrations of its value, as removing entirely the effects of chromatic aberration.[1]

CHAPTER VIII.

ON THE PREPARATION OF THE OBJECT AND THE EYE FOR MICROSCOPICAL OBSERVATIONS.

In using lenses of short focus, either singly or in doublets and triplets, the object is so near the lens, and its thickness, even when very small, forms such a considerable part of its distance from the nearest refracting surface, that any bend or want of flatness in the object completely interferes with the distinct vision of its parts. When the object will bear pressure, the best way is to lay above it a thin transparent film, with perfectly parallel and polished surfaces, such as a splinter of New Holland topaz, a thin plate of sulphate of lime, or a film of mica.[2] If these plates are a little less thick than the distance between the lens and the object, a little bees' wax should be interposed between the brass setting of the lens and the plate, so that the lens in the act of adjustment would press the wax against the plate, and the plate against the object, till distinct vision is obtained. The object should be placed upon a deeply-curved concave surface.

The proper flattening of the object, when it is tender, may be effected by pressing a thick balsam above it, and allowing the lens to dip into the balsam. If the surface of the lens is flat, its magnifying power will suffer no diminution.

When grooved spheres are used, such as the garnet one above mentioned, the object requires to be very near its surface. It should therefore be placed in a concave lens of glass, of a little greater radius than the sphere, and pressed into the concave form by interposing a narrow strip of a thin film of mica, and, if necessary, pieces of wax or India-rubber, as before; the pieces filling up the space between the lens and the mica, so as not to interfere with the part of the object under examination.

If a diminution of the magnifying power can be permitted, a fluid may be placed between the concave object-plates and the grooved sphere, and the chromatic aberration greatly reduced. By the interposition of a fluid, a grooved diamond sphere may be used; for though its focus for parallel rays falls within the sphere when the refractions are made from air and into air, yet, when the first refraction is made from a suitable fluid, the focus will fall without the sphere.

When the object is put into the best possible condition for observation, and the illuminator applied in the best possible manner, the observer will have every advantage in his researches; but still the structure which he seeks to develop may escape his eager research. Under these circumstances, he must perform his part of the observation in the best possible manner.

Unless particular arrangements are made by the observer for his own comfort, there is no bodily fatigue to be compared with that of the use of the microscope. The eye, the mind, and the whole frame, are on the stretch. The observer must therefore first try if his own eye is in a right state for observation. The fluid which lubricates the cornea, which must be considered as a lens and as part of the microscope, is sometimes in such a viscid state, that when the eyelids roll over the cornea by that beautiful provision of nature by which it is kept smooth and clean, the lubricating fluid, which is pushed into a ridge between the eyelids, does not quickly recover a convex surface. This state of the cornea is incompatible with delicate microscopic observations, and its existence may be ascertained by viewing the expanded image of a luminous point held close to the eye, and, after shutting the eyelids and again opening them slowly, observing if the luminous disc recovers its uniform luminosity quickly or slowly. If the luminous line produced by the fluid accumulated between the eyelids continues to be visible, and the general surface mottled and spotted, the lubricating secretion should be excited by exposing the eye to the vapour of hartshorn, raised by pouring a few drops on the surface of boiling water. The secretion will now flow copiously, the cornea will be swept clean by the purer and less viscid fluid, and the vision of the observer greatly improved. But this movable fluid surface of the cornea generates another imperfection of vision, which has already been referred to. This fluid, when undisturbed by the eyelids, descends by the influence of gravity in vertical lines, and the minute ridges thus formed obliterate and render indistinct all horizontal lines seen by the eye, but have a tendency rather to improve the vision of vertical lines. In proof of this, we may state the unquestionable fact, that if we take a striped pattern of any fabric, and bend part of it into a horizontal direction, while the rest remains vertical, or *vice versa*, the vertical part will always appear the most distinct. Hence, in viewing lined objects, when the position of the observer's head is either vertical or oblique, the lines of the lined object should be always placed parallel to the direction of the descending fluid. If the axis of the lenses is vertical, and the eye looks downwards, the lubricating fluid will collect irregularly at the apex of the cornea, and injure vision. If the axis of the lenses is horizontal, and the observer's head in its natural position, the fluid will descend in vertical lines; but if the observer lies on his back and looks into the microscope upwards, a position, we admit, not favourable for research, the fluid will flow equally in all directions from the apex to the margin of the cornea, and leave a clear centre well fitted for distinct vision. We may here notice the beautiful contrivance, not mentioned by natural theologians, that the effect of the vertical descent of the lubricating fluid is counteracted by the eyelids opening horizontally, and consequently effacing the tendency of the fluid to form vertical currents. Had the eyelids opened vertically, the vertical ridges would have been increased, and vision greatly impaired.

When everything has been done to fit the *cornea* (the only part of the eye over which we have any direct command) for accurate vision, the general state of the health, or any casual irregularity of diet, or the accumulation of those minute transparent vessels which produce *muscæ volitantes*,[1] will be sometimes found to affect the state of the organ, and unfit it for nice observation. To remedy this defect of vision, we must refer the patient to the prescriptions of his physician.

When these precautions have been taken, the observer must protect his eye from all extraneous light; and the most effectual way of doing this is to use the snow spectacles of the Greenlanders, which are cut out of wood, so as to exclude all light whatever, except what enters through a circular aperture the size of the pupil, and directly in front of it.[2] A cast should be taken in plaster of Paris, from the part of the face to which they are to be applied, to enable the artist to cut them of a proper shape; and when finished they should be lined with black velvet.

---

[1] See Pritchard's *Microscopic Illustrations*, pp. 271, 272, 3d edit., 1845.

[2] Plates of very thin glass are now made for the express purpose of inclosing objects for the microscope.

[1] See *Edinburgh Transactions*, 1843, vol. xv., p. 377.

[2] In the snow spectacles a long narrow slit is used, to enable the wearer to look on each side of him. An interesting account of the great value of these spectacles, by the celebrated Professor Blumenbach, will be found in the *Edinburgh Phil. Journal*, vol. viii., p. 261.

The last requisite for accurate microscopical observation is *steadiness in the microscope*,[1] and a steady and comfortable position for the observer. The first is easily attained; the second may be accomplished by the observer resting his doubled arms upon a stool or frame nearly the height of the eye-glass of the microscope, but unconnected with it, while his chin rests either upon his arms or upon his breast.

When all these means and precautions fail in unravelling a mysterious structure, we have often derived advantage, in the case of lined objects, by looking through cylindrical lenses or good prisms; the length of the cylinder, or the refracting edges of the prism, being at right angles to the lines. Narrow slits may also be used with advantage next the eye; but in all these cases, while we improve and give a finer definition to the lines and the spaces between them, we deteriorate vision for other parts of the structure.

CHAPTER IX.

APPLICATION OF PHOTOGRAPHY TO THE MICROSCOPE.

Photography may be applied to the microscope in two ways,—1*st*. In furnishing us with magnificent photographs of microscopic objects; and, 2*d*. In converting, for special purposes, large objects into small ones which are visible only in the microscope.

1. Mr Richard Hodgson seems to have been the first person who obtained microscopic photographs upon daguerreotype plates by the sun's direct rays. In Oct. 1852 Mr Joseph Delves, of Tunbridge Wells, exhibited to the Microscopical Society beautiful magnified photographs both on paper and glass,[2] namely, the spiracle and trachea of the silk-worm, magnified 60 diameters, and the proboscis of the fly magnified 180 diameters. In November Mr George Shadbolt exhibited a photograph of a fly's proboscis, taken by a very small camphine lamp.

The method of taking these pictures is very simple. The eye-piece of the microscope being removed, the end of the tube from which it was taken is fixed into a dark box (or a photographic camera), at the opposite end of which is a groove for carrying the ground-glass plate. When the object is well illuminated either by solar or artificial light, a distinct picture of the object is thrown upon the ground-glass plate, and the sensitive plate is placed so as to be in the chemical focus of the object-glass, which, in low powers, is at some distance beyond the luminous focus.

Mr Shadbolt obtains the chemical focus by altering the luminous focus by the fine adjustment; an alteration of two turns of the milled head, or $\frac{1}{50}$th of an inch, being sufficient for an inch-and-half object-glass; an alteration of half a turn for a $\frac{2}{3}$d inch object-glass, or $\frac{1}{200}$th of an inch; and an alteration of about 2 divisions, or the $\frac{1}{1000}$th part of an inch, for a $\frac{4}{10}$th of an inch object-glass. The time of exposure varies from 1 to 10 minutes.[3]

Mr F. H. Wenham has greatly improved the process of microscopic photography by using the ordinary microscope as a solar one, and using a dark room in place of a camera, by a new mode of combining the chemical and visual foci, and by obscuring for a time the parts of the object which are either easily solarized and lost, or out of focus. He prefers sunlight to artificial light, though he justly considers it of great importance to have what he calls a *photographic fusée* that will burn with the necessary actinic power for sufficient time to take nocturnal or underground photographs. He has produced photographic pictures by burning phosphorus, by balls of fine zinc turnings, by a succession of electric sparks, and by the oxyhydrogen or lime light.

Mr Wenham has succeeded in obtaining by the photographic microscope the markings on the most difficult tests. One of these, of the *P. angulatum*, magnified about 15,000 diameters, shows the configuration of the markings, perfectly black and distinct, in a far greater degree than we can ever hope to see them through the compound microscope; and Mr Wenham is of opinion "that if ever the structure of those difficult tests is to be proved, it will be by the aid of photography."[1]

Microscopic photographs by M. Bertsch.

Photographs of a still more minute character were presented to the Academy of Sciences on the 10th August last by M. Bertsch.[2] They were five in number.

The *first* was one of the Diatomaceæ, from guano, obtained by a magnifying power of 500 diameters. The focal length of the object-glass was the 50th of an inch (a demi-millimetre). It was achromatized for the superior rays of the spectrum, and its chemical focal length was 24 centimetres. The focus for the inferior rays was the $\frac{1}{180}$th of a millimetre from the luminous focus.

The *second* specimen was two Naviculæ, of that species of which it is difficult to see the structure and the striæ with the best microscopes. One is magnified 800 and the other 500 diameters. They were illuminated with light so oblique that the field of view was almost dark.

The *third* represented, with a power of 500, the globules of the human blood. The annular space and the depression were distinctly shown on a larger field than is given by the best microscope, and the light traversed them without changing its direction.

The *fourth* specimen consisted of two pictures of the crystals of salicine, seen in polarized light; the one illuminated by the ordinary, and the other by the extraordinary ray.

M. Hartnach constructed for M. Bertsch a complete instrument for taking this class of photographs, with a magnifying power of from 50 to 1000 diameters for transparent objects, and from 50 to 150 for opaque objects.[3]

2. Photography has been successfully applied in reducing, for special purposes, large objects into such small dimensions that they are invisible to the naked eye, and can be seen only with a good microscope.

Microscopic lines of writings by Sir John Barton;

By M. Nobert.

It has long been a trial of skill to include the Lord's Prayer in the smallest circle by the unaided hand of the writer. More recently results of the most remarkable kind have been obtained by machinery. Sir John Barton drew with a diamond point, upon steel, lines at the distance of the 10,000th of an inch. M. Nobert exhibited at the Crystal Palace in 1851 ten groups of lines upon glass in which the number of lines in an English inch varies from 11,265 to 49,910; and M. de la Rue examined another specimen of ten groups in which they varied from 11,261 to 56,306!

In order to see the lines in the widest of these groups, a power of 100 is sufficient, but one of 2000 is required to separate those in the closer groups. They thus become test-plates for determining the power and excellence of microscopes.

---

[1] This suggestion has been specially attended to in the latest form of Mr Ross's microscope. He has obtained the most perfect steadiness by giving solidity to those parts which are most liable to tremor; and he attaches so much importance to this property of the instrument, that he tests it by the "inverted pendulum." The object of this apparatus is to exhibit vibrations which could not otherwise be perceived. He varies the size of the parts of the stand till he obtains such an equality of vibration between the stage and the body of the microscope as will prevent any visible tremor in the object under examination.

[2] They were produced in from 5 to 10 seconds in sun-light. With low powers "a moment's exposure" is sufficient.

[3] *Cosmos*, Aug. 14, 1857, vol. xi., p. 179.

By M. Froment.

Microscopic effects still more wonderful have been produced by M. Froment of Paris, one of the most distinguished artists of modern times. A piece of writing, for example, about $3\frac{2}{10}$ inches in diameter, was compressed into the space of $\frac{1}{30}$th of an inch. The mode of doing this has not yet been published; but Dr Lardner[1] informs us "that it consists of a mechanism by which the point of the graver or style (a diamond point generally) is guided by a system of levers, which are capable of imparting to it three motions in right lines, which are reciprocally perpendicular; two of them being parallel, and the third at right angles to the surface on which the characters or design are written or engraved. The combination of the motions in the direction of the axes, parallel to the surface on which the characters are engraved or written, determines the form of the characters; and the motion in the direction of the axes, at right angles to that surface, determines the depths of the incision, if it be engraving, or the thickness of the stroke, if it be writing."

By Mr Peters.

Wonderful as are the specimens published by M. Froment, they have been greatly surpassed by those produced by our countryman Mr Peters, who has invented and described the machine by which they are produced. Mr Peters has inscribed the Lord's Prayer in 6 lines in a rectangular space one of whose sides is the $\frac{1}{250}$th part of an inch, and the other the $\frac{1}{600}$th part of an inch; that is, the area of the rectangle is $\frac{1}{250} \times \frac{1}{600}$, or the $\frac{1}{150000}$th of a square inch. The height of each letter is the $\frac{1}{10000}$th part of a linear inch, and therefore the space occupied by any letter, such as *u* or *n*, which are as wide as they are high, is no more than the *hundred millionth of a square inch!*[2]

Microscopic photographs by Mr Dancer.

Among the wonders of microscopic photography not the least interesting and useful are the fine microscopic portraits taken by Mr Dancer of Manchester, and copies of monumental inscriptions so minute, that the figures in the one, and the letters in the other, are invisible to the eye. A family group of seven complete portraits occupies a space the size of the head of a pin; so that *ten thousand* single portraits could be included in a square inch. They are executed upon films of collodion as transparent as glass; so that a family group could be placed in the centre of a brooch, a locket, or a ring, and magnified by the central jewel cut into a lens sufficient to exhibit the group distinctly when looked into or held up to the light.

Microscopic copies of despatches and valuable papers and plans might be transmitted by post, and secrets might be placed in spaces not larger than a full stop or a small blot of ink.

We have already had occasion to mention in the article MICROMETER the application of photography in making micrometers and micrometrical scales of all kinds; and it is obvious that groups of test-lines like those of Nobert could be produced upon transparent collodion with an accuracy and distinctness greater than could be done upon glass. The original groups, drawn on a large scale either by the hand or a ruling-machine, could thus be copied and reduced *ad infinitum*.

CHAPTER X.

ON TEST OR PROOF OBJECTS FOR TRYING THE PERFORMANCE OF MICROSCOPES.

Test-objects.

This class of objects, and their application to the microscope, we owe to Dr Goring; and to their introduction we must ascribe much of the rapid improvement which this instrument has undergone. The finest test-objects are the scales of butterflies and moths, which were suggested to Dr Goring by the following passage in Leuwenhoeck:—

Test-objects. Leuwenhoeck.

"If we examine the wings of this creature (the silk-worm moth, *Phalæna mori*) by the microscope, we shall find them covered with an incredible number of feathers (scales), of such various forms, that if a hundred or more of them were to be seen lying together, each would appear of a different shape. To show more clearly this wonderful object, I caused eight feathers to be delineated, for I do not remember that I ever saw them of so curious a make in any flying insect.

"Although the microscope by which these feathers were drawn represented objects very distinctly, *the limner could not through it see the ribs or streaks in each feather until I pointed them out to him.* Therefore I put into his hands a microscope which magnified objects almost as much as that by which the silk-worm's thread was drawn, desiring him to give the figure of that feather which through it he could see the most distinct."[1]

Dr Goring.

From this passage Dr Goring naturally inferred, that there were some peculiar properties in the lines on the feathers and scales of insects, which rendered them more difficult to be discovered than other microscopic objects; and hence he discovered their properties as *test* or proof objects for trying the penetrating powers of microscopes. Dr Goring regards the *penetrating*[2] power of a microscope as dependent on its angle of aperture, and its *defining* power as in the inverse ratio of the quantity of chromatic and spherical aberration. When the angle of aperture was less than a certain quantity, he found that the lined structure of the scales could not be rendered visible, however perfect the instrument was.

Mr Pritchard.

These new and apparently important results were confirmed by Mr Pritchard; and since that time opticians, both in this and in foreign countries, have contended with each other in producing object-glasses with the largest angles of aperture. Mr Ross, as we have seen, has produced object-glasses $\frac{1}{12}$th of an inch focus, with an angle of aperture of 170°; and in a communication to Mr Quekett[3] from Mr Ross himself, he gives a history of the steps by which he advanced to this remarkable angle:—

Angles of aperture.

	Focal length.	Angle of aperture.
1832 Mr Ross	1 inch	14°
1833 Do.	„	18
1834 Do.	$\frac{1}{4}$ „	55
1836 Do.	„	15
—— Do.	$\frac{1}{8}$ „	60
—— Do.	$\frac{1}{10}$ „	72
—— Do.	1 „	22
—— Do.	$\frac{1}{8}$ „	63
1842 Do.	$\frac{1}{2}$ „	44
—— Do.	$\frac{1}{4}$ „	67
—— Do.	$\frac{1}{8}$ „	74
1844 Professor Amici	$\frac{1}{7}$ „	112
—— Mr Ross	$\frac{1}{8}$ „	85
—— Do.	$\frac{1}{12}$ „	135
—— Do.	$\frac{1}{12}$ „	170
—— Do.	$\frac{1}{16}$ „	—

In closing his communication to Mr Quekett, Mr Ross remarks *that* 135° *is the largest angular pencil that can be passed through a microscopic object-glass*, and yet he had increased it in 1855 to 170°. Some writers speak of angular apertures of 175°, and even 180°!

---

[1] *Treatise on the Microscope*, 1856, chap. ii., p. 73.

[2] The ingenious machine invented by Mr Peters is described by Mr Farrants in the *Transactions of the Microscopical Society*, vol. iii., p. 55.

[1] *Select Works*, p. 63.

[2] Some writers have very unwisely substituted the term *resolving* in place of *penetrating*, and have applied the latter to a property of the microscope which all low powers possess; that is, seeing into an object, or seeing parts out of focus. The term *resolving*, applied to the telescope, is the power of separating minute luminous points.

[3] *Practical Treatise on the Microscope*, 1848, p. 430.

Angular aperture.

It is well known to every observer with the microscope that object-glasses of large angular aperture exhibit objects which are not seen with those of a smaller aperture and the same focal length; but it is equally well known that they often show objects *less distinctly than those of a smaller aperture.* This being the fact, we ask, What great advantage is derived from merely *seeing* that there are lines in an object, unless the object-glass shows us what is the nature and structure of these lines?

As instruments for studying structures and making useful discoveries with the microscope, let us compare the object-glass of large aperture with one of small aperture:—

1. It is obvious that, owing to the larger size of the lenses in the large-aperture lenses, the rays must pass through a much greater thickness of glass of *doubtful homogeneity.*

2. With large apertures, the spherical aberrations and the chromatic aberration, primary, and *secondary* especially, must be less perfectly corrected.

3. The surface of glass with the most perfect polish must have pores produced by the attrition of the polishing material, and light falling upon the sides of these pores with extreme obliquity must be refracted less perfectly than when incident at a greater angle.

Errors of large angular apertures.

4. The structures actually seen, however distinctly, and *even if the lenses are absolutely perfect*, are *false structures*, the falsehood of the picture being *proportional to the angle of aperture.*

This result, which the optician and the optical student will receive not only with scepticism, but we fear with disdain, as the photographers have done an analogous truth, may be illustrated in the following manner:—

It has been demonstrated[1] that all objects in relief are misrepresented by large lenses when their pictures are taken in the camera obscura. The human face divine is caricatured. Parts invisible are displayed, and parts visible are deformed. When Polyphemus admired Galatea she was not the beauty who fascinated Acis; and we think a national reward should be offered to the daring Ulysses who should extinguish the orb of every photographic Polyphemus in the land. But if the photographic lens thus deforms youth and beauty and age, and even trespasses upon inanimate nature, what may we not expect from the cyclopean eye of a twelfth-of-an-inch object-glass viewing microscopic objects in relief, several thousand times less in diameter, and so near it that it would see nearly the whole of its surface were it a sphere? For the purpose of illustration, we may suppose the microscopic object to be the head, in relief, of the Venus de Medicis, on a much smaller scale than the beautiful microscopic portraits of Mr Dancer of Manchester, and that the microscopical observer is requested to make a drawing of it. We cannot venture to say what would be its expression, but we are sure that it could have no resemblance to the original, both ears being fully brought out, and almost the whole round of the head. In like manner, every ridge in a microscopic object will show to the observer both its perpendicular sides as well as the side opposite the eye, and the resulting picture will be an incoincident combination of a thousand different pictures, as seen from every point of the object-glass. The reason is therefore obvious why a large aperture shows lines that are invisible with a small aperture. The relief of a bust, or of a relievo, either *basso* or *alto*, is best seen when we look at it in profile. Its height is then actually seen, whereas it is merely inferred when we look it full in the face. When the *raised* lines of a test-object are illuminated only obliquely, they are seen obliquely, and consequently much better than with a small aperture, which may not show them at all; not because the object-glass is inferior in penetrating power, but because the thing looked at in the one case is not the thing looked at in the other, and is actually a smaller object.

Errors of large angular apertures.

Hence the perfection of a microscope consists in its having the smallest angular aperture consistent with distinct vision. Such a microscope will not show certain objects of great minuteness, but it will give a perfect representation of what it does show. The large angular aperture will show the same objects, and others far more minute, but whatever it does show will be a mockery of the truth.

Admitting the truth of these observations, it follows that an observer who examines a microscopic structure in relief, and executes a correct drawing of it with an object-glass of *large* aperture and an eye-piece of *small* magnifying power, will obtain a very different and a much more correct drawing if, with the same magnifying power, he uses an object-glass of a *less* focal length of *small* aperture, and an eye-piece of a high magnifying power.

In the use of high magnifying powers obtained by object-glasses of short focal length we encounter another evil, well known to every microscopical observer. We can see only at one instant the parts of the object which are in the same focal plane, and by a fresh adjustment we see in succession the parts in other planes nearer to or farther from the object-glass.

New form of the microscope.

We are thus led to a new form of the microscope, in which object-glasses of large angular aperture should not be employed. In place of observing the object with such object-glasses, observe an image of the object formed with another achromatic object-glass with a proper angular aperture. This image may be the exact size of the object as produced by placing the object at a distance equal to twice its focal length, or it may be made greater by diminishing that distance, or less by increasing it. In all these cases the distance of the object from the first lens is so great that opaque objects may be illuminated by a Lieberkhun, or any method that may be preferred, and large objects may be submitted to examination to which the microscope in its present form cannot be applied. When the angular aperture is large, and the magnifying power great, the object approaches so near to the lens that the microscope becomes quite unfit for important physiological researches. It is unfit also for all researches in which experiments require to be made upon the objects under examination, for the examination of objects inclosed in minerals or other transparent bodies, and for objects in which there is any distance between their near and remote parts.

Mr. Pritchard's list of test-objects.

The following is the list of test-objects given by Mr Pritchard, and arranged in relation to *penetrating* and *defining* power,—a distinction which the preceding observations justify us in preserving; the word *penetrating* meaning nothing more than the effect produced by angular aperture:—

I.—PENETRATING POWER.

SECT. I. *Easy.*
1. Petrobius maritimus, scales of.
2. Lepisma saccharina, scales of.

SECT. II. *Standard.*
1. Morpho Menelaus, feathers of.
2. Alacita pentadactyla, feathers of the.
3. Alacita hexadactyla, feathers from the body of it.
4. Lycænæ Argus, feathers of the.
5. Tinea vestianella, or clothes-moth, feathers from under ends of the wing.

SECT. III. *Difficult.*
1. Pieris or Pontia brassica, or cabbage-butterfly, feathers from the.
2. Podura plumbea, scales from the.

II.—DEFINING POWER.

1. Hair of the common mouse.
2. Hair of the bat genus.
3. Leaf of the moss Hypnum, species unknown.
4. Spotted scales of the Lycænæ Argus.

---

[1] Brewster's *Optics*, chap. vii., p. 65, edit. of 1853.

Since the publication of Mr Pritchard's *Micrographia* the microscope has undergone great improvements, and the structure of test-objects has been more successfully examined. Mr Quekett, in his treatise of 1848, has given the following list of test-objects as furnished by Mr Topping:[1]—

Hairs.

Bat.
Larva of Dermestes.
Mole.
Mouse.
Rabbit.
Squirrel.

Scales.

Azure blue, P. argiolus.
... P. Argus.
Pontia brassica.
Vanessa Io.
Morpho Menelaus.
Alacita pentadactyla.
Catocala nupta.

Scales.

Tinea vestianella.
Lepisma saccharina.
Podura plumbea.
... aquatica.
Hipparchia janira.
Plumed gnat.

Infusoriæ.

Navicula hippocampus.
... Spenceri.
... angulata (Humber.)
... ... (America.)
Tripoli from Kritchelberg.

Muscular fibre.

From each class of these test-objects Mr Quekett has selected a certain number, and given in four plates highly-magnified representations of them, which exhibit great skill in the engraver, and still more in the artist, Mr Leonards. The magnifying power employed was sometimes 2000 diameters.

Plate of test-objects.

Very fine drawings of test-objects have been recently made by Dr Griffith, one of the able authors of the *Micrographic Dictionary.* Those drawings, which we have been kindly permitted to copy, occupy the first eighteen figures of Plate XX. We have added to these figures a few from Mr Quekett's practical *Treatise on the Microscope*,[2] the best work on the subject which has appeared in our language.

The following is a particular description of Plate XX:—

Fig. 1. The hairs of the larva of *Dermestes lardarius*, placed in Canada balsam.
2. Hairs of the common bat (*Vespertilio pipistrellus*), in balsam. *a*, *b*, coloured hairs; *c*, a white hair.
3. Hairs of mouse (*Mus domesticus*), in balsam.
4. Pits of coniferous wood, common deal (*Abies excelsa*), viewed dry.
5. Mucus (or salivary corpuscles), seen with different powers.
6. Scales of *Lepisma saccharina*, dry.
7. Scale from the wing of *Morpho Menelaus*, dry.
8. Scale from under side of wing of common clothes-moth (*Tinea vestianella*), dry.
9. Scales of *Hipparchia janira*: *a*, dry, and by oblique light; *b*, in balsam, by direct light; *c*, dry, after Schacht.
10. *Didymohelix ferruginea*, under different powers: *b*, with imperfect adjustment; *c*, with perfect adjustment; *d*, separate fibres.
11. *Didymoprium Borreri*, empty cells.
12. Scales of *Podura plumbea* under different powers: *a*, 220 diameters.
13. *Pygidium of flea.*
14. Frustule of *Grammatophora marina*: *a*, front view; *b*, side view.
15. Frustule of *Grammatophora subtilissima*: *a*, front view; *b*, side view.
16. *Gyrosigma angulatum*; dry valve showing the dots.
17. *Gyrosigma attenuatum*; dry valve showing the lines.
18. *Gyrosigma elongatum*; dry valve showing the lines.

The following ten figures are from Mr Quekett's plates:—

19. Hair of a species of bat from India.
20. *a*, Large scale from *Podura plumbea*; *b*, the same magnified 1250 diameters.
21. *Navicula Spenceri* as drawn by Mr Warren de la Rue, magnified 1900 diameters. Mr Spencer saw lines only with the power of 800; M. de la Rue saw the dots as holes or depressions.
22. *Navicula angulata*: *a*, magnified 1200 diameters; *b*, magnified 2000 diameters.
23. Ultimate fibrillæ of muscular fibre. Their true structure is shown in *b*, *d*, *f*.
24. Scale from the wing of the male *Pontia brassica*, dry.
25. Portion of wing of *Pontia brassica*, showing the imbrication of the scales.
26. Portion of valve of *Gyrosigma strigosum*, magnified 1800 and 4700 diameters.

The following observations, showing the relation between the magnifying powers and angles of apertures of English microscopes, and the objects most useful for testing object-glasses, have been given by Dr Griffith and Professor Henfrey.[1] The magnifying power is given in diameters:—

1. *Object-glass* $1\frac{1}{2}$ *or* 2 *Inches.*—Magnifying power, 20; aperture, 12° to 20°. *Test-objects:* The pygidium of the flea, Plate XX., fig. 13, *a*—the outline and the hairs should be distinct; the hair of the mouse, fig. 3.
2. 1-*Inch or* $\frac{2}{3}$*ds Object-glass.*—Magnifying power, 60; aperture, 22° to 27°. *Tests:* Hair of Dermestes, fig. 1; of bat, fig. 2; the pygidium of the flea, the outline of the areolæ being distinguishable under the high eye-piece with power 120 to 200, but not the rays.
3. $\frac{1}{2}$-*Inch or* $\frac{4}{10}$*th-Inch Object-glass.*—Magnifying power, 100 to 200; aperture, 55°. *Tests:* Hairs, figs. 1, 2, 3; disks on deal, fig. 4; the coarser scales of Lepisma, fig. 6, *a*; the pygidium of the flea, fig. 13, *a*, *b*, the entire structure being visible with the high eye-piece; a dark scale of Podura, fig. 12, *a*.
4. $\frac{1}{4}$*th-Inch Object-glass.*—Magnifying power, 220; aperture, 75° to 140°. *Tests:* The hair of Dermestes; disks of deal; salivary corpuscles, fig. 5, the moving molecules being clearly distinguishable; the smaller scales of Lepisma, fig. 6, *a*, *b*; the scales of Podura; filaments of Didymohelix, fig. 10, *a*; the pygidium of the flea, and the scales of Pontia brassica, fig. 26.
5. $\frac{1}{8}$*th-Inch Object-glass.*—Magnifying power, 420 to 450; aperture, 110° to 150°. *Tests:* The paler scales of Podura; the pygidium of the flea; the scales of Pontia brassica; the filaments of Didymohelix, showing the component fibres; the salivary corpuscles.
6. $\frac{1}{12}$*th or* $\frac{1}{16}$*th-Inch Object-glass.*—Magnifying power, 600 to 650; angular aperture, 80° to 120°. *Tests:* The paler scales of Podura; the filaments of Didymohelix, mounted in balsam; and the ultimate fibrillæ of muscular fibre, fig. 27.

Different writers have proposed different objects for testing microscopes. The test employed by Professor Amici is the exhibition of the lines on the *Navicula gracilis*, which the writer of this saw beautifully displayed by the professor himself. It is a good test for angular apertures.

Mohl uses the scales of *Hipparchia janira* for testing penetrating power; and pollen grains, the scaly elytra of the diamond beetle, or bat's hair, for testing definition.

Nobert's test-lines.

The most perfect of all tests are the test-lines of M. Nobert of Barth in Prussia.[2] These tests consist of ten separate bands of parallel lines, traced upon glass with the point of a diamond, the lines being drawn closer and closer to each other, from No. I., where they are widest, to No. X., where they are closest, varying, as shown in the following table, from the 11,000th to the 50,000th of an inch:—

	Thousandths of an English inch.		Thousandths of an English inch.
No. I.	11,265	No. VI.	24,309
II.	13,142	VII.	28,433
III.	15,332	VIII.	33,153
IV.	17,873	IX.	38,613
V.	20,853	X.	49,910

All these bands are engraven on the same plates of glass; and when seen by the naked eye they appear like the small black line *mn* in the annexed fig., ABCD being the size of the plates of glass on which they are engraven.

---

[1] New Winchester Street, Pentonville. Mr Norman, Fountain Place, City Road, also supplies excellent sets of test objects.

[2] This work forms vol. vi. of Mr Bailliere's *Library of Illustrated Standard Scientific Works*, a collection of treatises of very rare merit.

[1] *Micrographic Dictionary*, art. *Test Objects*, p. 636, 637.

[2] See *Poggendorff's Annalen der Physik*, 1846.

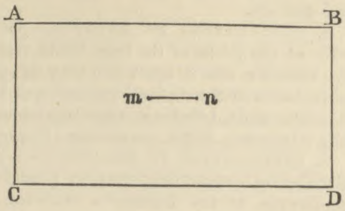

Fig. 100.

The subdivision of an inch has been more recently carried farther by M. Nobert. In a plate of fifteen bands the lines amount to *fifty-six thousand* in an inch. The following table, calculated by Mr Warren de la Rue, shows not only the number of the lines, but their distance also, in parts of an English inch:—

	Distances.	Number of Lines.
No. I.	0·00008880	11261
II.	0·00007548	13248
III.	0·00006482	15427
IV.	0·00005506	18162
V.	0·00004884	20475
VI.	0·00004202	23463
VII.	0·00003552	28153
VIII.	0·00003108	32175
IX.	0·00002664	37537
X.	0·00002442	40950
XI.	0·00002220	45045
XII.	0·00002113	47326
XIII.	0·00001998	50056
XIV.	0·00001891	52882
XV.	0·00001776	56306

The resolution of these lines is regarded as the best test for angular aperture and oblique light. Dr Griffith states that even the group of the 60,000 (56,306 in the above table) can be resolved by the ⅛th of an inch object-glass, and he considered the resolution of it "much easier than that of the markings upon the valves of many of the Diatomaceæ." A considerable difference of opinion exists respecting the magnifying power necessary to resolve different groups of these lines.[1]

CHAPTER XII.

ON MICROSCOPIC OBJECTS.

Microscopic objects.

In the preceding chapter we have already described some of the most interesting objects for microscopical observation. Every department of nature is full of objects, from the examination of which the most important discoveries may be expected; but though the zealous observer can never be at any loss for subjects of research, it is desirable to know what has been done by our predecessors, and what trains of inquiry are most likely to prove of general interest. There are subjects of microscopic inquiry which are closely connected with the most interesting parts of physiology; and even geology itself, conversant with the grandest subjects of research, has recently been illustrated by the aid of the microscope.

Ehrenberg's discoveries.

Dr Ehrenberg of Berlin, to whom we are indebted for so many important discoveries respecting the organization of infusorial animalcules,[2] has made the most remarkable discovery of *infusorial organic remains*. These remains are the siliceous shells of animalcules belonging to the division Bacillaria, and form strata of tripoli, or polischiefer (polishing-slate), at Franzenbad in Bohemia.[3] M. Ehrenberg has more recently discovered them in the semi-opal found along with the polishing-slate in the tertiary strata of Bilin, in the chalk flints, and even in the semi-opal or noble opal of the porphyritic rocks.[1] The size of a single individual of these animals is about $\frac{1}{288}$th of a line, or $\frac{1}{3456}$th of an inch. In the polishing-slate from Bilin, in which there appear to be no vacuities, *a cubic line* contains, in round numbers, 23,000,000 of these animals, and *a cubic inch* contains 41,000,000,000 of them!

The weight of a cubic inch of the polishing-slate is 270 grains. There are therefore 187,000,000 of these animals in a single grain, or the siliceous coat of one of these animals weighs the 187,000,000th part of a grain!

In the annexed figure we have given representations of these singular microscopic objects, as seen by Ehrenberg. The siliceous shells found in the Franzenbad poli-schiefer are much more distinct than those found in the Bilin strata.

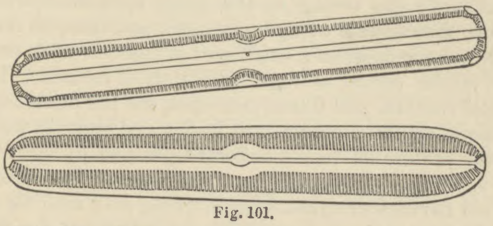

Fig. 101.

Fibres of the crystalline lenses of fishes.

Another example of the value of microscopical observations may be drawn from the discovery of the teeth of the fibres which compose the crystalline lenses of almost all animals. The crystalline lens is composed of innumerable fibres of nearly the same length, each of which tapers from its middle to its two extremities, where it comes to the sharpest point. The sides of each of these fibres are furnished with teeth like those of a watch-wheel, and the teeth of the one lock into those of the adjacent ones, as shown in the annexed figure. When the power is small, or the microscope not good, or the laminæ too thick, and not nicely detached, each row of interlocking teeth appears as a dark line, sometimes as sharp as a black line drawn upon paper with a pen. Sometimes the lines appear rough and ragged; and as the fibres become less and less in approaching the poles, the black lines are as difficult to resolve into teeth as the lines on test-objects already described. The following measures, taken by Sir David Brewster, will show what a wonderful structure in the eye has been thus disclosed to us by the microscope. The calculations refer to the lens of a cod, 4-10ths of an inch in diameter:—

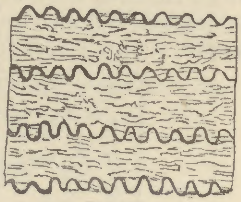

Fig. 102.

Number of fibres in each lamina or spherical coat	2,500
,, teeth in each fibre	12,500
,, teeth in each spherical coat	31,250,000
,, fibres in the whole lens	5,000,000
,, teeth in the lens	62,500,000,000

or the lens of a cod contains five millions of fibres and sixty-two thousand five hundred millions of teeth; and if we reckon the curved end of the tooth as one surface, each tooth will have six surfaces,[2] which come into contact with the corresponding surfaces of the adjacent tooth, so that the number of touching surfaces will be *three hundred and seventy-five thousand millions*;[3] "and yet this little sphere of tender jelly is as transparent as a drop of the purest water, and allows a beam of light to pass across these almost innumerable joints without obstructing or reflecting a single ray!"

There is another class of objects of extreme interest,

Microscopic cavities in minerals.

which Mr Pritchard and other writers have omitted to notice, and the development of which calls forth all the resources of optical knowledge and optical experience with the microscope. These objects are the microscopic cavities in minerals, containing two fluids unknown to the chemist; groups of crystals of different forms, and floating balls, and exhibiting actual chemical operations going on in these minute laboratories when exposed to changes of temperature. These various phenomena have been described and represented in drawings, in two papers by Sir David Brewster published in the *Transactions of the Royal Society of Edinburgh*.[1] In some of the precious stones, particularly in diamond, garnet, &c., these cavities are perfect spheres; but owing to the great refractive power of the gem, they appear completely black and opaque, though the microscope descries a small spot of light in their centre, which is the pencil of light which they refract. These spherical cavities, and this central spot, are the finest objects for examining the aberration of lenses and specula, and are infinitely preferable to the reflected patches of light from small spherules of quicksilver. Dr Goring has observed spherical cavities or air-bubbles in fluids, and, with his usual ingenuity, recognised their utility for indicating the effects of aberration. Those which we have used in the gems are, however, permanent instruments of much greater utility, not only from our being able to use the same bright spot with all instruments and on all occasions, but from the dark ring round the bright spot being incomparably greater in the gems than in fluids.[2] Representations of some of the cavities containing the two new fluids, which will not mix, though in the same cavity, are given in fig. 103. The little white circle is the bubble either of gas or of vacuity. The fluid round it, shown by dots, is a highly evaporable fluid, and the fluid in the angles and ends of the long cavities, shown by the shading, is a thick and unevaporable fluid, which indurates when exposed to the air. These cavities lie in strata, and millions of them, which no microscope can resolve, occupy a very small area.

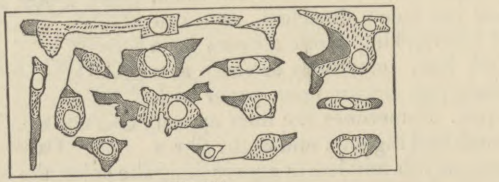

Fig. 103.

List of microscopic objects.

Our limits will not permit us to pursue this subject further, and we shall conclude the article with a very brief selection of microscopic objects from Mr Pritchard's admirable little pamphlet, entitled *A List of Two Thousand Microscopic Objects.*

1. Insects (eggs, wings, tongues, antennæ, and scales of).
   Eyes of Agrion, 12,000 eyes; Bombyx mer, 6236 eyes; Phalæna cossus, 11,300; Scarabæus, 3180; Hawk-moth, 20,000; Libellula, 12,544; Melalontha, 8820; Mordella, 25,088; Papilio, 17,000.

2. Hairs of Animals.—Hair of an infant, Ornithorynchus, mouse, bat, bee, Acilius canaliculatus, Melecta punctatus, Siberian fox, spider, wing of Tipalis, stag-beetle, white cat, dormouse, dermestes, caterpillar, badger, ant-eater, civet cat.

3. Sçales of Insects.—Podura plumbea, Pontia brassica, Pieris brassica, Parnassus Apollo, Atlas moth, diamond-beetle, Euplœa limniacæ, house-moth, Lepisma saccharina, 10-plumed moth, 20-plumed moth, Morpho Menelaus, Papilio Apollo, Papilio Paris, Urania leilus, privet-moth.

4. Circulation in Plants, or *Cyclosis*.—Nitella hyalina, Nitella translucens, Chara vulgaris, Caulinia frigalis, Hydrocharis or frogbit in the stipulæ of the leaves and the ends of the roots, Tradescantia virginica or spiderwort in the filaments around the stamina, Senecio vulgaris or groundsel in the hairs surrounding the stalks and flowers.

5. Circulation in Animals.—In the arachnoidæ or spider tribe at the joints of the legs, Peria viridis and Semblis bilineata on the antennæ and wings when they have just emerged from the chrysalis, larva of the Ephemera, larva of Hydrophilus, small Dysticus, Agrion puella, Libellula, round Lynceus, fresh-water shrimp, water-hog (Oniscus), Ligia, water-flea (Daphnia pulex).

6. Circulation in Zoophytes.—Mr Lister has discovered a circulation resembling that in plants in some of the polypiferous zoophytes, as the Tabularia indivisa, Sertulariæ, Campanulariæ, Plumulariæ, &c.

7. Crystals.—For an account of various interesting microscopic phenomena observed by H. F. Talbot, Esq. of Lacock Abbey, we must refer the reader to a series of papers in the recent numbers of the *London and Edinburgh Philosophical Magazine*, and to others which will be found in the *Philosophical Transactions*.

The oxalate of chromium and potash dissolved in water, and rapidly crystallized, is a fine object. In polarized light a very splendid object is the Faro apophyllite, when the prisms are complete, as represented by Sir David Brewster in a coloured drawing in the *Edinburgh Transactions*, vol. ix., p. 317, plate xxi., fig. 1. But the most beautiful of all objects, as seen by polarized light, are the circular crystals, first described by Mr Talbot, as produced by a peculiar process. In a recent paper "On Circular Crystals," by Sir David Brewster,[1] no fewer than about eight circular crystals have been described, with twenty-five coloured drawings of the most interesting. Several of these are to be found in the slides sold by the preparers of microscopic objects.

8. Animalcules:—

Monas Termo, 18,000th of an inch.
Monus atomus, 4000th of an inch.
Monas volvox, 3456th to 1728th of an inch.
Volvox globator, found in stagnant water, 30th of an inch.
Vibrio bipunctatus, 200th of an inch.
Vibrio spirillum, like a screw, 2000th to 1000th of an inch.
Vibrio glutinis.[2]
Kolpoda cucullus, 28th of an inch.
Cercaria podura.
Cercaria viridis.
Cercaria hirta.
Leucophrys fluida, 400th of an inch.
Trichoda vulgaris, 1200th to 240th of an inch.
Trichoda longicauda.
Vorticella polymorpha.
Vorticella convallaria.
Vorticella senta, 100th of an inch.
Vorticella rotatoria.[3]

References to works on microscopic objects.

The reader will find beautiful drawings and full descriptions of these and many other animalcules in Mr Pritchard's interesting work entitled *The Natural History of Animalcules*, London 1834; in the *Microscopical Illustrations* of Mr Pritchard and Dr Goring; and in the *Microscopic Cabinet* by the same authors he will find much information respecting microscopic objects.

In the more recent work of Ehrenberg, Quekett, and Lardner, already cited; in Pritchard's large work recently published, entitled *A History of Infusorial Animalcules, Living and Fossil*, illustrated with 24 plates; and in Dr Griffith and Professor Henfrey's *Micrographic Dictionary*, the reader will find everything that he desires. This last work is illustrated with no fewer than 41 engravings and coloured plates, and with 816 wood-cuts admirably executed; and owing to these illustrations and its alphabetical arrangement, the general reader will find in it a store of easily-accessible and popular information, apart from its science, which cannot fail to amuse and instruct him. (D. B.)

MIDAS, in Greek mythology, a king of Phrygia, was the son of Gordius, and, according to some authorities, of Cybele. He seems to have been a disciple of Orpheus; and, like him, a worshipper of Dionysus. When that deity was passing through Phrygia, on his way from Thrace, Silenus, who accompanied him, having become intoxicated, was found in the gardens of Midas, and brought before the king, who received him hospitably, and sent him back to Dionysus. In return for this, the god desired Midas to ask whatever favour he wished. He accordingly requested that he might have the power of turning whatever he touched into gold. This favour was granted; but Midas finding that he ran the risk of being starved, from his food and drink being changed into gold, he begged the god to recall his gift. He was accordingly directed to wash in the river Pactolus, which ever after had gold in great abundance among its sands. Another legend of Midas is, that having been appointed judge in a musical contest between Apollo and Pan, he decided in favour of the latter; whereupon Apollo in revenge gave him the ears of an ass. These Midas endeavoured to conceal under his cap, but was obliged to disclose the disagreeable fact to his barber, who being bound to secresy, and yet unable to keep his discovery to himself, dug a hole in the earth, and having whispered into it the singular intelligence, closed it up again. But there seemed to be a fate in it, for the very seeds which grew from the spot murmured in a low tone as they rustled in the wind, "King Midas has the ears of an ass;" and thus disclosed to the world the deformity and disgrace of the monarch. Midas seems to have been a common title of the reigning dynasty in Phrygia; and a king of that name is mentioned by Herodotus as having sent offerings to the temple of Apollo at Delphi.

MIDDLEBURG, a town of Holland, capital of the province of Zealand, is situated near the centre of the island of Walcheren, 4 miles N.E. of Flushing. It is surrounded by a bastioned mound of earth and by a broad and deep ditch. It is partly intersected by canals, and has a small harbour, being connected with the West Scheldt by a canal. The town is generally well built, and has wide and regular streets. Among the public buildings are—the town-house, an elegant Gothic building; St Peter's church and the Abbey church, both containing fine paintings and monuments; a Jewish synagogue; and an exchange. Its institutions comprise an athenæum, Latin school, school of design, museum, public library, and agricultural society. The manufactures, including starch, glass, paper, salt, &c., are considerable; and an active import trade in wine, and export trade in corn, is carried on. Pop. (1855) 16,253.

MIDDLESBOROUGH, a town and river-port of England, in the North Riding of Yorkshire, on the River Tees, not far from its mouth, and about 3 miles E.N.E. of Stockton, with which it is connected by railway. Little more than twenty years ago the site of Middlesborough was occupied by a solitary farm-house. It is now the most considerable port on the Tees, though still reckoned as subordinate to Stockton. It owes its rise chiefly to its convenient situation as a port for the shipment of coals. There are commodious docks, ship-building yards, foundries, rope-walks, sail-cloth manufactories, ironworks, &c. The church of St Hilda, erected in 1840, is an elegant Gothic structure surmounted by a spire. There is also a national school, observatory, reading-room, mechanics' institute, and savings-bank. Pop. (1851) 7431.

MIDDLESEX, the metropolitan county of England, the smallest in size, with the exception of Rutland, and the greatest in density of population, wealth, and importance. London, the capital of England is situated in its S.E. corner. The county is bounded on the N. by Hertfordshire, on the E. by Essex, on the S.E. by Kent, on the S. by Surrey, and on the W. by Buckinghamshire. The eastern boundary is formed by the River Lea, the southern by the Thames, and the western by the Colne. The shape of the county is very irregular: in the N.E. a spur of Herts penetrates deeply within its boundaries, and on the S.W. a large portion of the county projects into Surrey. The greatest length of the county is from near Waltham Abbey in the N.E. to Chertsey in the S.W., 28 miles; and its greatest breadth from near Rickmansworth in the N.W. to the Isle of Dogs in the S.E., 17 miles. The area of the county is 180,168 statute acres, or about 282 square miles.

The surface of the county is a sloping plain, bounded by a range of hills about 400 feet high: these hills partly form its northern boundary. There are some gentle undulations of the ground, of which Hampstead is one; but the general aspect of the county is flat, and would be monotonous if it were not diversified by buildings, gardens, and the rich verdure which high cultivation imparts to vegetation. Neither is the landscape picturesque, as seen from the hills; but the most pleasing view is obtained at Harrow, an insulated hill overlooking the whole county, and the seat of the famous seminary.

The county is entirely situated within the basin of the Thames. The substratum consists of the blue clay known as London clay, lying in the great chalk basin extending from Berkshire to the east coast, and it varies in thickness from 40 to 240 feet. The only exceptions to this formation are at Uxbridge, on the western boundary, and at Enfield, in the N.E. corner of the county, where the plastic clay crops out. The hills consist of sand and gravel, and have been formed by the sea. The soil in the northern part of the county is a clayey loam, difficult to plough, and indeed altogether unfit for cultivation until chalk, lime, and ashes have been incorporated with it; and in the southern part it is formed by gravel, which is naturally very sterile, but which, being enriched by the vast quantities of manure afforded by London, is converted into a garden mould of prodigious fertility. The soil is generally dry; and the temperature being raised by the chimneys of London, the climate is remarkably healthy.

The rivers of the county are,—the Cray, the Colne, the Brent, the Lea, and the Thames. The Cray rises within the county, near Harrow, and, after a very eccentric course of twenty miles, falls into the Thames at Isleworth. The Colne enters the county from Herts, near Rickmansworth, and flows by Watford, Harefield, Uxbridge, and Colnbrook, throwing off several branches; but the main stream falls into the Thames at Staines. The length of its course within the county is 18 miles. This river, though small and devoid of beauty, is sacred to the admirers of genius, for on its banks Milton lived and composed some of his great poems. The Lea enters the county from Essex at Walthamstow, and flows by Stamford Hill, Tottenham, Bow, and Bromley, into the Thames at Limehouse, after a course of about 18 miles within the county. The first stone bridge built in England stood on the river at Stratford-le-Bow, and its curved form gave the village its familiar name of Bow. The Brent rises on the northern boundary of the county, near Monken-Hadley, and flows through its centre, by Finchley, Hendon, Kingsbury, Twyford, and Hanwell, to Brentford in the W., and after a course of 20 miles falls into the Thames. The Cray and the Colne are not navigable. The lower part of the Brent forms a portion of the Grand Junction Canal; and the Lea is rendered navigable by a series of artificial cuts. The Thames, "great father of the British floods," enters Middlesex a sylvan river. It reaches the county at Staines, and flows by Shepperton, Kew, and Kingston, in many a mazy fold to London, and here it joins the sea. The length of its course within the county is about 15 miles. The Thames is rendered navigable for barges within a short distance of its sources in Gloucestershire by a series of locks and weirs, the lowest of which is at Teddington, within the county, where the tide is felt at high water. The Thames is crossed by 13 bridges below this point, viz., Richmond, Kew, Hammersmith, Putney, Battersea, Chelsea, Vauxhall, Westminster, Hungerford, Waterloo, Blackfriars, Southwark, and London bridges; and there is also a communication between the opposite banks by a tunnel carried under the bed of the river, 2 miles below London Bridge, and in the centre of the shipping. The port of London, consisting of the upper, middle, and lower port, lies between London Bridge and Limehouse; but for legal purposes it is extended for 6½ miles below the bridge to a point beyond Blackwall called Bugsby's Hole. Other articles in this work render it unnecessary to describe here the vast population, the features, and operations of the great and wonderful city which lies stretched along the banks of the Thames for 7 miles, the lines of wharfs, the capacious docks, the gigantic warehouses, the cellars, measured in acres, the dockyards, the defences, the public establishments, and all the other wonders of what, to use the words of M. Say, " is no longer a city, but a province covered with houses." (See LONDON.)

The facilities of inland navigation which the Thames and the Lea afford are increased by two canals, which conjointly traverse the county from end to end. The chief is the Grand Junction Canal, opening out of the Thames at Brentford, and passing by Crayford, Hanwell, West Drayton, and Uxbridge, from whence it enters Herts, and ultimately communicates with the Irish Sea. At Crayford this canal throws off a branch which passes by Twyford to Paddington, and there it joins the Regent's Park Canal, which traverses Camden Town, Islington, Hackney, Mile-end, and communicates with the Thames at Limehouse. The most remarkable artificial water-course in the county is the New River, constructed by Sir Hugh Myddleton to convey pure water into the city of London. He chose for the fountain-head some springs of water, very copious and beautifully clear, at Ware in Herts; and from thence carried to London, through hills and deep cuttings, over valleys in wooden troughs, and by a serpentine channel 37 miles long, a stream of pure water on the average 24 feet wide, 4 deep, and flowing with a fall of 3 feet per mile. The New River was completed five and a half years after its commencement, and was put in operation with much ceremony, on the 29th of September 1613. The stream has since been enlarged by adding to it some of the water of the River Lea, which runs parallel to its course, and close to its banks at some points, and two large purifying reservoirs have been constructed at Stoke-Newington.

The county is completely intersected by railways issuing out of the metropolis. The London and North-Western Railway traverses it from the Isle of Dogs, passing by Camden Town, Kilburn, Willesden, Sudbury, Harrow, and Pinner, into Hertfordshire near Watford; the Great Northern Railway, from King's Cross, by Holloway, Hornsey, and Barnet, passing into Herts near Hatfield; the Eastern Counties Railway, from Shoreditch, by Stratford-le-Bow, Leabridge, Tottenham, and Enfield, and also passing into Herts near Waltham Cross; the Great Western Railway, from Paddington, passing by Ealing, Hanwell, Southall, West Drayton, and Uxbridge, into Buckinghamshire; and the London and South-Western Railway, which crosses the Thames from the Surrey side of the metropolis at Barnes, and passes by Kew, Brentford, Isleworth, Hounslow, and Staines, also into Bucks. These lines are linked together by branches; and it may be added that several other railways connect the Surrey side of the metropolis with the eastern and southern coasts.

Middlesex possesses no agricultural importance, its cultivated land being the mere fringe of a great metropolis. That part of it which is not encumbered with buildings and ornamental grounds is mainly converted into gardens and grass lands. Spade husbandry and an abundant application of manure compensate for the natural sterility of the soil; the ground is converted into a hotbed, and crop after crop is obtained without intermission, yet without exhausting the soil. Two, and sometimes even three crops are grown at once: an upper crop, as it is called, consisting of apples, cherries, pears, plums, and walnuts; an under crop, consisting of currants, gooseberries, raspberries, strawberries, and other fruit which will thrive in the shade uninjured by the dripping of trees; and a third crop, consisting of esculent vegetables, placed between the other two. The garden walls are also clothed with fruit trees adapted to the aspect they present, such as apricots, nectarines, peaches, and plums. The ground is also sometimes raised in banks sloping to the sun, in order to give it increased warmth and shelter in autumn, and thereby augment its productiveness. In short, by continual manuring, stirring, and moving the soil, sterility is replaced by fertility, crops succeed each other without a moment's respite, and a garden of 10 acres is rendered as profitable as a farm ten times that size.

The extent of the farms averages about 100 acres, the majority of them being below that area; and rents average 40s. an acre. A skilfully managed farm at Willesden, consisting of 100 acres of grass land, is let at 60s. an acre; the tenant paying besides 15s. an acre for tithes and taxes. White and green crops are grown alternately; but the rotation is so irregular that no general description can be given. The arable land, when thoroughly pulverized, produces wheat of good quality. Potatoes are not so much grown as might have been expected, considering the almost insatiable demand of the metropolis; distant counties, in which rent is lower and labour not so highly paid, being enabled by superior cheapness to monopolize the market. Haymaking in this county is not the simple operation which it is in other counties. The grass is constantly shaken, moved, and exposed to the action of sun and wind, by the aid of machines and a large number of labourers; thus, the quality is heightened, and when cut out of the mow, the hay exhibits a bright green colour. The spring crop averages 2 tons per acre, and the aftermath about half that quantity. The farm at Willesden, already noticed, produced no less than 6 tons per acre, there being nine cuttings in the year. The grass lands of the county are generally well manured after the first mowing, and provided with water-furrows when the closeness of the soil renders it impervious. Under-draining is, however, much neglected, and in consequence the clay land is so wet that stock cannot safely be put on it after October. On the whole, Middlesex is backward as regards farming; in common, however, with the adjacent counties. " The state of agriculture which prevails in the surrounding counties," says M. Lavargne, "makes itself felt up to the very gates of the greatest existing centre of consumption." But this may be said in explanation of the apparent anomaly, —that though the distance between the metropolis and the farms is small, the advantage is greatly diminished by the cost of bringing manure along crowded thoroughfares.

The clay soil itself in many parts of the county is turned into produce. *Breeze*, the technical term for cinders, is mixed with the clay, and the compound is baked into bricks, for which an enormous demand is created by the unceasing growth of the metropolis; and brickmaking is probably the most profitable mode of employing the soil. After the soil has been manufactured into buildings in this way, yielding from L.4000 to L.20,000 per acre, the excavations are levelled, ploughed, and manured, and the surface is converted into grass land.

Very few cattle are kept for farming purposes, as it is more profitable to buy manure, and in consequence root crops are not much grown. About 15,000 cows are, however, kept in London and its environs, for the supply of milk and cream. Though every kind of breed may be met with in the county, the short-horn or Holderness is preferred, because it yields the heaviest carcass to the butcher. The cows being highly fed, increase in weight while they continue to give milk, and when they become dry are fat and fit for market. Grass lands near London of course acquire a high value from the number of milch cows and horses kept to supply the wants of that great city; they are used for grazing as well as haymaking, thousands of over-worked horses being annually turned out to grass during the season.

The manufactures of the county are concentrated in the metropolis, which, however, is rather a great exchange than a seat of industry. The silk manufacture is extensively carried on in Bethnal Green, Spitalfields, and at Mile-end; sugar-refining in Whitechapel; and watch and clock-making in Clerkenwell; and there are large manufactures of shoes, cutlery, plate, printing-type, soap, spirits, vinegar, &c., which have no particular locality. A large number of ships is also built within the port of London. But the greatest manufacture of all, and the distinctive feature of the metropolis, is the brewing of the favourite beverages of the metropolitan population—ale and porter. The consumption of malt by the brewers within the London revenue district annually amounts to upwards of 6,000,000 quarters. It is estimated that 1,200,000 barrels, or 43,200,000 gallons of ale and porter are brewed for London consumption alone; besides a great quantity sent to other parts of the United Kingdom and exported to the Continent, the United States, and the East and West Indies. The principal brewers produce from 200,000 to 270,000 barrels a-year.

The county is divided into 6 hundreds, and 208 parishes, of which 118 are within the cities of London and Westminster. For ecclesiastical purposes, it forms part of the diocese of London, and is divided into the archdeaconries of London and Middlesex. The total number of places of worship in 1851 was 962, with 572,338 sittings. Of these 419, with 344,489 sittings, belonged to the Church of England; 155, with 84,514 sittings, to Independents; 102 to Baptists; 119 to Methodists; 32 to Roman Catholics; 16 to Mormons; and 9 to Jews. There were 3427 day schools; having 200,257 scholars, of whom 110,861 were males, and 89,396 females;—772 of these, with 138,108 scholars, were public day schools; and 2655, with 62,149 scholars, private day schools. Sunday schools 589, with 111,595 scholars. The county returns 2 members to parliament, the city of London 4, of Westminster 2, the three boroughs, 2 each; in all 14.

The population of the county was in 1821, 1,345,067; 1831, 1,358,330; 1841, 1,576,636; 1851, 1,886,576. The population of the cities, boroughs, market-towns, and other places was,—city of London, 127,869; city of Westminster, 241,611; borough of Marylebone, 370,957; borough of Finsbury, 323,772; borough of Tower Hamlets, 539,111; Brentford, 8870; Staines, 2430; Uxbridge, 3593. The number of houses in the county in 1851 was 251,236, of which 11,874 were building. The amount of real property rated to the property tax, was L.13,867,829. (F. C.)

MIDDLETON, Conyers, D.D., a celebrated English divine, was the son of the Rev. William Middleton, rector of Hinderwell in Yorkshire, and was born at Richmond on the 27th December 1683. At the age of seventeen he was admitted a pensioner of Trinity College, Cambridge, and after being chosen a scholar of his college, and gaining a bachelor's degree in 1702, he took deacon's orders, and exercised the clerical function for some time at Trumpington, near Cambridge. Having been elected a fellow of Trinity in 1706, he took the degree of M.A. during the following year; and in 1708 joined some of the fellows of his college in a petition to the Bishop of Ely, their visitor, against Bentley, the celebrated master of Trinity. Middleton did not at first take a very active part in this painful contest; yet the unpopular master soon saw in this strong, fiery youth one of his most dangerous enemies, and Bentley's partizans made an early attempt to blast his reputation. Such an attack only increased Middleton's popularity in the university, while it served to deepen his hostility towards the irascible and imperious scholar. After his marriage he held a small rectory in the Isle of Ely, in the gift of his wife, but was soon compelled, from the unhealthiness of the place, to return to Cambridge. Middleton, with a number of others, was created Doctor of Divinity by the royal mandate of George I., who visited Cambridge in 1717; but Bentley, who was regius professor of divinity at the time, would only grant the degree on terms by no means of a highly honourable kind. This gave rise to a fresh dispute between the two antagonists, in which Middleton gained a complete victory, and Bentley was degraded and deprived of his professorship. After "dragging the character of the fallen hero through three triumphant pamphlets," as a writer of the time phrases it, comparing the revenge to that of Achilles with Hector at his chariot wheels, Middleton found that he had established for himself a very considerable literary reputation. Whatever might be thought of the temper displayed in those productions, every one was ready to admit that in sprightly energy, scholarly elegance, and powerful invective, their author had few equals in England. Dr Monk remarks in his Life of Bentley that this production of Middleton's "was the first published specimen of a style, which for elegance, purity, and ease, yields to none in the whole compass of the English language. The acrimonious and resentful feeling which prompted every line is in some measure disguised by the pleasing language, the harmony of the periods, and the vein of scholarship which enliven the whole tract." Flushed with his pamphleteering success, and still thirsting for further revenge against his fallen enemy, he rushed into print for the fourth time with his accustomed intrepidity, when his zeal overcoming his discretion, his vigilant antagonist succeeded in proving him guilty of libel in the Court of King's Bench. The court, however, was unwilling to pronounce sentence, and Middleton escaped by begging Bentley's pardon and paying the expenses of the action. The arrogant master of Trinity had little reputation now left him but that of a great scholar and critic; and he resolved to present the public with a fresh testimony to his merits in a new edition of the Greek Testament. The proposals and specimens were drawn up, however, with too great precipitation; and Middleton, who doubtless submitted the matter to a minute scrutiny, succeeded in detecting not a few serious flaws in the production, and boldly assaulted this corypheus of critics in his last and greatest stronghold. This exposure ran through two successive pamphlets, characterized by all Middleton's accustomed power, and with an additional display of learning and critical sagacity for which no one, even among his friends, would have given him credit. But the virulent personal abuse was often of the lowest kind; and while disclaiming at the outset any personal spleen against his learned antagonist, it nevertheless soon became obvious that Middleton's former animosity had not yet been cooled down, and that he was prepared not only to strip Bentley of his reputation as a scholar, but also to rival him in that species of personal abuse in which the doctor of Trinity was so great a master.

The labour and expense to which Middleton had been subjected during those proceedings were regarded by his friends in the university as of such a public nature, and so much a vindication of the rights of their venerable institution, that they, by way of acknowledging his services, created the office of principal librarian, and conferred it upon him. His election met with much opposition, and his old enemy keeping close upon the watch, found Middleton speaking too freely in the dedication to his *Bibliothec. Ordinand. Method.*, respecting the jurisdiction of the King's Bench Court, for which he had him prosecuted and mulcted in L.50.

In 1724 Middleton was compelled, from declining health, to seek some milder climate, and accordingly visited Rome, where he spent about twelve months, collecting, among other objects of interest, materials for his future work on the *Paganism of the Popish Religion.* On returning to England in 1725, Middleton, from some personal pique against the celebrated physician Dr Mead, published an attack upon the whole medical profession, entitled *De Medicorum apud veteres Romanos degentium Conditione Dissertatio*, &c. It gave rise to much keen pamphlet-writing, and Middleton was not slow to reply. In 1729 he published one of his greatest works, and one which met with a large share of popularity among the learned. This was his celebrated *Letter from Rome, showing an exact conformity between Popery and Paganism*, &c., in which he attempted to show that the rites, ceremonies, &c., of the Romish Church were borrowed from the pagan religion. Notwithstanding the great power put forth on this book, in the way of solid argument and forcible writing, it was nevertheless the means, from its free attack upon the Romish miracles, of giving offence to not a few Protestant divines, who charged the author with a want of respect for the apostolic miracles. Nor was his anonymous letter to Dr Waterland in 1731, respecting his method of defending the Christian cause, calculated to remove the impression. On the contrary, the views respecting the partial inspiration of the Scriptures expressed in that work almost led to his being deprived of his situation and of his college honours. At this juncture he felt called upon to come publicly forward, and in *Some Remarks on a Reply to the Defence of the Letter to Dr Waterland*, &c., to disavow his alleged hostility to Christianity, and express emphatically his belief in that system. But these assertions were not sufficient to drown suspicion, and not a few of his reverend brethren were still inclined to regard him as an unbeliever. They could not get over his allegation that there were "contradictions in the four evangelists which could not be reconciled," or that the "story of the fall of man was a fable or allegory;" and his opinions thus proved an effectual barrier to his clerical promotion. His merits as a scholar, however, were never called in question, and in 1731 he was appointed to the chair of natural history, just founded by Dr Woodward,—a position which he held till his second marriage in 1734. He wrote during the subsequent year *A Dissertation concerning the Origin of Printing in England;* and in 1741 appeared his greatest work, *The History of the Life of M. Tullius Cicero*, written at the request of Lord Harvey, and published by subscription. He spent six years on this cherished task, and it met with great encouragement. The subscribers amounted to 3000, and the profits arising from the sale of the work enabled him to purchase a small estate at Hildersham, near Cambridge, where he spent the rest of his life. This work, while written with singular elegance and perspicuity, has been accused of partiality, in making too much of the great Roman. Middleton has, besides, been accused by Dr Parr, the editor of Bellendenus, of having borrowed largely in his *Life of Cicero* from the *De Tribus Luminibus Romanorum* of that eminent writer. Middleton's next publication was a translation of *Cicero's Correspondence with Brutus*, defending at the same time the authenticity of those epistles. Being resolved now to close his studies in profane literature, he in 1745 gave an account in his *Germana quædam Antiquitatis Eruditæ Monumenta*, &c., of the specimens of ancient art which had come into his possession during his residence at Rome; and in 1747 he wrought up into a *Treatise on the Roman Senate* the substance of his letters to Lord Harvey twelve years before, on the constitution of that celebrated institution. Now that his classical studies were completed, he immediately brought forward his *Introductory Discourse*, &c., *to the Free Inquiry into the Miraculous Powers which are supposed to have subsisted in the Christian Church from the earliest ages through several Successive Centuries*,—a work which appeared in 1749, and met with all but universal condemnation from the clergy, on account of its supposed antagonism to the authority of miracles. All that Middleton intended, however, in this vigorous work, was to place Protestant divines in the dilemma of either denying the authority of the fathers altogether, or, by accepting their testimony, to embrace the doctrines of the Romish Church, which he held to be clearly established by the evidence of the fathers. Gibbon, the historian, among others, chose the patristic horn, and became a Roman Catholic. In 1750 Middleton published his last work, *An Examination of the Bishop of London's* [Sherlock] *Discourses on the Use and Intent of Prophecy*, &c., which was not considered equal to some of his previous productions. He died at Hildersham on the 28th of July 1750, in the sixty-seventh year of his age. Shortly before his death he subscribed the Thirty-nine Articles, on occasion of receiving a small living from Sir John Frederick,—an act which some of his brethren, as might have been expected, were inclined to characterize as insincere.

Middleton's miscellaneous works, exclusive of the *Life of Cicero*, were published in 1755 in 5 vols., containing some short pieces not previously published. Among his papers were found some materials for a life of Demosthenes, similar to that of the Roman orator, but he did not survive to complete his design.

MIDDLETON, *Sir Hugh*, was the sixth son of Richard Middleton, Esq., governor of Denbigh Castle in Denbighshire. The date of Sir Hugh's birth and the events of his early life are not known, until his great undertaking of supplying the city of London with water. He had been, however, a goldsmith in the metropolis, and had enriched himself by the successful working of certain copper mines in Wales. Nothing had been done by the citizens of London beyond securing the legal right during Elizabeth's reign of bringing water from any part of Middlesex or Hertfordshire to the metropolis, when, on 28th March 1606, this "citizen and goldsmith" came forward and proposed to bring a supply of water to London at his own cost. Two years afterwards he commenced his work at the Chadwell and Amwell springs, near Ware in Hertfordshire, and after encountering much annoyance and hard labour, the indefatigable and princely goldsmith saw the water in the cistern at Islington on Michaelmas day 1613. But if Middleton had the pleasure of seeing his stupendous undertaking completed, he had also the mortification to find his fortune well-nigh exhausted. He had been aided in the work by King James I.; and in acknowledgment of the generous services of this worthy citizen, his majesty knighted him, and afterwards created him a baronet. Sir Hugh was one of the principal shareholders in connection with the New River Company, but the profits amounted at first to the merest trifle—being little more than L.10 during the first eighteen years; and it is supposed that Middleton at his death left a numerous family not very well provided for.

MIDDLETON, *Thomas*, a distinguished dramatist, who flourished during the reigns of Elizabeth, James I., and Charles I., and respecting whom very little is known. He was chronologer to the city of London in 1620, and is supposed by Malone to have died in 1626. While Middleton does not belong to the first rank of dramatic writers, he was nevertheless highly esteemed by the men of his time, and had the honour of being joint worker, according to the generous fashion of that age, with Jonson, Massinger, Fletcher, and Rowley. His plays, which are very numerous, are often characterized by extravagant incidents, rough rollicking scenes from low life, and bustling, lively plot. His most popular plays, perhaps, are his *A Mad World my Masters*, and the *Roaring Girl;* the latter of which abounds in curious and richly-coloured pictures of London life, interspersed with plenty of slang and coarseness, not unbecoming the heroine, the well-known Moll Cutpurse, who was a real character, and who was brought upon the stage by more than one dramatist of that period. Shakspeare is said to be considerably indebted in the incantations of his *Macbeth* to a play of Middleton's called the *Witch*.

MIDDLETON, *Thomas Fanshaw, D.D.*, the first English Bishop of Calcutta, was born at the village of Redleston in Derbyshire, on the 26th of January 1769, where his father, Rev. Thomas Middleton, was rector. He received his early education at Christ's Hospital, London, and then entered Pembroke Hall, in the university of Cambridge, where he graduated with honours in 1792. Having received ordination, he became a curate at Gainsborough in Lincolnshire, where he for some time edited a periodical publication called the *Country Spectator*. In 1795 he was presented by Dr Pretyman, Archdeacon of Lincoln (to whose sons he had for some time been tutor), to the rectory of Tansor in Northamptonshire; and in 1799 he was made curate of St Peter's, Mancroft. His former patron in 1802 presented him to the rectory of Bytham in Lincolnshire, when he commenced to write *The Doctrine of the Greek Article, applied to the Criticism and Illustration of the New Testament*,—a work which caused considerable controversy, especially among the Unitarians, on its first appearance in 1808. In 1812, after taking his degree of Doctor of Divinity at Cambridge, he received the archdeaconry of Huntingdon, and took up his residence at St Pancras, Middlesex, of which he had been recently appointed vicar.

Calcutta having about this time been made a bishop's see, Dr Middleton was appointed the first bishop on the 8th May 1814. In this position he displayed great diligence and zeal in promoting the cause of Christianity. He founded the Bishop's College at Calcutta for the education of missionaries for Asia in 1820, and instituted a consistory court at Calcutta. He died of fever at this eastern capital on the 8th of July 1822. Some of his sermons, charges, &c., were collected into a volume, and published at London, with a memoir of the author prefixed by Dr H. K. Bonney in 1824.

MIDDLETON, a manufacturing town of England, county of Lancaster, on the Manchester and Leeds Railway, and on the Rochdale Canal, 5 miles N.N.E. from Manchester. In 1775 it was only an inconsiderable village with 300 inhabitants, but it has now become an important seat of the cotton and silk manufactures. It contains several good streets and well-built houses, and has a parish church erected in the sixteenth century. It has also a grammar and other schools, a mechanics' institute, reading-room, and savings-bank. Coal mines are wrought in the vicinity. Pop. (1851) 5740.

MIDDLETON, a market-town of Ireland, province of Munster and county Cork, at the mouth of a small stream flowing into the N.E. branch of Cork harbour, 14 miles E. from Cork. It has a neat parish church, a Roman Catholic chapel, convent, free grammar school, two national schools, a fever hospital, dispensary, market-house, court-house, and bridewell. There are also two large distilleries, breweries, and flour-mills. It is within a mile of Ballinacurra harbour, where large shipments of agricultural produce and flour take place. Pop. (1851) 3676, besides 2334 in workhouse.

MIDDLETOWN, a city and river-port in the United States of North America, Middlesex county, Connecticut, on the right bank of the Connecticut River at the head of its ship navigation, and 24 miles N.E. from New Haven. It is pleasantly situated, partly on an acclivity commanding a fine prospect. The elevated portion contains many elegant mansions surrounded with spacious and highly ornamented ground. The rest of the town consists of broad parallel streets of usually well-built houses. The principal public buildings are the custom-house and court-house, both elegant edifices, and the latter adorned with a fine Grecian portico. The Wesleyan university here is a flourishing institution, having about 120 students. The wharves are commodious, and have 10 feet of water. The shipping of the port amounted on 30th June 1852 to 14,431 tons enrolled and licensed, of which 14,005 were employed in the coasting trade, and the remainder in the cod and mackerel fisheries. Pop. (1850) 4211.

MIDDLEWICH, a market-town of England, county of Chester, at the confluence of the Rivers Dane and Croke, 20 miles E. of Chester. The town, though small, contains many good houses, and has a commodious parish church, three dissenting places of worship, a free grammar school, a newsroom, and library. Salt is largely manufactured here from brine springs in the vicinity. There are also manufactures of silk and cotton stuffs; breweries and brick works. Pop. (1851) 1235.

MIDHURST, a parliamentary borough and market-town of England, county of Sussex, pleasantly situated on a rising ground on the right bank of the Rother, 11 miles N.N.E. of Chichester, and 50 miles S.W. by S. of London. The town is well built and clean; and the principal buildings are the town-hall, which is neat, and the parish church of St Denis, a plain structure in the Gothic style, which, though formerly small, has been recently considerably enlarged. There are also places of worship for Independents and Baptists. Midhurst has a free grammar school, a national school, several almshouses and other charitable establishments, a literary and scientific institution, and a savings-bank. The remains of the castle of the Bohuns, formerly the lords of Midhurst, are to be seen on an eminence near the river; and in the neighbourhood of the town are the ruins of Cowdray House, the seat of the Montagu family, which was built in the time of Henry VIII., and burnt down in 1793. A new house has been built not far from the old, and is now in the possession of the Earl of Egmont. From the time of Edward II. till the passing of the Reform Bill, Midhurst returned two members to Parliament, but the number has now been reduced to one. Midhurst is the seat of a county court; and three annual fairs are held here. The market-day is Thursday. Pop. (1851) of the parliamentary borough, 7021.

MIDNAPOOR, a district of Bengal, in the province of Orissa, containing an area of 4015 square miles, and about half a million of inhabitants. The bulk of the people are Hindus, but there is a greater proportion of Mohammedans than in most other parts of India. Some portion of this extensive district consists of a jungle swarming with noxious animals, and exceedingly unhealthy, although the land is rich and fertile. This district was formally ceded to the East India Company in 1761. It is traversed by numerous rivers, the principal of which are the Soobunreeka and the Kosai. The country produces abundance of grain, sugar, tobacco, cotton, and indigo. On the sea-shore salt is an important object of manufacture. Its principal towns are Midnapore, Jellasore, Piply, and Narraingur. Midnapore, the capital, formerly possessed a fort, which has been converted into a criminal prison. It is 70 miles W. by S. from Calcutta. Long. 87. 23. E., Lat. 22. 25. N.

MIEL, JAN, called by the Italians *Giovanni della Vite*, a Flemish painter, was born in 1599 at Vlaenderen, a village in the neighbourhood of Antwerp. He studied under Gerard Seghers; and after making considerable progress in his art, he went to Rome, and entered the academy of Andrea Sacchi. But in consequence of a disagreement with his master he left the imperial city for a time, and went to Bologna and Parma, where he further improved himself by the study of the works of the Caracci and of Correggio. Returning to Rome, he executed for the pope several historical paintings of great excellence; but his taste, which seems to have been capricious, now rather inclined to the painting of familiar scenes, after the manner of Bamboccio. He was invited to the court of Charles Emmanuel, Duke of Savoy, whose patronage he enjoyed, and by whom he was honoured with the order of St Maurice. Miel died in 1664 at Turin. His pictures represent chiefly carnivals, fairs, beggars, gypsies, and hunting scenes; and are remarkable as spirited and correct representations of nature; but his colours are in many instances too dark and gloomy.

MIERIS, Francis, an artist, was born at Leyden in 1635. His father, who was a goldsmith, was not favourable at first to the wishes of his son to study the art of painting; but owing to the progress made by Francis in painting on glass, he was induced to allow him to enter the school of Gerard Douw. The young artist soon outrivalled all his fellow-students. Mieris is remarkable for the beauty of his colouring and the minuteness and truth of his delineations. The quality of the dresses of his figures can be easily distinguished; and his paintings of silk, satin, and velvet, are highly admired. His subjects are for the most part ordinary domestic scenes. One of these, the picture of a fainting lady and a physician, was sold for 1500 florins. Mieris died in 1681.

Mieris, *Francis*, grandson of the preceding, was born at Leyden in 1689. Although he learned from his father the art of painting, he did not achieve any great success in that department. He is more celebrated as a historian and antiquary, and is the author of several works, of which the most important are:—*Historie der Nederlandsche Vorsten*, the Hague, 1732–35; and *Groot Charterboek der Graven van Holland, Zeeland, en Vriesland*, Leipsic, 1753–56. He died suddenly in 1763, while engaged in writing a history of his native town.

Mieris, *William*, an artist, the son of Francis Mieris the Elder, was born at Leyden in 1662. He imitated the style of his father, but having lost him by death just as he was entering on the study of his art, he was deprived of the advantage he might otherwise have derived from his skill and experience. As a painter, he is not equal to his father in the nice and elaborate accuracy of his works; but for bright and gorgeous colouring, and for the minuteness of his imitation of natural objects, his pictures are much esteemed, and sometimes even placed above those of his father. He has painted many ordinary scenes from nature, and also many historical and poetical pieces. His landscapes are often unnatural, and his costumes are not always appropriate. He died in 1747.

MIGNARD, Nicolas, a French artist, was born at Troyes in Champagne about the year 1605. He was brought to Paris by Mazarin, who was his constant patron; and Louis XIV. employed him to execute several paintings in the Tuileries. He was most successful in historical and poetical subjects; but he also painted many portraits of the lords and ladies of the French court, which are much admired. He died in 1668.

Mignard, *Pierre*, an eminent French artist, brother of the preceding, was born at Troyes in 1610. At the age of eleven he was placed in the school of Jean Boucher at Bourges; and he afterwards studied under Vouet. Such was his genius, and so rapid was his progress in his art, that his works could hardly be distinguished from those of his master; and at the age of fifteen he was commissioned by the Marshal of Vitry to execute some paintings in his castle. In 1636 he went to Rome, where he remained for twenty-two years, engaged in the study of the works of the best Italian painters, and forming his style so much upon the model of the Roman school that he acquired the surname of *Il Romano*. He painted many historical pieces and portraits; among the latter, in which he displayed his genius and skill in a remarkable manner, were those of the Popes Urban VIII. and Alexander VII. In 1658 he was invited to the court of Louis XIV. He immediately set out on his journey thither; and on his way through the duchies of Tuscany, Modena, and Parma, he executed portraits of the reigning princes of these states. At Paris Mignard was made head of the academy of St Luke; and after the death of Le Brun, became chief painter to the king. He painted Louis XIV. no less than ten times. The following anecdote is related of him as he was taking the tenth portrait of that monarch:—The king, seeing the painter looking at him with attention, said, "Mignard, you think I look older?" "Sire," answered the painter, "it is true that I see some more victories on the forehead of your majesty." Among the principal works of Mignard was the fresco-painting in the dome of the Val-de-Grâce, one of the greatest works of that sort of which his country can boast. It was celebrated in verse by Molière; with whom, as well as with Boileau and Racine, Mignard was very intimate. The paintings of this artist are certainly inferior to those of the great masters whom he took as his models; but they are distinguished for grace and beauty, and he was so extremely successful in his imitations of other painters, as to deceive even the best judges. He died in 1695.

MIGNON, Minion, or Minjon, Abraham, a painter, was born at Frankfort-on-the-Maine in 1640, and studied at Utrecht under Jan David de Heem. Having a natural taste for art, and also great skill and aptitude in painting, he added to these advantages the most unwearied diligence in the imitation and study of nature, and thus soon rose to great eminence as a painter. Mignon is remarkable for the accuracy of his representations and the beauty of his colouring, and his works are in general very highly prized. His paintings, which are rare, represent chiefly flowers, fruit, insects, birds, fish, &c. He died in 1679.

MIHIEL, St, a town of France, department of Meuse, and arrondissement of Commercy, on the right bank of the River Meuse, 9 miles N.N.W. of Commercy. It is a neat and well laid-out town, and has several remarkable churches, in one of which is a fine bas-relief of the "Entombment of Christ." St Mihiel has also a court of assize, communal college, public library; and manufactures of cloth, yarn, and leather. Pop. 5274.
